THE

ENGLISH CYCLOPÆDIA.

NATURAL HISTORY.

HABENA'RIA, a genus of Plants belonging to the natural order *Orchidaceæ*. This genus has a ringent hooded perianth, a 3-lobed entire spurred lip. There are three species natives of Great Britain.

H. viridis, the Frog-Orchis, has a very short 2-lobed spur, linear flat 3-pointed lip, the middle point the shortest. The flower is green, and the lip of a brownish colour. It is the *Persistylus* of Lindley, and the *Himantoglossum* of Reichenbach. It grows in pastures.

H. bifolia, the Lesser Butterfly-Orchis, is distinguished by the lip being linear and entire, and the pollen-masses parallel. The flowers are white. It is found in heathy places.

H. chlorantha, the Great Butterfly-Orchis, has the same general characters as the preceding species; but the flowers are larger, and the plant is taller and stouter. The pollen-masses ascend obliquely and converge upwards. It grows in moist woods and thickets.

(Babington, *Manual of British Botany*.)

HABROCOMA, a genus of Mammalian Animals belonging to the order *Rodentia* and the sub-order *Hystricidæ*. Two species were taken by Mr. Darwin near Valparaiso, *H. Cuvieri* and *H. Bennetii*. [HYSTRICIDÆ.]

HABZE'LIA, a genus of Plants belonging to the natural order *Anonaceæ*. It has a 3-lobed calyx; 6 petals, the inner ones smallest; the stamens very numerous; the torus convex; the carpels distinct, indefinite in number, long, cylindrical, obsoletely ventricose or torulose, smooth, striated lengthwise, becoming many-celled by the pericarp growing together; many-seeded, the seeds elliptical, arillate, somewhat erect, numerous, shining, one in each of the cells of the fruit; the arillus formed of two white unequal obcordate membranes.

H. Æthiopica has ovate-acute leaves, 3 inches long, 12 to 14 lines broad, smooth on the upper surface, and downy beneath; the carpels are pod-shaped, 1-2 inches long, knotted, striated, quite smooth, with the taste of pepper. The fruit has a pungent aromatic taste, and is often substituted for other spices. It is the *Piper Æthiopicum* of the shops, and the *Anona Æthiopica* of Duval and other botanists. It is a native of Sierra Leone. *H. aromatica* is another species, yielding a pungent aromatic fruit. It grows in the forests of Guyana, and the fruit is used by the negroes as a condiment.

(Lindley, *Flora Medica*.)

HACKBOLT. [PUFFINUS.]

HADDOCK. [MORRHUA; GADIDÆ.]

HÆMANTHUS. [AMARYLLIDACEÆ.]

HÆMATITE, a name given to certain forms of the native Peroxide of Iron. When of a red colour it is called Red Hæmatite; and when brown, Brown Hæmatite. [IRON.]

HÆMATOCOCCUS (from αἷμα, blood, and κόκκος, a grain), a genus of Plants belonging to the natural order of *Algæ*. It is characterised by being composed of spherical or oval cells of various sizes, each cell being invested with one or more concentric vesicles or membranes, multiplied either by division or by granules formed within the parent cells. Several species of this genus have been described. One of the first observed was the *H. sanguineus*, which, like the Red Snow-Plant (*Protococcus nivalis*), has its cells coloured red; hence the generic name. Several of the species however are of a green colour, and Kützing and others on this account have proposed the name *Microcystis* for this genus of plants.

The species are found upon moist rocks, on the walls of caverns and in damp places. [RED SNOW; PROTOCOCCUS.]

(Hassall, *British Freshwater Algæ; Botanical and Physiological Memoirs of the Ray Society*.)

HÆ'MATOPS, a name given by Mr. Gould to a genus of Birds inhabiting Van Diemen's Land and New South Wales, and thus characterised by him:—

Bill shorter than the head, slightly curved, without any denticle at the apex, rather compressed. Nostrils longitudinal, and covered by an operculum; no bristles at the gape. Wings moderate, first quill short, third and fourth nearly equal and longest. Tail moderate, equal or slightly forked. Tarsi moderate, the rather strong hallux and claw equalling the middle toe and claw; external toes equal in length. Ensanguined spots or marks (nævi sanguinolenti) above the eyes.

Mr. Gould recorded two species, *Hæmatops valdirostris*, 6¾ inches in length (Van Diemen's Land), and *H. gularis*, 6 inches long (New South Wales).

HÆMATOPUS. [CHARADRIADÆ.]

HÆMATORNIS. [FALCONIDÆ.]

HÆMATOXYLON, a genus of Plants belonging to the natural order *Fabaceæ* or *Leguminosæ*. It has 5 sepals united into a permanent tube. The petals, 5 in number, are scarcely longer than the sepals. There are no stamens; the filaments hairy at the base; the anthers without glands; style capillary. The legume is compressed, flat, lanceolate, acuminate at each end, 2-seeded; the sutures indehiscent; the valves bursting longitudinally.

H. Campeachianum, Logwood, a tree common all over the West India Islands. It is a low spreading tree, with a stem generally crooked and deformed, seldom thicker than a man's thigh; the branches somewhat flexuose, terete, covered with whitish dots. In mountain and moist situations it is unarmed, but in the plains, or where the tree is stunted, it is furnished with spines below the leaves; the leaves 2 or 4 from the same point (an irregular tough tubercular prominence), pinnate, sometimes dividing in a bipinnate manner at the lowest pair of leaflets; the leaflets 4-paired, shortly stalked, obovate or obcordate; the racemes at first about the length of the leaf, afterwards, as the pods form, elongating; the flowers on pedicels half an inch in length, yellow, and slightly fragrant; the calyx deeply 5-parted; the lobes unequal, thrice membranous, purplish, deciduous; the tube short, green, and bell-shaped; the petals nearly equal, obovate, wedge-shaped at the base, scarcely longer than the sepals; the stamens alternately short, inserted (as also the petals) on the inside of the margin of the persistent tube of the calyx; anthers ovate; ovary lanceolate, compressed, 3-seeded; style projecting beyond the stamens and petals; stigma capitate, expanded; the pods compressed, flat, lanceolate, acuminate at both ends, 2-seeded, not opening at the sutures, but bursting longitudinally by a division passing down through both the valves. It is chiefly used by dyers. It is a powerful astringent, and may be employed as a substitute for kino, catechu, &c. In diarrhœa and dysentery the decoction is used with benefit.

HÆMOCHARIS. [ANNELIDA.]

HÆMODORA'CEÆ, *Blood-Roots*. Under this name Dr. Robert Brown proposed, in the year 1810, to separate from the natural order *Iridaceæ* the genera *Hæmodorum*, *Conostylis*, *Anigozanthos*, *Phlebocarya*, *Dilatris*, *Lanaria*, *Heritiera*, and *Wachendorfia*. He remarked that they are abundantly different, especially in being hexandrous, or in having the stamens, if only three in number, stationed opposite the petals, and in having the anthers opening on the side next the stigma; the habit was moreover different. This distinguished botanist mentioned in connection with his new order, without actually adding it, *Xiphidium*. The latter genus has more recently been introduced along with *Hagenbachia* as an undoubted member, notwithstanding its having a superior ovary. All the species have equitant leaves, and perennial fascicled fibrous roots or bulb-like corms, and there is also a general appearance of wool upon their flowers, in some cases to such an extent as to bury all the outer surface. The order may be considered a connecting link between *Iridaceæ* and *Liliaceæ*. One species, *Dilatris Heritiera*, yields a dyeing matter in its rhizoma. The species occur in North America sparingly, and at the Cape of Good Hope; several are described from the temperate parts of Australia, and some occur in Brazil and the Mascarene Islands. The natives of Swan River live on the roots of some plants belonging to this order, especially of *Hæmodorum paniculatum* and *H. spicatum*, which are mild and nutritious when roasted, but acrid when raw. One of the most intense bitters known is *Aletris farinosa*. There are 13 genera and 50 species.

Hæmodoraceæ.—Wachendorfia thyrsoidea.

1, a flower spread open to show the position of the three stamens; 2, a ripe capsule; 3, a seed.

HÆMULON, a genus of Fishes of the section *Acanthopterygii* and family *Sciænidæ*. It has the following generic characters:—A single dorsal fin; seven branchiostegous rays; lower jaw compressed, a small oval opening and two small pores under its symphysis; the vertical fins partially covered with scales.

These fishes generally approach to an elongate oval form; the body is moderately compressed; the tail is forked; the dorsal fin, which occupies the greater portion of the distance between the back of the head and the tail, although continuous, has a considerable indentation at that part where the spinous rays join the flexible. The portion of the under jaw which is covered by the upper when the mouth is closed, is invariably of a bright red colour. The species of *Hæmulon* chiefly inhabit the Caribbean Sea, and are eaten by the inhabitants of the West Indian Islands. They are of moderate size, varying from six inches to one foot in length, and generally adorned with longitudinal or oblique dark markings on a pale ground colour.

HAGDOWN. [PUFFINUS.]

HAIDINGERITE. [ANTIMONY.]

HAIL. [SNOW.]

HAIR. The hairy coverings of the *Mammalia* are composed of long delicate processes of a horny substance, which grow from bulbs situated in or beneath the skin. Each hair is contained at its lower part in a delicate sheath, or follicle, which passes obliquely from the surface of the skin on which it opens to a greater or less depth, and at its base dilates into a pouch containing the bulb of the hair. The

bulb of the hair consists of a small cone-shaped body, the pulp soft and delicate, and apparently made up of blood-vessels and nerves, and covered by a reflection of the smooth lining of the sheath of the hair, which is continued from the cuticle covering the surrounding skin. On the whole surface of this bulb the substance of the hair is secreted, and as each layer which is deposited pushes that previously formed onwards, the whole gradually advances along the sheath till it projects beyond the skin, and thence continues to grow free. In the early embryo the sheath or follicle in which the hair is afterwards formed is alone seen, then a delicate vessel may be traced to its base, where a little black spot is soon formed, and this, as all the other parts increase, is gradually developed into a hair. Into each hair-follicle, as Gurlt has shown, there open the ducts of one or two little glands, by which the oily matter is secreted to lubricate the hair and keep it supple and firm, and where these are deficient the same purpose seems to be performed by the follicle itself. The annexed cuts will explain the general mode of formation of hairs, which, it may be observed, is effected in the same manner as that of horn, nail, and many other extra-vascular appendages of animal bodies, namely, by the deposition of successive layers of organic matter on the surface of an abundantly vascular tissue. *Fig.* 1 represents an oblique section of the pulp and lower part of the whisker of a lion, in the Hunterian Museum, in which *a* is the body of the hair, *b* the conical pulp, and *c* a blood-vessel passing into and ramifying in it. *Fig.* 2 is a section of the skin of the upper lip of a lion, with part of a whisker completely formed, and another in progress of growth, from the same collection; *a* is the outer part of the hair-follicle, formed by a deep depression in the skin; *b* is its internal cuticular lining; *c* the contained hair; *d* the sheath containing the vessels and nerves, passing to the base of the follicle and bulb of the hair. *Fig.* 3 is a section of the skin, containing a hair from the human scalp, from the figure by Gurlt, in Müller's 'Archiv für 1835:' here *a* is the thin cuticle, *b* the cutis, *c* the subjacent fat, *d* the cellular tissue, in which the base of the hair-follicle *e* is seen; *f* is the hair itself, enlarged at its base, and *g g* are the two sebaceous glands opening into the sheath.

Fig. 1.

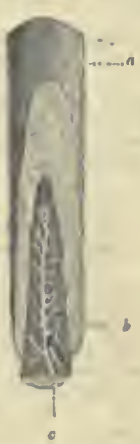

Fig. 3.

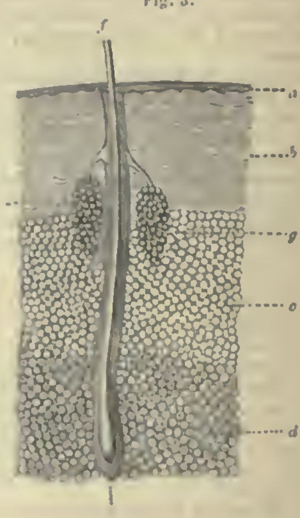

Fig. 2.

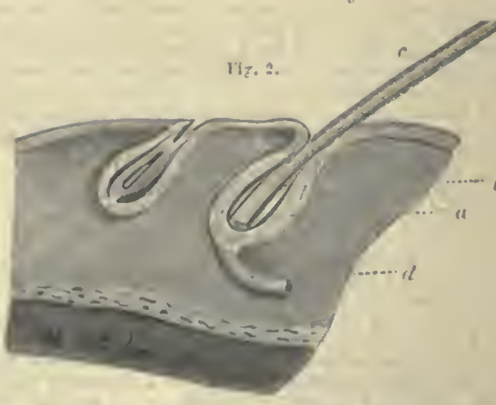


In man the hairs are not, as has been generally supposed, perfectly cylindrical. Weber has shown that they are all more or less flattened, so that a transverse section presents an elliptical form, or sometimes, from one side being grooved, has the shape of a bean. The hair of the whiskers, beard, and mustachios, and in general all short curly hair, is most flattened. In most instances flatness and curliness are directly proportionate, and both attain their maximum in the crisp woolly hairs of the negro, which are sometimes as much as two-thirds broader in one direction than in the other. The hair of the negro however, though called woolly, differs considerably from the wool, properly so -named, of sheep and other animals: the latter is not spirally curled, but wavy, all its curves being nearly in the same plane; it is much more delicate, and perfectly round, and hence, from its being equally fitted to curl in any direction, is peculiarly adapted for spinning, while the flattened hairs of men have always a tendency to turn their broadest surfaces towards the middle of the curl.

Except at their base, into which the conical pulp enters to a variable distance, the hairs are perfectly solid, and in most animals their substance is similar throughout. Weber has shown that the appearance of a central canal running along them, and of a softer internal than external material, has resulted from microscopic errors, occasioned by the unequal refraction of light passing through their rounded or grooved surfaces. Only in the lion, zebra, and llama, did Weber find that the internal part seemed rather paler than the outer; in the roebuck and a few other animals he found the cellular structure which has been sometimes erroneously supposed to exist in all hair. The cells are all hexagonal, much like those in the cellular tissue of plants. The average diameter of hairs from the human head are respectively about 1-300th and 1-500th of an inch, and hairs often attain a length of 6 or 7 feet in women. Instances are recorded also of the hair of the beard growing to a length of 9 feet. They are generally of the same thickness throughout their whole length in man, but in the finer kinds of wool they are of unequal size at different parts. This seems to indicate an occasional alteration in the size or activity of the pulp, a supposition which is further supported by the varieties of colour which the same hair sometimes presents, as in those animals which seem to have gray furs, but in which each hair is made up of alternate bands of black and white. In man however nothing of this kind occurs; the colour of each hair is uniform, the appearance of grayness being produced by a mixture of completely white with dark hairs. The colour of the human hair generally varies with the colour of the iris and the general dark or light hue of the skin. Commonly, the darker the hair the more robust the body, and the coarser the skin and other tissues; and this holds still more with animals than in man, for not only are white or gray horses less healthy and vigorous than dark ones, but if one or two of a dark horse's legs be white they are always more liable to injury and to disease.

Hairs are capable of movement, and the standing of the hair on end from alarm is not imaginary. It is found that each bulb of the hair is supplied with a minute muscle, which acts in producing movement of the hair. (Lister, On the Muscular Tissue of the Skin, 'Microscopical Journal,' vol. i. p. 263.)

Hairs are very elastic; they admit of being stretched nearly one-third of their length, and regain their original length almost completely: in proportion to their size they are very tough and firm. In masses they are impenetrable, except to very great violence, and hence one of their uses in the thick coverings of animals; they are also adopted in armour, as for the coverings of helmets. They are extremely bad conductors of heat, and they are generally found most thick and abundant in animals subject to long exposure to cold, in whom moreover an additionally thick coat is provided at each winter after the annual shedding. They are non-conductors of electricity, and when rubbed with almost any other substance so large a quantity of negative electricity is developed that in the dark even sparks may be seen, and the peculiar crepitating sound of rapid little electrical discharges may be heard. This is especially the case with the drier hairs of cats, dogs, &c.; but the weaker electrical phenomena may be observed by rubbing the human scalp. Hair is also remarkably hygrometric, attracting and retaining in its tissue a large quantity of moisture, in consequence of which it becomes flaccid and lengthens, and hence it is used in the construction of the more common hygrometers. It assists also to shield the skin from moisture by its oily surface, and when thick presents almost an impenetrable barrier to water. Thus serving to isolate the animal from the three most powerful external agents, heat, electricity, and moisture, it is scarcely possible to imagine any structure better adapted for the external covering of the whole body, whose motions it is too light to impede, and to whose beauty it so remarkably contributes.

In chemical properties hair resembles horn, nails, &c. It is soluble in water at a very high temperature, as in a Papin's digestor, leaving a large quantity of oil mixed with sulphuret of iron, and some sulphuretted hydrogen. It is this oil, with the sulphuret of iron, which gives the colour to the hair, and by whose absorption grayness is produced. The iron is most abundant in the darkest hair, and the sulphur is the ingredient on which the action of the various black dyes for red or gray hair depends. These are all composed of some salt of silver or lead, which, mixed with some oily or fatty substance in the form of pomatum, insinuates itself into the hair, where it is decomposed and a black sulphuret of silver or lead is formed. Hair is soluble in alkalies and alkaline earths, and for this reason the depilatories in common use are chiefly composed of quick-lime, which however is materially injurious to the skin at the same time that it removes the hair. Hair contains a very small quantity of water, and when burnt leaves a large proportion of ashes, containing iron, manganese, and various salts of lime; it is owing to these properties that hair is peculiarly indestructible, and has been found unaltered on mummies more than twenty centuries old. It has even been supposed to grow after death, but it is probable that, in the few authentic cases in which this is stated, it was owing to the lengthening of the hair by the attraction of moisture from the body or surrounding atmosphere, and to the more rapid drying and contraction of the adjacent tissues.

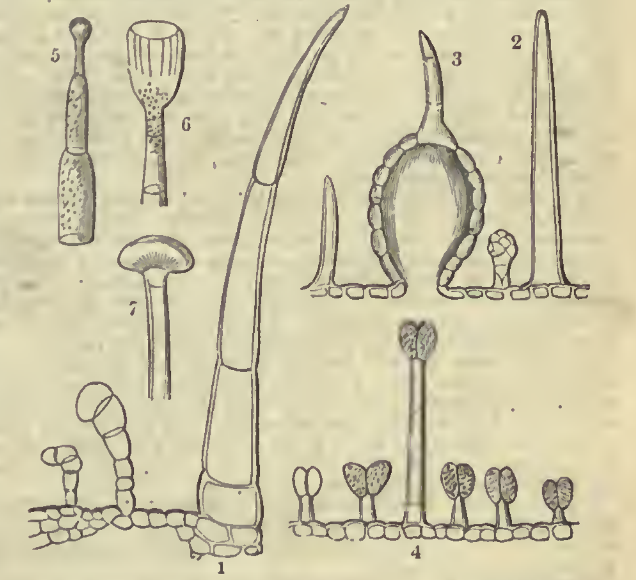
Little need be said of the diseases of hairs. Possessing neither vessels nor nerves, except at their base, they are rarely altered except by the diseases of the skin itself. [ENTOPHYTA.] Their fall, as it is called, is in most animals annual, but in man seems not to occur except by accident, or after particular diseases. The process by which it takes place is unknown, but is probably similar to that of the shooting of the quills of the porcupine, by the gradual approximation of the base of the follicle to the surface. Their loss of colour, which is sometimes exceedingly rapid, is owing to deficient secretion of the colouring oil, and can only very rarely be remedied. When sufficient moisture is not supplied they sometimes split at their points like bristles; at others they break at the middle of the shaft, snapping off, and leaving a little fringed extremity to the stump. The most singular alteration however to which they are subject is that called the 'plica polonica,' from its occurring almost exclusively in some towns in Poland, in which, with so much general disease as sometimes proves fatal, the hair of the head becomes sticky and matted together, when touched gives extreme pain, and is sometimes said even to bleed when cut. This fact cannot however be regarded as evidence of the hair naturally containing vessels, though it indicates an elongation of the pulp to some distance beyond the skin, just as is the case in dogs, whose whiskers will sometimes bleed if cut very close to the surface. [SKIN.]

(Weber, in Hildebrandt's *Anatomie*, vol i.; Gurlt, in Müller's *Archiv für Anatomie und Physiologie*, 1835; Kölliker, *Manual of Human Histology*, translated by Busk and Huxley for Sydenham Society.)

HAIRBELL. [CAMPANULA.]

HAIR-GRASS. [AIRA.]

HAIRS. In plants these are long expansions of the cuticle, chiefly intended to answer the double purpose of collecting moisture from the atmosphere and of protecting the surface of a plant from the too powerful influence of the sun's rays. It is supposed that they are also destined to assist in the conveyance of certain kinds of seeds through the air, and in other cases, as in that of cotton, they are specially adapted for the use of man. That the two first purposes are those for which hairs growing on the surface of plants are intended, seems sufficiently indicated by the following facts:—



1, common hairs of the stem of *Bryonia alba*, becoming glandular at the base or apex; 2, 3, a mixture of hairs (2) and glands (3) from the stem of *Dictamnus*; 4, double glands at the point of the hairs of *Lysimachia vulgaris*; 5, a hair glandular at the apex, from *Primula Sinensis*; 6, gland on the end of the hairs of *Sisymbrium Sophia*; 7, one of the yellow glands found on the head of the hairs of *Scrophularia nodosa*.

In all cases hairs are composed of lengthened cells of cellular tissue, extending from one or more of the cells of the cuticle. Most commonly they are quite simple, and are merely formed of several cells of equally diminishing size, placed end to end, or of a single cell. Of the latter kind are the long entangled hairs that clothe the surface of the cotton-seed, and which are manufactured into thread and linen.

Sometimes several such hairs spring from a common point as in Malvaceous and Euphorbiaceous plants, and *Marrubium creticum* (*fig.* 8); these are technically called stellate. Others branch in various ways, as in *Nicandra anomala* (*fig.* 9), and from such the woolly appearance of the surface of plants often takes its origin. It sometimes happens that the cell, out of which a hair is formed, instead of growing perpendicular to the surface, lengthens in a parallel direction, growing at two opposite sides; cases of this sort are found commonly in Malpighiaceous plants, and in the common hop. (*Fig.* 10.) Finally, in those instances where the terminal cell enlarges and is furnished with an aperture, hairs become glands, and consequently secreting organs. (*Figs.* 1, 2, 3, 4, 5, 6, 7, 10, 11.)

Hairs of Plants.

The mechanism of stinging hairs in *Urtica*, *Wigandia urens*, and the *Loasaceæ* is very interesting. Almost all stinging hairs end in a little knob-shaped swelling, which is exceedingly brittle, and easily knocked off by a touch. The opened point, on being pressed against, exudes the secretions contained in the cells at the base of the hair, and will produce poisonous effects when introduced into animal tissues. Our indigenous nettles are the least injurious. The stings of the *Loasaceæ* are much more so, while the *Urtica crenata* and *U. crenulata* of the East Indies produce wounds in which pain is felt for weeks and months after touching them. The most dangerous of all is the *Urtica urentissima* of Blume, called in Timor, Daonn Setan, and by the English Devil's Leaf. The wounds of this plant give pain for years after, especially in damp weather, and occasionally death from tetanus is the result. Could we separate this poison, it would be the most powerful vegetable poison known.

In the early stages of growth these hairs, all of them, possess an active circulation of the sap. Some hairs have their contents absorbed at a special time, so that the hair is, as it were, absorbed into its own proper cavity. This remarkable phenomenon takes place in the hairs of the style in *Campanulaceæ*. Also in the globular cells of knob-shaped hairs, which then look as if half had been cut through, or as if a cover had been removed. Meyen has published a work on hairs, distinguished by many peculiarities, but will repay perusal.

Aquatic plants are said to have no hairs, but in the case of *Callitriche verna* and *Hippuris vulgaris*, Dr. Lankester has demonstrated the existence of rosette-shaped bodies, which are evidently homologous with hairs. In *Callitriche* they are composed of four or five cells attached to a central cell, which serves as the point of attachment to the epiblema or cellular layer of the leaf and stem. An organ of a similar kind occurs in *Pinguicula vulgaris*.

The hairs of the *Drosera rotundifolia* contain spiral vessels. This would indicate that the bodies thus named belong to the vascular system of the plant, and ought rather to be regarded as segments of the leaf than as true hairs.

In consequence of the hairs of plants being an extension of cellular tissue, which is naturally thin-sided, all hairs are much weaker than the tough thick-sided tubes of which woody tissue is composed. This accounts for the well-known fact that all goods manufactured from cotton, which is vegetable, are far less tough and durable than those which, like linen, are prepared from the tissue of bark or wood. When the two forms of matter are submitted to microscopical examination, the thin sides and transverse partitions of the former will usually distinguish it from the thick-sided tubes of the latter, in which no partitions are discoverable.

(Schleiden, *Principles of Scientific Botany*, tanslated by Lankester; *Report of Twentieth Meeting of British Association*.)

HAIR-SALT. The efflorescence of native Sulphate of Magnesia is thus called.

HAIR-TAIL. [TRICHIURUS.]

HAJE, a name of a venomous Serpent, *Coluber Haje* of Linnæus. [NAIA.]

HAKE. [MERLUCIUS.]

HALCYONIDÆ, a family of Birds belonging to the Fissirostral Tribe, of the order *Insessores*, or Perching Birds, according to the system of Mr. Vigors. [INSESSORES.] This family includes the beautiful birds known by the name of Kingfishers.

In Willughby's 'Ornithology,' edited by John Ray, the "Kingfisher —*Ispida* an veterum *Alcyon*?" is placed at the head of "Land-Birds that feed upon Fish."

Ray, in his 'Synopsis,' gives the bird the same title and position; but the heading varies a little from that of Willughby; for Ray makes the Kingfisher the first of his "Aves terrestres, aquas frequentantes, rostris longis, piscivoræ."

Brisson arranged the Kingfishers (Martin-Pêcheurs) in company with the Todies, as the two genera forming the third section of his fourteenth order, consisting of those birds which have the middle of the three anterior toes united to the external one up to the third joint, and to the internal one up to the first.

Linnæus placed the Kingfishers under his order *Picæ*, between *Todus* and *Merops*, with the generic appellation of *Alcedo*, and the following definition:—" Bill trigonal, thick, straight, and long. Tongue fleshy, very short, flat, and acute. Feet gressorial in most."

Latham's second order, *Picæ*, is divided into three sections. The third of these consists of birds with gressorial feet, and consists of the Motmots, the Hornbills, the Kingfishers, the Todies, and the Bee-Eaters.

Lacépède's thirteenth subdivision consists of birds whose external toes are united almost throughout their length (Platypodes): his seventeenth order (which, with the sixteenth, eighteenth, nineteenth, and twentieth, comes under this subdivision) consists of the genera *Alcedo* and *Ceyx*.

The tenth and last family of M. Duméril's second order (Passereaux) consists of the *Tenuirostres*, or *Leptorhamphes*. It contains many genera, the Kingfishers, the Todies, the Bee-Eaters, the Humming-Birds, the Creepers, the Hoopoes, &c.

The fourth order in the method of M. Meyer comprises the genera *Merops* and *Alcedo* only.

Illiger's *Ambulatores* form his second order, the first division of which, the sixth in relation to the consecutive numbers, is termed *Angulirostres*. This division comprehends the genera *Alcedo* and *Merops* only. It is preceded by the *Syndactyli*, the last division of his first order, *Scansores*; and the *Syndactyli* consist but of one genus, *Galbula*. It is immediately succeeded by the *Suspensi*; and *Trochilus* is the only genus of this division.

Cuvier's *Syndactyles*, the fifth division of his second order, Passereaux, comprise the genera *Merops*, *Prionites* (Motmots), *Alcedo*, *Ceyx*, *Todus*, and *Buceros*.

M. Vieillot makes the *Sylvicolæ* the second order in his arrangement. The second tribe of this order (*Anisodactyli*) is made up of numerous families. The twenty-fourth consists of the Bee-Eaters and Kingfishers. It is immediately preceded by the *Epopsides*, and immediately succeeded by the *Antriades* (*Rupicola*), the twenty-sixth (*Prionotes*) consisting of the Motmots and *Calao* (Hornbills).

The Alcyons, the seventh order of M. Temminck, consist of the Bee-Eaters, the Kingfishers (Martin-Pêcheurs), and the Kinghunters (Martin-Chasseurs).

In the method of M. De Blainville h's *Scansores* are divided into the Hétérodactyles, the Zygodactyles, and the Syndactyles. *Alcedo* (Linn.) is the representative of the latter. In the method of the same zoologist, as developed by M. Lherminier, the Kingfishers (Martin-Pêcheurs—*Alcedo*, Linn.) are placed in the first or normal subclass, and form the thirteenth family, coming between *Merops* and *Buceros*.

Mr. Vigors, in his paper 'On the Natural Affinities that Connect the Orders and Families of Birds,' observes, that if the genus *Todus* of authors be examined with reference to its general affinities, an intimate resemblance will be found between it and the succeeding group of *Halcyonidæ*; since the only species known when he wrote exhibits the exact representation of a Kingfisher, with the exception of a shorter and more depressed bill. He is of opinion that we are thus conducted to the Halcyon of Mr. Swainson, a genus which he thinks extremely distinct and well-defined (regretting however—and with justice—that the name had not been retained for that group of the family which includes the European Kingfisher, the bird known to the ancients under that name), and from that genus to the *Dacelo* of Dr. Leach, until, in the more slender bill of *Alcedo*, is found an approaching conformity to the more delicately-shaped bills of the succeeding family of *Meropidæ*. In the group of *Halcyonidæ* he places the *Galbula* of Brisson, which, though distinguished from the groups of which Mr. Vigors is treating by its zygodactyle feet, and as such arranged by modern writers among the true *Scansores*, was, Mr. Vigors observes in continuation, originally included in the genus *Alcedo* by that great master of natural affinities, Linnæus, on account of the identity of the general structure and economy of both groups. Here

Mr. Vigors thinks that it must necessarily be placed, if we look to natural affinity rather than the strict dictates of artificial arrangement; and with it he fancies may be placed some apparently conterminous groups, *Capito* of Vieillot, and some of its affinities, &c., of which the toes are equally disposed in pairs. The relationship of all to the true *Scansores* may, he says, be accounted for by the consideration of that tendency which opposite sides of a circle of affinity generally evince to approach each other. The very difference however between the feet of *Alcedo* and *Galbula* (which two groups, at the same time, he adds, it must be remarked, agree more intimately in every particular of the leg and foot, except the scansorial disposition of the toes, than *Galbula* accords with any of the *Scansores* in the same characters), is lost in a species of *Galbula* which Mr. Vigors had lately inspected from Brazil, where one of the hind toes is wanting, and where the foot thus exactly corresponds with that of the three-toed *Halcyonidæ*, or the genus *Ceyx* of M. Lacépède. The singular and beautiful species of the Linnæan *Alcedo*, the Ternate Kingfisher, which Mr. Vigors characterises as a genus under the name of *Tanysiptera*, shows, in his opinion, the equal approximation of that genus to *Galbula*, and a deviation from its own type, its tail deserting the shortened character of that of the true Kingfisher, and assuming the lengthened and graduated conformation of the same member in the Paradise Jacamar and the other long-tailed *Galbulæ*. Having now arrived at the last family of the tribe, Mr. Vigors directs us to look for that connecting affinity which will lead us back to that other family of it with which he commenced his observations. Here again, he remarks, the universally-acknowledged relationship between the *Halcyonidæ* and the *Meropidæ* leaves him nothing to observe. He refers to the gradually-attenuated bills of *Alcedo* and *Galbula*, and the increasing length of the tail in the latter genus, as softening down the differences by which those families, united by general habits and economy, alone appear to be separated. Thus the circular succession of affinities by which the tribe of *Fissirostres* returns into itself appears to Mr. Vigors to be complete.

The fifth and last family of M. Latreille's second order (Passereaux) consists of the Bee-Eaters, Motmots, Todies, Kingfishers, the genus *Ceyx*, and the Hornbills. The fourth family comprises the *Tenuirostres*, and the *Scansores* (Grimpeurs) form the order which immediately follows the Passereaux.

Prince Bonaparte, in his 'Tabella Analitica de' Generi' ('Specchio Comparativo,' 1827), makes the tribe *Ambulatores* immediately follow the tribe *Scansores*. The first family of the *Ambulatores* consists of the genera *Alcedo* and *Merops*.

In M. Lesson's 'Projet' the third tribe (Syndactyles) of the first order, *Insessores* or *Scansores* (Grimpeurs), includes four families, in the following order:—*Meropidæ*, *Halcyonidæ* (Alcyonées), *Rupicolidæ* (Rupicolées), and *Buceridæ*.

In the 'Table Méthodique,' at the end of his 'Manuel,' Lesson makes the family *Meropidæ* comprise the genera *Merops*, *Alcedo*, *Dacelo*, *Ceyx*, *Syma*, *Todiramphus*, *Momotus*, and *Buceros*.

Mr. Eyton, in his arrangement, published in his 'History of the Rarer Species of British Birds' (1836), makes his fourth family (*Tenuirostres*, Cuv.) of his second order (*Passeres*, Linn.) consist of three divisions:—1st, the *Anisodactyli*, Temm.; 2nd, the *Syndactyli*, Cuv.; and 3rd, the *Alcyones*, Temm. The latter division contains the genus *Alcedo*, Ray, whilst *Merops* is arranged under the *Syndactyli*.

Mr. Swainson, in the first volume of his 'Classification of Birds' (1836), when treating of the Syndactyle foot, allows the term to be good, if limited to such feet, with united toes, as are of a different formation to all others; and would not, even if the toes were free, come under any of the definitions which he had previously given. Such a form of foot, he says, will be found in the genera *Merops* and *Alcedo*, containing the Bee-Eaters and Kingfishers, to whose feet, 'par excellence,' he limits the term Syndactyle. "The habits of these two groups," continues Mr. Swainson, "as far as concerns the use of their feet, are nearly the same, for in neither are these members ever employed but to rest the body. The Kingfisher watches patiently from a fixed station, generally a naked twig overhanging the water, for such fish as come within its reach; and then, after a time, flies to another station, where it alights and remains. The feet, from not being used for walking or standing, are consequently very small, and the toes imperfectly developed: there are three in front and one behind, but two of the former might almost be reckoned as only one, since they are united together even to the commencement of their respective claws; the inner toe is not half the length of the others, and seems rudimentary; it has a claw, and is rather more detached at its tip than the other two; in some, as in the three-toed Kingfishers, this inner toe disappears. The hinder toe is very short, and scarcely longer than the inner one; the scales of the whole foot are so thin and transparent that they can scarcely be seen in the small species by the naked eye. Those who have seen so much of the true Kingfishers, so scarce in England but so common in Tropical America, know that they never perch upon any other than small or slender branches; and this we may infer from the shape of the foot. The two outer anterior toes are very long, so that they would completely clasp two-thirds of the circumference of a small branch, the other third being embraced by the hinder toe. This fact is further confirmed by the unusual flatness of the soles of all, and by the acuteness of the claws, which from being but slightly curved would not upon a small branch come into contact with the wood; the union of the three anterior toes, by producing considerable breadth of sole, gives an unusual degree of steadiness to the bird, highly conducive to its remaining very long in one position. Thus we see that the foot of the Kingfisher, which at first appears so very imperfect, and so totally useless for ordinary purposes, is that which is most of all suited to the habits and the wants of the bird. The Bee-Eaters, like the Swallows, feed upon the wing, yet, unlike those birds, they never perch upon the ground; at least we can affirm this of the European species (*Merops Apiaster*), which visits the island of Sicily every year in great numbers, and remains for near a month, on its passage from Africa to middle and southern Europe. During this period we have sought for many years every opportunity of detecting these birds in their resting position, but never were successful in finding them otherwise than on the tops of the olive-trees, where they rest immoveable until they again dart off for another long excursion. It is indeed obvious that they could not walk, for their feet are much the same as the Wood Kingfishers (*Dacelo*), with this only difference, that the three anterior toes are divided the whole length of their last joint, the scales being rather more conspicuous."

In the second volume of the same work Mr. Swainson speaks of the *Halcyonidæ*, or Kingfishers, as obviously connected with the *Meropidæ*, next to which he arranges them. These comprise, he observes, several well-marked genera, agreeing among themselves in the great length of their bill and in the extreme shortness of their feet. These characters, he adds, it is true, belong also to the true Bee-Eater; but a remarkable difference in economy is developed in the Kingfisher. "We have seen," continues Mr. Swainson, "that the Goat Suckers, Swallows, and Bee-Eaters trsverse the air to search after and pursue their prey; their wings are consequently adapted for long and continued flight; but the family before us have a different economy, and therefore a different organisation. The whole of the genera are sedentary, watching for their food from a fixed station, which they only quit as soon as their prey approaches sufficiently near to come within the sweep of their wings; if unsuccessful in their first attack they do not pursue their game, but return again to their post, and patiently wait for another luckless straggler; if their first attack is successful they return with their victim to the same station, and then proceed to swallow it. Every one knows that these are the habits of the European Kingfisher (*Alcedo ispida*), and travellers affirm that the Kinghunters (*Halcyon*) pursue the same method in the forests of the Old World. But it has unfortunately happened that systematic naturalists, totally unacquainted with the natural habits of the other genera (nearly all of which are confined to Tropical America), have fancied they were climbing-birds, and have consequently placed them in other orders whose organisation and economy are widely different. Thus the Jacamars in the 'Règne Animal' are placed after the Hornbills, and the Puff-Birds (*Tamatia*) are associated with the Cuckoos."

The following characters are assigned by Mr. Swainson to the *Halcyonidæ*:—Wings rounded, not formed for rapid flight. Feet very feeble. Toes in pairs. He makes the family consist of the following genera and sub-genera:—Genus *Tamatia*, comprising *Tamatia*, Cuvier; *Capito*, Vieillot; *Lypornix*, Wagler; *Monassa*, Vieillot; and *Brachypetes*, Swainson.—Genus *Halcyon*, Swainson, including *Dacelo*, Leach; *Halcyon*, Swainson; *Syma*, Lesson; *Todiramphus*, Lesson; and *Ceyx*, Lacépède.—Genus *Alcedo*, Linnæus, comprehending *Alcedo*; *Ispida*, Swainson; *Tanysiptera*, Vigors; and *Alcyone*, Swainson.—Genus *Lamprotila*, Swainson.—Genus *Galbula*, Linnæus (Brisson, we suppose, is meant; Linnæus has no such genus).

Tamatia (Puff-Birds).—Bill straight, compressed. Nostrils defended by long stiff incurved feathers and bristles. Rictus strongly bristled. Toes versatile, as in *Cuculus*. (Swainson.)

Under the article BARBETS is a figure of *Tamatia macrorhynchos*, with Mr. Swainson's description of the habits of the Puff-Birds in general. In his 'Classification of Birds,' vol. ii., the same author states that the Hermit-Birds (*Monassa*) have similar habits, and frequently rise up perpendicularly in the air, make a swoop, and return again to their former station.

The sub-genera he characterises as follows:—

Tamatia.—Bill moderate, thick, conic; the tip but slightly bent. Tail narrow. Conirostral. *T. maculata*, 'Brazil. Birds,' pl. 11.

Capito.—Bill long; the tip abruptly bent, so as to form a hook. Tail narrow. Dentirostral. *C. leucotis*, 'Brazil. Birds,' pl. 11; *C. somnolentus*, *ib.*, pl. 9.

Lypornix.—Bill moderate, defended by very long bristles. Both mandibles nearly equal. Wings very short, rounded. Tail narrow. Tenuirostral. *L. striata*, 'Brazil. Birds,' pl. 34; *L. rubicula*, *ib.*, pl. 25.

Monassa.—Bill as in *Lypornix*, without the basal bristles, but with short setaceous feathers. Wings short. Tail lengthened, and very broad. Scansorial. *M. leucops*, 'Brazil. Birds,' pl. 12.

Brachypetes.—Bill as in *Lypornix*, but shorter, higher, and more curved; the margins greatly inflexed. Wings long. Tail short and even. Fissirostral. *B. tenebrosa*, 'Brazil. Birds,' pl. 35.

All these are inhabitants of the New World.

Halcyon.—Bill long, very straight, cylindrical; the sides widened;

the base more or less depressed; gonys ascending. Feet syndactyle. (Swainson.)

The following sub-genera are thus characterised:—

Dacelo.—Margin of the upper mandible considerably sinuated near the tip. Wings lengthened; the quills slightly mucronate. Tarsus [illegible] with rough scales. Australian range. (Swainson.)

D. gigantea, the Gigantic Dacelo, *Alcedo gigantea* of Latham; *Alcedo fusca* of Gmelin.—Body olive-brown, beneath whitish; tail banded with black and ferruginous, the tip white; upper mandible blackish, under one whitish with a blackish base. Male, with its head slightly crested, the crest fuscous; legs yellow; belly banded with blackish. Female with the crown of the head brown, without a crest; legs [illegible]. ('Zoological Miscellany,' vol. ii.)

Gigantic or Great Brown Kingfisher (*Dacelo gigantea*).

Dr. Leach gives Australia as the habitat of this bird, where, he adds, it is a very common bird, and he says that it is known by the appellation of Gigantic or Great Brown Kingfisher. In Governor Phillip's 'Voyage to Botany Bay' (London, 4to, 1789), the Great Brown Kingfisher is described at length, with the observation that these birds vary much, the colours being more or less brilliant, and in some of them the tail is marked as to be wholly barred with white and black, and the legs brown or blackish. The species is there said to inhabit various places in the south seas, being pretty common in New Guinea; but the specimen from which the figure given in the work was taken was sent from Port Jackson, where it is said to be not unfrequently met with. It is the Laughing Jackass of the colonists of Sydney, and Cuck'unda of the natives, according to Lesson, who says it is very common on the banks of Fish River, where he killed a great number.

Halcyon.—Bill long, straight, broad, nearly quadrangular; culmen slightly inclining towards the tip, near which the margin is slightly sinuated; gonys smooth. Wings broad, short, rounded. Tail very short. Feet syndactyle, scales of the tarsus obsolete. (Sw.)

The generic character above given appears in Mr. Swainson's 'Classification of Birds.' In his 'Zoological Illustrations' (1st series), he states that the two extreme points of difference in the Linnæan Kingfishers are seen in *Alcedo ispida* and *A. gigantea*, "the last of which has been made into the genus *Dacelo*. It will nevertheless be found that [illegible] among the birds left in the old genus there are a great number (of which indeed this bird, *Halcyon cinnamomina*, as it is there named, is a striking example), which are much nearer allied to *Dacelo* than to *Alcedo*, where they now stand. It will appear therefore more natural to consider *Halcyon* and *Dacelo* as one genus, which may be called by either name, but which must be distinguished by the characters herein given to *Halcyon*, inasmuch as the generic definition of *Dacelo* (founded on one bird) will be found too restricted to comprehend all."

Mr. Swainson then proceeds to give the following description of "*Halcyon cinnamomina*, the Cinnamon Crab-Eater," from a bird in the possession of Mr. Leadbeater, by whom it was received from New Zealand, and who gave Mr. Swainson the opportunity of publishing his figure and description.

Total length ten inches; bill two and a half inches from the gape, and one and a half inches from the nostrils; the tip of the upper mandible with a slight inclination downwards, and with an appearance of a notch; the whole head, neck, and under plumage of a delicate fawn colour; under wing-coverts the same; the remaining upper plumage with the wings and tail changeable blue green; ears sea-green and dusky united to a narrow black nuchal collar; wings four inches long, and the tail, which is even, three and a quarter inches; the hind head is slightly crested, and the feet pale-brown. (Swainson.)

Cinnamon Crab-Eater (*Halcyon cinnamomina*). Swainson.

Syna.—Bill long, enlarged at the base, compressed and thin on the sides towards its extremity, upper mandible slightly curved from the base to the point (which is very sharp), and longer than the lower mandible, which is carinated below and convex, and very sharp at its point, which is lodged in the groove (rainure) of the upper mandible; edges of both mandibles furnished for two-thirds of their length with sharp serrated teeth, strong and numerous, and directed from before backwards. Lower space around the eye naked. Third and fourth quills equal, long, the first short. Tarsi moderate, the three anterior toes united, the external toe shortest. Wings short. Tail moderate with unequal feathers to the number of ten great ones, and two external small ones. (Lesson.)

S. Torotoro, Less. (*Alcedo ruficeps*, Cuv.). Length 7 inches from the tip of the bill to the extremity of the tail. The bill 2 inches from the commissure to the point, and the tail 17 lines. Bill entirely of a brilliant golden yellow; head and cheeks of a bright uniform cinnamon yellow separated by a brighter tint in the form of a collar from the mantle (manteau) by two spots of a deep black, which do not entirely unite upon the neck. Around the eye a black circle; feathers of the mantle velvet-black, those of the wing-coverts uniform blue-green, rump bright green; quills brown within and bordered with metallic greenish externally; tail-feathers equal, of a rather deep-blue above and brown below. Throat of a light but very clear yellowish, which becomes deeper on the sides of the belly and breast, to become lighter and pass into whitish on the abdomen (bas-ventre). Feet rather strong, of a bright yellow; nails black. (Lesson.)

M. Lesson, who established this genus, states that it haunts the banks of the sea, among the Mangroves—palétuviers—(*Bruguiera*). He says that it skims the shores (grèves) for the purpose of seizing as it flies the small fishes which its strongly dentilated bill secures. He also observed many individuals skimming in their flight the waters of the small streams which are discharged into the harbour of Dorery at New Guinea, and he says that the Papuans name the bird Torotoro, doubtless from its cry.

Todiramphus.—Bill straight (the lower mandible very slightly swollen or convex), very much depressed, wider than it is high, without any arête, the mandibles equal, obtuse at the end and flattened, the edges being entirely smooth. Nostrils basal, the fissure oblique and hardly apparent, bordered by the frontal feathers. Wings short, rounded; first quill shortest, and the fourth longest. Tail long, the feathers equal, and twelve in number. Tarsi elongated, moderate, and reticulated. (Lesson.)

M. Lesson, who established this natural group, states that they live in the islands of the South Seas. They inhabit the woods, and perch almost constantly on the cocoa-palms (cocotiers). Their nourishment is only composed of small flies (moucherons), which they seize when the insects come to pitch on the spathes charged with the flowers of the palm. The islanders name them O-tataré. They were sacred birds, and it was forbidden to kill them under severe penalties. Their skins were offered to the great god Oro.

T. sacer; Alcedo tuta, Gm. and Lath.; *Alcedo sacra*, Gm. and Lath.; Sacred King's-Fisher, Lath. Total length, 8 inches 6 lines; bill, 21 lines from the commissure to the point; tail, 3 inches. Bill black, white at the origin of the lower mandible; summit of the head covered with brownish-green feathers, which form a sort of hood (calotte), separated by a large white streak which rises on the front, passes above the eyes, and continues behind the occiput. A large black line (trait) springs from the eye, and taking a tinge of green and then of brown, forms a border to the white line and circumscribes it. Throat, breast, and all the upper part of the body pure white; a very large, whitish, demicollar, waved (sinuolé) with light brown and very light chestnut, occupies the upper part of the mantle, and is bordered with black; the back, coverts of the wings, rump, upper part of the tail and wings, are uniform bluish-green; the greater quills are brown and blue on their external border; the other quills (remiges moyennes) terminated with brown. Tail brown below. Tarsi black. The wings extend to the upper third of the tail.

Sacred King's-Fisher (*Todiramphus sacer*).

M. Lesson, whose description we have selected, says that the species is very common in the Islands of Otaheite, or Taheite, and Borabora. It perches on the cocoa-palms, and the natives call it O-tataré. Its flight is short, and it is not timid. It lives on the insects which the honied exudations of the cocoa-flowers attract. This species and *Psittacus Tahitensis* remain constantly on the cocoa-nut trees, which form girdles on the shores of all those islands.

Dr. Latham remarks that his Sacred King's-Fisher has been found in Dusky Bay, New Zealand, where it is called Ghotaré.

Ceyx.—Bill entirely straight, long, a little flattened vertically, the mandibles of equal height, smooth on their edges, having each a rounded arête on their middle and the points equal and blunt; nostrils basal, oblique, and small. Third quill the longest. Tail very short, the feathers slightly unequal. Tarsi short, delicate, with only three slender toes, of which the two anterior are strongly united, and the hind toe free. (Lesson.)

M. Lesson remarks that the genus is founded on the *Alcedo tridactyla* of Latham, of which the Martin-Pêcheur de l'Île de Luçon of Sonnerat is only regarded as a variety. He also notices the *Ceyx azurea*, *Alcedo azurea* of Latham, and the *Ceyx Meninting* (*Alcedo Biru* of Horsfield?). He remarks that *C. azurea* was killed on the edge of the harbour of Doréry, in New Guinea, and that Latham indicates Norfolk Island, and Lewin, Port Jackson, as its habitats. The *C. Meninting* (Meninting-Watu, or Burung-Biru of the Javanese), which he considers identical with *Alcedo Bengalensis* of Edwards, inhabits, he says, the banks of the small streams round the harbour of Doréry, at New Guinea.

Dr. Horsefield describes the Burung-Biru as by no means uncommon in Java. He observed it chiefly in the interior, in low situations; but it was also found in the maritime districts. Its habits and manners were those of the European Kingfisher. It darts in short rapid flights along the surface among rivulets and lakes, emitting as it moves shrill sounds in a high key. These sounds are so strong and acute, that when the bird is near they strike the ear in an unpleasant manner. It is not unfrequently observed perched on trees on the banks of rivulets, and its food consists of small fishes and of aquatic insects. ('Zool. Researches in Java.')

Sonnerat describes his second species of Kingfisher, from the Isle of Luçon, as about one-third less than the Kingfisher of Europe, and as one of the most brilliant of birds. The whole head, the neck behind, the sides of the neck, the back, the rump, and tail, are of a deep lilac; the wings indigo-blue, approaching to black, but a bright and shining border of blue surrounds each feather; the throat, the neck, the belly, and the under part of the tail are white; the bill is very long, of a carmine-red, "dont la nuance est foible," the feet are red; "that," adds Sonnerat, "which especially characterises it, is that it has but three toes upon each foot, two before and one behind." ('Voyage à la Nouvelle Guinée.')

Meninting-Watu, or Burung-Biru (*Ceyx Meninting*). Horsfield.

Le Martin-Pêcheur de l'Île de Luçon, 2nd species (copied from Sonnerat's plate, which was apparently taken from an ill-stuffed specimen).

Mr. Swainson refers to this plate, only under the name of *Ceyx tridactyla* as an example of the genus.

Alcedo.—Bill very straight, compressed its whole length; the tip of both mandibles acute, and the upper one not inclined, commissure perfectly straight; feet syndactyle, all the tarsal scales obsolete; tail very short; feet with three toes before and one behind, claws simple; culmen of the bill sharp, carinated, and simple; inner and hinder toes of equal length. The species inhabit only the Old World. (Sw.)

A. ispida, Linn. This is the Martin-Pêcheur of the French; and also Pescheur, Martinet Pescheur, Tartarin, Artre, and Mounier, according to Belon; Piombino, Uccello del Paradiso, Pescatore, Pescatore del Re, Martino Pescatore, Uccello di Saucta Maria, and Vitriolo, of the Italians, according to Belon; Uccello della Madonna, Uccello Santa Maria, Piombino, and Alcione, of the same, according to Prince C. L. Bonaparte; Gemeine Eisvogel (Bechstein), and Grosser, Kleiner and Fremder Eisvogel (Brehm), of the Germans; Glâs y dorlan of the Welsh, and Common Kingfisher of the English.

Whether this species is one of the birds named 'Αλκυών (Halcyon) or 'Αλκυὼν (Alcyon)—for some of the learned doubt whether the word should be aspirated or not—by Aristotle and the Greeks, is by no means satisfactorily made out, though the better opinion seems to be that it is the 'Αλκυὼν ἄφωνος of the Greek zoologist. Belon and Pennant think that it is; Klein and M. De Bomare, on the contrary (and Camus seems to agree with them), consider it as doubtful which of our birds was meant by the Halcyon of the ancients, whose seven placid days while brooding over its poetical floating nest have become proverbial.

It has the following characters:—Bill blackish-brown, reddish at the base. Behind each eye is a patch of light orange-brown, succeeded by a white one; from each corner of the under mandible proceeds a streak of verditer-blue, tinged with verdigris-green; crown of the head deep olive-green, the feathers tipped with verdigris-green; from the nape of the neck to the tail is a strip of verditer-blue feathers, tinged in some shades with verdigris-green; chin and throat yellowish-white; breast, belly, and vent orange-brown, palest towards the under tail-coverts; tail greenish-blue; the shafts of the feathers black; legs pale tile-red. (Selby.)

The irides are hazel; the bill of the female is not so long as in the other sex; the colours also are deeper and more of a green shade.

Kingfisher (*Alcedo ispida*).

Setting aside the fable of the floating cradle in which during the Halcyon days the bird was said to rear its young, we shall find that ornithologists have differed not a little as to the actual nest of this brilliant bird. Pennant says that it makes its nest in holes in the sides of cliffs, which it scoopes to the depth of 3 feet, and in holes in the banks of rivers, chiefly those which before belonged to the water-rat; and he states the number of the eggs to be from five to nine, of a most beautiful trasparent white. The nest, he adds, is very fetid. Pennant then refers to Aristotle's description of the nest of the 'Αλκυὼν ἄφωνος, or Mute Halcyon, in which the latter states that it resembled those spherical concretions that are formed by the sea-water (ἁλοσάχνη), that it was hollow within, that the entrance was very narrow, so that if it should upset, the sea would not enter; that it resisted any violence from iron, but yielded to a blow of the hand, and when thus broken was soon reduced to powder, and that it was composed of the bones of the βελόνη (Belone), a sea-fish so named—for the bird lives on fish. Aristotle then states the number of eggs at five or thereabouts ('Hist. Anim.' ix. 14). Pennant, who, as we have observed, considers the Mute Halcyon of Aristotle to be our Common Kingfisher, observes that much of the description above quoted seems to be founded on truth. The form of the nest, he remarks, agrees almost exactly with the curious account of it by Count Zinnani. "The materials, which Aristotle says it (the nest) was composed of, are not entirely of his own invention. Whoever has seen the nest of the kingfisher will observe it strewed with the bones and scales of fish, the fragments of the food of the owner and its young; and those who deny that it is a bird which frequents the sea must not confine their ideas to our northern shores, but reflect, that birds inhabiting a sheltered place in the more rigorous latitudes may endure exposed ones in a milder climate. Aristotle made his observations in the east, and allows that the Halcyon sometimes ascended rivers, possibly to breed, for we learn from Zinnani, that in his soft climate, Italy, it breeds in May, in banks of streams that are near the sea; and having brought up the first hatch, returns to the same place to lay a second time." Now, it will be observed that Pennant, in his own description of the nest, speaks of nothing but the hole and the fetid remains, and though Zinnani gives a very good description of the excavated hole, he speaks with caution of the collection of fish-remains therein; for though, he says, of the "scaglie di pesci" with which the nest was covered, "restrano vagamente intrecciate," he adds, "ma forse non sono cosi disposte ad arte, bensì per accidente," showing that he thought their disposition about the nest was probably more the result of accident than design.

Montagu, in his 'Ornithological Dictionary,' says that the bird generally takes possession of a rat's hole to deposit its eggs; he then proceeds as follows:—"The many curious accounts which have been given of the nest of this bird induced us to take some pains to discover the fact. The result of our researches are (is), that the hole chosen to breed in is always ascending, and generally 2 or 3 feet in the bank; at the end is scooped a hollow, at the bottom of which is a quantity of small fish-bones, nearly half an inch thick, mixed in with the earth. This is undoubtedly the castings of the parent birds, and not the young, for we have found it even before they have eggs, and have every reason to believe that both male and female go to that spot, for no other purpose than to eject this matter, for some time before the female begins to lay, and that they dry it by the heat of their bodies, as they are frequently known to continue in the hole for hours, long before they have eggs. On this disgorged matter the female lays to the number of seven eggs, which are perfectly white and transparent, of a short oval form, weighing about one dram. The hole in which they breed is by no means fouled by the castings; but before the young are able to fly it becomes extremely fetid by the fæces of the brood, which is (are) of a watery nature, and cannot be carried away by the parent birds, as is common with most of the smaller species. In defect of which, instinct has taught them to have the entrance of their habitation ascending, by which means the filthy matter runs off, and may frequently be seen on the outside. We never could observe the old birds with anything in their bills when they went to feed their young; from which it may be concluded they eject from their stomach for that purpose."

Mr. Selby, after noticing the ejection of bones and other indigestible parts, in pellets, by the mouth of these birds, goes on to state that they breed in the banks of the streams they haunt, either digging a hole themselves, or taking possession of that of a water-rat, which they afterwards enlarge to suit their convenience. He then proceeds as follows:—"The bearing of the hole is always diagonally upwards, and it pierces two or three feet into the bank. The nest is composed of the above mentioned pellets of fish-bones, ejected into a small cavity at the farther end of this retreat, and upon which the eggs are laid, to the number of six or seven, of a transparent pinkish-white." He then quotes the remarks of Montagu on the sloping direction of the hole, and the use of that direction in carrying away offensive matter. ('Illustrations of British Ornithology,' vol. i.)

Mr. Rennie, in his edition of Montagu's 'Dictionary,' observes, that from the high authority of Montagu, the description above given has been copied by every recent writer, with the exception of Temminck,* who says nothing on the subject, and Wilson, who says ('Am. Orn.,' iii. 60), of his Belted Kingfisher (*Alcedo Alcyon*), that "its nest is neither constructed of glue nor fish-bones." Mr. Rennie then proceeds thus:—"We are certain of the fact that this will apply equally to our own kingfisher. In the bank of a stream at Lee in Kent, we have been acquainted with one of these nests in the same hole for several successive summers, but so far from the exuviæ of fish-bones ejected, as is done by all birds of prey, being dried on purpose to form the nest, they are scattered about the floor of the hole in all directions, from its entrance to its termination, without the least order or working up with the earth, and all moist and fetid. That the eggs may by accident be laid upon portions of these fish-bones is highly probable, as the floor is so thickly strewed with them that no vacant spot might be found, but they assuredly are not by design built up into a nest. The hole is from 2 to 4 feet long, sloping upwards, narrow at the entrance, but widening in the interior, in order perhaps to give the birds room to turn, and for the same apparent reason the eggs are not placed at the extremity. I am not a little sceptical as to its sometimes selecting the old hole of a water-rat, which is the deadly enemy to its eggs and young; but it seems to indicate a dislike to the labour of digging. It frequents the same hole for a series of years, and will not abandon it, though the nest be repeatedly plundered of the eggs or young. The accumulation of cast-bones in one of these old holes has perhaps give origin to the notion of the nest being formed of them."

Mr. Gould, in his 'Birds of Europe,' states that the eggs are deposited in a hole, such as those above alluded to, by the female, without making any nest.

Small fish, such as Sticklebacks and Minnows, form the food of the Kingfisher principally, but M. Temminck and Mr. Rennie say that the bird will also eat fry or spawn (frai), slugs, worms, and leeches.

It sits immoveable on some overhanging twig, watching for its

* But Temminck ('Manuel,' 1820) says that the bird nestles in holes in the earth, most frequently in those abandoned by the water-rats, along the abrupt banks of rivers, often under the roots of trees, in the hollows of trees, and sometimes in the holes of rocks, and that it lays from six to eight eggs of a lustrous white.

prey, and when it has secured a passing fish by a sudden dash, beats it to death against a stone on the ground, and then swallows it. At other times it will hover suspended over the water, and dart on its prey, but the bird usually makes its attack from a station. The editor of the last edition of Pennant states that it has been seen balancing itself over the water in which a great many of the small, round, shining beetles were swimming swiftly in circles (*Gyrinus natator?*), and which it makes its prey.

This species, when adult, appears to be mute except at the season of pairing; but the young are very clamorous, and frequently betray their retreat before they leave the nest—which they do not quit till they are fully fledged—by their cries. Before they provide for themselves, which they soon do, they sit on some branch while the parents fish for them, and on their approach with food are very noisy.

The flight of this bird is most rapid; it darts by like an iridescent gleam.

Temminck states that *Alcedo ispida* occurs more in the south of Europe than in the north. In Holland, he says that it is not widely spread. Mr. Selby says that it is generally dispersed through Europe, and that our birds differ in no respect from those of the same species in Asia and Africa, as he has had an opportunity of examining specimens from both continents. M. Temminck observes that the most common of the three species of Kingfisher must not be confounded with our *A. ispida*, though it differs but little from it. The Common Kingfisher is a resident with us, as it is in Italy and other European countries. Mr. Gould says that the young in the British Islands appear to have habits of partial migration, as they wander from the interior along the rivers to the coasts, frequenting in the autumnal and winter months the mouths of small rivulets and dykes near the sea; but more particularly along the line of the southern coast and the shores of adjacent inlets. We may here remark, that in the 'Portraits d'Oyseaux' of Belon, the following quatrain is printed under the cut of the Common Kingfisher:—

"Le Martinet-Pescheur fait sa demeure
En temps d'hyver au bord de l'ocean :
Et en esté sur rivière ou estan :
Et de poisson se repaist à toute heure."

It may be imagined that a bird of which so many marvellous stories have been told, under the idea of its being the Halcyon of the ancients, whose so-called nest, the *Halcyoneum*, was supposed to be endowed with medical properties, did not entirely escape the attention of the superstitious moderns. Thus its dried body was said to preserve woollen cloth from the moth, and if suspended by a thread from the ceiling of a room with doors and windows closed, to turn its bill towards the quarter whence the wind blew.

Barabas, in Marlowe's 'Jew of Malta,' says—

"But now how stands the wind?
Into what corner peers my Halcyon's bill?
Ha! to the east? yes."

Kent ('King Lear,') when, in his answer to Cornwall, he is rebuking such 'slaves' as the 'Steward,' declares that they—

"Renege, affirm, and turn their Halcyon beaks
With every gale and vary of their masters."

Mrs. Charlotte Smith states that she once or twice saw a stuffed bird of this species hanging from the beam of a cottage-room as a weather-vane to show the way of the wind. It has lately been seen in a similar position at Botley near Southampton. In the same part of the country some of the common people fancy that if a dead Kingfisher be suspended by the bill it will turn its breast according to the ebb and flow of the tide. The bird was also supposed to be a protection against thunder, to increase hidden treasure, to bestow grace and beauty on the person who carried it, and to renew its plumage, dead as it was, every season by moulting.

With reference to the question as to what species was meant by Aristotle, the reader should be aware that another Kingfisher, *Alcedo rudis* of Linnæus (*Ispida* (?) Swainson), occurs in the islands of the Grecian Archipelago, though Africa and Asia appear to be its more particular localities. The species is figured in Mr. Gould's beautiful work on the 'Birds of Europe.'

Ispida.—Habit of *Alcedo*. Culmen obtuse, somewhat flattened, and margined on each side by an indented groove. Tail lengthened, rounded. Inner toe much longer than the hinder. Claws either deeply notched, or cleft, so as to present two acute unequal points. (Swainson.)

Geographical Distribution.—Chiefly the New World. (Swainson.)

Mr. Swainson, who, in his 'Classification of Birds,' gives the habitat above stated, describes two species, *Ispida gigantea* and *I. bicincta*, in his birds of Western Africa. He states, and with reason, that among the largest-sized Kingfishers that have long been imperfectly known and incorporated in our systems, there is the greatest confusion, not only as to the characters of the birds themselves, but likewise in regard to their native countries. We have therefore, knowing the accuracy of Mr. Swainson's pencil, copied his figures of *Halcyon cinnamomina*, *Ispida gigantea*, and *Alcyone Australis* (the latter from Mr. Swainson's figure in the 'Zoological Illustrations,' with the aid of a specimen in the Museum of the Zoological Society of London),

as the best, if not the only mode of conveying to the reader the forms that he would designate under the names of *Halcyon*, *Ispida*, and *Alcyone*.

Above, cinereous, spotted with white; chin and cheeks white, immaculate; breast with a broad rufous collar; head above black, crested behind.

It is a native of Senegal.

Ispida gigantea. Swainson.

Tanysiptera.—Bill rather short, somewhat thick, straight, acute; nostrils oval. Tail graduated; two middle tail-feathers longest. (Vigors.) Mr. Swainson gives India as its habitat.

T. Dea; Alcedo Dea, Linn.; *Ispida Ternatana*, Briss. Above, intense black azure, white beneath; head and wing-coverts cærulean; tail-feathers white margined with cærulean, the two middle ones cærulean, with their apices club-shaped and white. (Vigors.)

Tanysiptera Dea.

Alcyone.—Bill as in *Alcedo*; but the feet with only three toes. Australia. (Swainson.)

A. Azurea. Body above, sides of the head and neck, shining ultramarine blue; beneath rufous; chin and throat whitish; wings blackish, inner fore toe wanting. (Swainson, 'Zool. Ill.,' 1st series, where it is figured and described as *Alcedo azurea.*)

Alcyone Australis.

It is found in Australia.

Habits.—Lewin, who has figured this Kingfisher in his 'Birds of New Holland,' states that it inhabits heads of rivers, visiting dead trees, from the branches of which it darts on its prey in the water beneath, and is sometimes completely immersed by the velocity of its descent.

Lamprotila.—Plumage metallic-green and gold. Bill very broad, dilated; the commissure and culmen curved; the upper margins folding over the lower. Nostrils membranaceous; the aperture round, protected by feathers. Wings as in *Galbula*, but longer; the third and fifth quills equal. (Sowerby.)

L. platyrhyncha.

Lamprotila platyrhyncha.

Galbula.—Plumage metallic. Bill very long, perfectly straight, greatly compressed; the culmen sharp; the tip not bent. Wings short. Tail lengthened, graduated. Toes in pairs, or with the hallux wanting. Nostrils with a few strong bristles. (Sw.)

Mr. Swainson remarks ('Classification of Birds,' vol. ii.) that the habits of the Jacamars and those of the Puff-Birds and Hermit-Birds are similar, although the flight of the latter is weaker. "The Jacamars," he says, "generally sit on low naked branches in the forest paths, from whence they dart upon butterflies, spearing them with their long bill: their haunts indeed may frequently be known by the ground being strewed with the beautiful wings of their victims, the body alone of which they devour."

Mr. Swainson further observes that in all the groups of this family previously noticed the bill is invariably compressed on the sides, and generally of considerable length; but in *Galbula grandis* a change from this structure is first discovered, and we see a bill considerably broad and depressed; that character, in short, which is in unison with the next family, according to Mr. Swainson's arrangement, namely, the *Trogonidæ*.

G. paradisea, Swallow-Tailed Kingfisher, Edw.; Paradise Jacamar, Lath. Size of a lark; colour golden-green; throat, neck, and lesser wing-coverts white; head violaceous-brown; bill and feet, the latter of which are feathered to the toes, black; two intermediate tail-feathers longest.

It is a native of Surinam.

Swallow-Tailed Kingfisher (*Galbula paradisea*).

HALE'SIA (named in honour of Stephen Hales, D.D., author of 'Vegetable Statics,' &c.), a genus of Plants belonging to the natural order *Styraceæ*. It has a monopetalous corolla ventricosely campanulate, with a 4-lobed erect border; the stamens 12 to 16; filaments combined into a tube at the base, and adnate to the corolla; the anthers oblong, erect, 2-celled, dehiscing lengthwise; the ovary inferior; the style single; the stigma simple; the fruit a drupe, which is dry, oblong, with 2-4 winged angles, terminated by the permanent style; the cells 1-seeded, with the seeds at the bottom of the cells. The species are trees with alternate serrated leaves, and lateral fascicles of pedicellate drooping white flowers. This genus has been made the type of an order *Halesiaceæ* by D. Don, who is followed by Link and others.

H. tetraptera, Common Snowdrop-Tree, has ovate, lanceolate, acuminated, sharply serrated leaves; the fruit with four wings. This plant is a tree, growing from 15 to 20 feet high, and is a native of South Carolina. It has fine white flowers, from 9 to 10 in a fascicle, drooping and resembling those of a snowdrop. The wood is hard and veined. It is one of the hardest and also one of the handsomest of the American deciduous trees. The rate of growth for the first five or six years is from 12 to 18 inches a year. It ripens its seeds freely in this country, and it may be propagated from these or imported seeds. There is another species, *G. diptera*, which is also an American plant, but does not attain so great a height as the last. *H. parviflora* is a native of Florida, and is supposed by some botanists to be merely a small flowered variety of the first. They will grow in any common garden soil, and may be propagated by slips from the root, as well as from seeds.

(Don, *Dichlamydeous Plants*; London, *Encyclopædia of Trees and Shrubs.*)

HALF-BEAK. [Esox.]

HALIÆETUS. [Falconidæ.]

HALIBUT. [Hippoglossus.]

HALICHŒRUS. Professor Nilsson's name for a genus of Seals. [Phocidæ.]

HALI'CORE, or HALI'CORA. [Cetacea.]

HALI'DRACON. [Plesiosaurus.]

HALIDRYS. [FUCACEÆ.]

HA'LIEUS. [PELECANIDÆ.]

HALIME'DA, a portiou of the genus *Corallina*, Linn., for which Lamarck had used the name *Flabellaria*, is thus styled by Lamouroux. ('Exposition Méthodique des Genres.') The articulatious are flat or compressed, rarely cylindrical, almost always flabelliform; the axis fibrous, surrounded by a thin cretaceous substance.

HALIMUS. [MAIADÆ.]

HALIO'TIDÆ, a family of Gasteropodous *Mollusca*, to which the shells commonly called Ear-Shells, or Sea-Ears, belong. Mr. Swainson, in his first series of 'Zoological Illustrations,' observes, when writing on the Small-Holed Californian Ear-Shell (*Haliotis Californiensis*, 1820-21), that "the definitions given by conchologists up to that time were so imperfect that they had left our knowledge of these shells nearly the same as in the time of Linnæus. Seventeen species only are enumerated in Mr. Dillwyn's work; although thirty-four have fallen within my own observation during the last few months."

Linnæus, who records the seven species known to him under the generic appellation of *Haliotis* (Sea-Ear), describes the animal as a Slug (*Limax*), and the Shell as ear-shaped and open (patens), with a lateral hidden spire, and the disc longitudinally pierced with holes (poris). He places the genus between *Nerita* and *Patella*.

Cuvier, in the first edition of his 'Règne Animal' (1817), makes the Ormiers (*Haliotis* of Linnæus) the first genus of his sixth order of Gastropods, *Scutibranchiata*. [GASTEROPODA.] He observes that it is the only genus of the order which has its shell turbinated, and that among these sort of shells that of the Ormiers is remarkable for the excessive amplitude of its aperture, its flatness, and the smallness of the spire, which is seen from within. This form, he adds, has caused it to be compared to the ear of a quadruped. Cuvier divides the genus into the following sub-genera:—1, the Haliotids, properly so called (*Haliotis* of Lamarck); 2, the Padolli of De Montfort; 3, the *Stomatiæ* of Lamarck. The Ormiers are immediately followed by the Cabochons (*Capulus* of De Montfort—*Patella Hungarica*).

Lamarck ('Animaux sans Vertèbres,' 1817) arranges the genus *Haliotis*, which is immediately preceded by *Stomatia*, as the last genus of his Macrostomes. The following is his definition of *Haliotis*:—

"Shell ear-shaped, most frequently flattened; with a very short spire, sometimes depressed, nearly lateral. Aperture very ample, longer than it is wide, entire in its perfect state. Disc pierced with holes disposed on a parallel line near the left-hand border, the last commencing with a notch."

The same zoologist makes the following observations on the genus as restricted by him:—"The Haliotids constitute a very beautiful genus, rather numerous in species and remarkable for the singular form and the brilliant nacre of their shell. They have received the name of Sea-Ears, because they in fact represent sufficiently well the form of the cartilage of the ear in man. Their shell is an oval-oblong, flattened in general, slightly spiral near one of its extremities, and furnished with a row of holes disposed on a curved line near the left-hand border and parallel to it. As the animal increases in growth, it forms for itself a new holo on the edge of the anterior part of the shell; this hole commences with a notch which serves to give a passage to the siphon of the animal, and is afterwards completed; when another is formed posteriorly. In its natural situation, and when the animal crawls, this shell may be considered as a reversed basin with its convexity upwards. Its circumference is then considerably exceeded by the very large foot of the animal, and the spire is found on the postorior part of its body. Following the description of the Ormier (tho animal of the *Haliotis*) giveu by Adanson, I had supposed that the branchiæ of this animal were exterior, like those of the Phyllidians: but M. Cuvier has undeceived me by showing me that they are hidden in a particular cavity. *Haliotis* therefore belongs to the family of Macrostomes. With regard to the tentacula, it has not perhaps really more than two. But as it is not uncommou (assez fréqnent) among the marino Trachelipods to find the eyes carried each upou a tubercle which springs at the external or posterior base of the tentacula, these tubercles are apparently more elongated hore than elsewhere: in this case the two larger tentacles are the anterior ones." Lamarck records fifteen species, iucluding *Haliotis dubia*.

Mr. Swainson ('Zool. Illustr.,' 1st series) remarks that "the genus *Padollus* of Montford (De Montfort ?) restiug entirely on the unevenness of the outer lip, without any knowledge of the auimal," appears to him an unnecessary distinction, for such, he observes, is the character of all young shells, and also of mature ones, whose outer surface is rugged or uneven.

De Montfort (1810) gives the following generic characters for *Padollus*:—Shell free, univalve, in the form of an ear, pierced with one or two holes; summit spiral, flattened, dorsal; aperture oval, wide open (évasée), entire, perpendicular; left lip reflected and trenchant; back covered with an epidermis, having a gutter in the middle and in the direction of the spire. He gives as the type of tho genus *Padollus rubicundus*, and proceeds nearly as follows:—"In arranging this shell as intermediate between the *Sigareti* the *Stomatiæ* and the *Haliotides*, we consider that wo have been ablo to establish upon it a new genus. Sufficiently similar to the *Haliotides* by its general contour (l'ensemble de ses formes), it is in some manner uevertheless approximated to tho *Stomatiæ*, iuasmuch as it has very few holes; but it presents, more than almost any of these shells, a spiral gutter, hollow in the interior, elevated on the back, placed in the middle and curved in the direction of the spire. This hollow, or gutter, is independent of the curved and serial liue of holes, which are nearly all obliterated. The right-lip is also more opened out (s'épanouit aussi d'avantage), it juts out and festoons (festonne) over the left lip towards the summit, and to the height of the spire: the interior offers an iridescent and undulated uacre. Externally it is of a brick-red, and the summit, in consequence of losing its exterior calcareous and coloured coat, is nacreous. The back is finely striated and reticulated, and the successive periods of growth are very strongly marked there. There is no doubt that the obliteratiou of the holes of the *Padolli* are a consequeuce of the absence of some organs, with which the *Haliotides* must be emiuently provided, and it is even probable that the single hole which notches their border serves during the life of these mollusks to lodge a fold of the border of the mantle, rolled into a tube and serving for respiration; a tube which we shall find among many of the spirivalve mollusks."

Considering the time at which De Montfort wrote, there is much good reasoning iu this passage; it must be recollected that he evidently gave his description from a young shell; for he says iu the course of it that the shell sometimes reaches more than an inch in its greatest diameter.

Dr. Leach (1814) adopted De Montfort's distinction and name. The doctor says that this genus is readily distiuguished from *Haliotis* (Ear-Shell) by the irregular form of the outer edge or lip; the disc, he adds, has fewer perforations and the spire is placed farther on the back. He states iu conclusion that the animal is unknowu, but is probably not very unlike that of the Ear-Shell.

Mr. G. B. Sowerby ('Genera of Recent and Fossil Shells'), observes, that with the exception of a few that are commonly kuown by collectors and Liunæans as Imperforate Ear-Shells, the genus *Haliotis* has not suffered any dismemberments. "An attempt," continues Mr. Sowerby, "has iudeed been made by Montfort to separate from the genuine *Haliotides* two or three species under the name of *Padollus*, in which he has been followed by Leach, but as far as respects general adoption this attempt appears to have been as unsuccessful as it was unnecessary. Not so the separatiou of the Imperforate *Haliotides*, which are easily distinguished by wanting the row of perforations so very characteristic of the true *Haliotis*."

The *Otidea* form the first family of *Scutibranchiata*, the third order of *Paracephalophora Hermaphrodita* iu M. De Blainville's arrangement ('Manuel de Malacologie,' 1825.) The first geuus of this family is *Haliotis*, divided into four sectious, aud iucluding the genera *Padollus* and *Stomatia*.

M. Rang ('Manuel,' 1829) continues the Ormiers (Macrostomes of Lamarck, *Otidea* of De Blainville, Auriformes of Latreille) as the first family of *Scutibranchiata* (Cuvier); but he makes it consist but of ouo genus, *Haliotis* (Liunæus). The genus *Stomatia* of Lamarck he places under the Sigarets of De Férussac, as well as the genus *Stomatella* of Lamarck, which he seems to consider as includiug the *Padollus* of De Montfort. The Sigarets in this arrangement are made to form the ninth family of the *Pectinibranchiata* of Cuvier.

In Cuvier's last edition of the 'Règne Animal' (1830), the position and arrangement of the Ormiers remains as iu the first editiou, with the exception that in the last edition tho *Scutibranchiata* form the eighth order of his Gastropods.

In the present state of our information it will perhaps be as well to select the arrangement proposed by Cuvier, and in great measure adopted by M. De Blainville. M. Rang, in his description both of *Stomatella* (iucluding *Padollus*) aud *Stomatia*, says, "Animal unknown."

Haliotis (properly so called; *Haliotis*, Lamarck).—Animal.—One of the most oruamented of Gastropods. All round its foot to its mouth there is, at least in the more common species, a double membrane cut out iuto leaflets (feuillages), and furnished with a double row of filaments. On the outside of its long tentacles are two cylindrical pedicles for carrying the eyes. The mantle is deeply divided on the right side, and the water, which passes by means of the holes in the shell, can, through this slit, penetrate into the branchial cavity; along its edges again are also three or four filaments, which the animal can also cause to come out through these holes. The mouth is a short proboscis. (Cuvier's description for all Gmelin's *Haliotides*, except *H. imperforata* and *H. perversa*.) Body oval, very much depressed, hardly spiral behind, provided with a large foot doubly fringed ou its circumference. Head depressed; teutacles a little flattened, joined (connés) at the base; eyes carried on the summit of prismatic peduncles, situated on the external side of the tentacles. Mantle very delicate, deeply divided on the left side; tho two lobes poiuted, forming by their junction a sort of canal for conducting tho water into the branchial cavity situated on the left, and inclosing two very long, unequal, pectinated branchiæ (peignes branchiaux). (De Blainville.)

Animal oblong, depressed, furnished with a large head and a short proboscis, at the extremity of which is the mouth, containing a tougue armed with points (aiguillons); tentacles two, long and cylindrical; eyes on pedicles, implanted at their external base, a little backwards. Mantle short, delicate; foot very large, oblong, furnished all round with a double row of festoons agreeably cut out or pinked (decoupés).

Organs of respiration composed of two unequal pectinated branchiæ, in a cavity open to the left, the muscle of attachment occupying the middle of the animal; vent (anus) opening into this cavity opposite the slit which forms its aperture. (Rang.)

In addition to the general account of the organisation given by Cuvier, we refer the reader to No. 489 (Gallery) of the Physiological Series of preparations in the Museum of the College of Surgeons. A small specimen is there prepared to show the stomach. The floor of the branchial cavity, the gills, and anus are turned back, and the integument is removed from above the œsophagus and first stomach. A bristle is passed through the mouth into the œsophagus, and another from the first to the second stomach. The latter cavity is imbedded in the liver, and receives the secretion of that gland by such wide orifices that portions of the alimentary substances have entered the biliary ducts, which thus appear to be ramifications of the alimentary canal. ('Catalogue,'—Gallery, vol. i.)

Shell nacreous, very much depressed, more or less oval, with a very small spire, very low, nearly posterior, and lateral; aperture as large as the shell, with continuous borders, the right border delicate and trenchant, the left flattened, enlarged, and trenchant; a series of complete or incomplete holes, parallel to the left side, serving for the passage of the two pointed lobes of the mantle; a single large muscular impression, median, and oval. (De Blainville.)

These, the true *Haliotides*, forming M. De Blainville's section

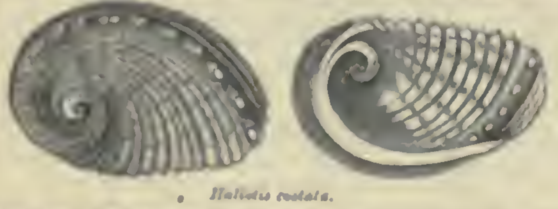
A. consisting of species whose disc is rounded forwards and pierced with a series of holes, vary much in size and shape.

The general form may be imagined from that of *Haliotis tuberculata*,

Haliotis tuberculata.

a, animal and shell; *b*, interior of shell.

the most common species, the size, shape, &c. of which is too well known to require description, and from *H. costata*; but there are some of the species from the warmer climates that are as large or larger than the crown of a hat, and are absolutely dazzling from the splendid



Haliotis costata.

iridescence of their nacre. The shape too varies considerably. Thus we have among the comparatively small species a form very nearly round (*H. excavata*), whilst *H. Asinina* is very much elongated.

There are about 75 recent species of *Haliotis* known, and 4 fossil species.

Both M. De Blainville and M. Rang state that species of *Haliotis* exist in all the seas; the latter uses the expression, "elles sont très répandues dans toutes les mers," but their limits seem not to go far beyond temperate climates. They are found in the Canaries, at the Cape, in India, China, Australia, New Zealand, the Pacific, and California. None appear to have been seen by our northern voyagers; and though *H. tuberculata* (which there can be little dout is the ἀγρία λεπάς, ἣν τινες καλοῦσι θαλάττιον οὖς—"the wild lepas, which some call the Sea-Ear"—of Aristotle, 'Hist. An.,' lib. iv. c. 4), is common at Guernsey and Jersey, and has been found (that is, the shell) on the south coast of Devonshire, we agree with Mr. Sowerby in thinking that, on the present evidence, this species cannot with propriety be considered a native of our own coasts, though the dead shells are sometimes thrown up on our southern shores after violent storms.

The *Haliotides*, which are all marine and littoral, being without opercula, adhere, like the *Patellæ*, by applying their under parts to the surface of the rocks. They are generally found near the water's edge, and, according to Lamarck, go during the fine summer nights to feed on the herbage which grows near the shore.

As an article of food this genus is by no means to be despised. We have eaten *Haliotis tuberculata*, and when served by a good cook it is tender and sapid. The large fleshy foot, if not properly managed, is apt to be tough. The people of Guernsey and Jersey ornament their houses with the shells of this species, disposing them frequently in quincunx order, and placing them so that their bright interior may catch the rays of the sun. We have often thought that some of the large and splendid intertropical species, whose exterior, after removing the outer coat, take a polish almost equalling the natural brilliancy of the inside, might be converted into dishes for holding fruit: if mounted with good taste, their indescribable iridescence would materially add to the richness of an elegant table. As it is, the shells of *H. tuberculata* are extensively used for making mother-of-pearl ornaments, especially in ornamenting papier maché articles. For this purpose great quantities are taken to Birmingham.

B. Species whose disc, besides the series of holes, is raised by a large parallel rib, hollowed interiorly, and whose anterior border is more or less irregular.

Padollus (De Montfort).—M. De Blainville refers to *Haliotis canaliculata* (Lamarck), as the example. The figure in Knorr, referred to by Lamarck, is red externally, and has the elevated rib; but the shape of the shell is longer than that of *Padollus scalaris* (Leach), and of other *Padolli* which we have seen. The specimen recorded by Dr. Gray in the Appendix to the 'Narrative of a Survey of the Intertropical and Western Coasts of Australia, performed between the years 1818 and 1822, by Captain Philip Parker King, R.N., F.R.S., &c.,' vol. ii., and which Mr. Gray notices as the largest he ever saw, measured 3¼ by 2½ inches. We have seen the shell, and never saw so large a specimen. Dr. Gray records it as *Padollus rubicundus* of De Montfort, with the synonyms of *Padollus scalaris*, Leach, and *Haliotis tricostalis*, Lamarck.

Padollus rubicundus (?).

Lamarck, on the authority of M. Leschenault, says that his *Haliotis tricostalis* inhabits the seas of Java. The fine specimen brought to England by Captain King was found upon Rottnest Island, on the west coast of Australia, and is now in his cabinet. It has only three holes, the anterior ones, open. All, both those which are closed and those which are open, are very highly elevated, and so is the curved longitudinal rib. The left border externally is very much raised and nodulous, looking at first sight as if it had another row of holes which had been closed; but it was evidently always imperforate.

C. Species whose disc is not pierced, but hollowed longitudinally by a decurrent canal.

M. De Blainville gives as an example of his section C. *Haliotis dubia* of Lamarck. It will be clear to the observer that the animal protected by such shells as the two next, must exhibit some differences from that of a true *Haliotis*.

D. Species whose disc is not pierced, and which offer the two gutters together, but approximated, so as to leave externally a decurrent rib between them.

Stomatia (Lamarck).—Cuvier, who says that the animal of *Stomatia* is much less ornamented than that of *Haliotis*, is of opinion that this form connects the *Haliotides* with certain *Turbines*.

Mr. G. Sowerby ('Genera of Recent and Fossil Shells,' No. xix.) observes that Lamarck, in his observations upon *Stomatella*, tells us that in respect to their general form those shells appear to be nearly related to the *Stomatiæ*; and that they are principally distinguished by the transverse ridge and the elevated outer lip of the *Stomatiæ*. Upon a careful examination however of ten species, Mr. Sowerby was unable to discover any difference in the outer lip; and he remarks that Lamarck places among his *Stomatellæ* one species, *S. rubra*, which has a nodular keel placed exactly in the same position as the transverse ridge, by which the latter characterises *Stomatia*; so that Mr. Sowerby does not find any generic difference whatever, and has therefore united the two Lamarckian genera under the appellation *Stomatia*. He thus characterises the genus thus reformed :—Shell pearly within, mostly coloured externally; suborbicular or long, generally ear-shaped and depressed. The spire, in most species, prominent, but not produced nor elongated ; sometimes very small, marginal and inconspicuous. Aperture mostly longitudinal, in some species nearly orbicular, in others much elongated, always very large ; its edges entire, united at the upper part, and scarcely modified or altered in form by any portion of the last volution. Volutions from two to four. Muscular impressions two, seldom distinct, nearly marginal, and in the open part of the shell.

Mr. Sowerby goes on to state that *Stomatia* appears to be related to *Haliotis*, and is therefore rightly placed by Lamarck among his Macrostomes. One of its species is arranged by Linnæus, he adds, as a *Haliotis*, under the name of *H. imperforata* (Gmel.). Mr. Sowerby does not pretend to discuss the question of their resemblance to Lamarck's Turbinacées ; but only observes that in general form some of them approach very nearly to some of Lamarck's Monodontes. The *Stomatiæ*, he states in conclusion, are marine, and he says that all the species he has seen wero brought from tho East Indies aud Australia.

Stomatia has been found at a depth of seven fathoms, adhering to *Meleagrinæ* and corals.

The following genera are referred by some writers to *Haliotidæ*, *Broderipia*, *Scissurella*, *Pleurotomaria*, *Murchisonia*, *Trochotoma*, *Janthina*. [TURBINIDÆ ; JANTHINIDÆ.]

HALISPO'NGIA. According to the structure and composition of the numerous species of Sponges, they may be divided into genera. If, in accordance with the observations of Dr. R. Grant, we consider sponges in three groups, one having a horny tubular structure, another containiug calcareous spiculæ, a third contaiuing siliceous spiculæ, we may adopt the three generic types, *Spongia*, *Calcispongia*, and *Halispongia*, of De Blainville.

Halispongia is thus characterised :—Mass more or less rigid or friable, of irregular figure, porous, traversed by winding canals, which eud in openings scattered over the surface; substance subcartilaginous, supported by simple siliceous spiculæ.

The species exhibit various external forms, encrusting, branching, or foliaceous. Dr. Fleming includes them under the titlo *Halichondria*. [SPONGIADÆ.]

HALITHE'A, a genus of marine Dorsibranchiate Annelids belonging to the family *Aphroditidæ*. [ANNELIDA.]

HALKET, a kind of Seal. [PHOCIDÆ.]

HALLI'RHOA, the name proposed by Lamouroux for a group of Fossil *Polyparia*, referred by many writers to *Alcyonia*. The spheroidal figure, contracted base, deep central pit, and pores on the surface, appear the characters most relied on by Lamouronx. Goldfuss gives characters for the genus *Siphonia* of Parkinson, which may include the two species meutioned by Lamouroux from the vicinity of Caen and the Vaches Noires. *Hallirhoa costata* of Lamouroux is found in the Greensand of Normandy and England.

HALLOYLITE, a Mineral named after Dr. Omalius d' Holly, a French geologist. It is a hydrous silicate of alumina. It occurs massive and earthy, resembling a compact steatite. It yields to the nail aud may be polished by it. It has a whito or bluish colour. Adheres to the tongue, and small pieces becomo transparent in water. It is found at Liègo aud at Bayonno in France. It has the following composition :—

Silica	39·5
Alumina	34·0
Water	26·5
	100·0

HALLOYSITE. [HALLOYLITE.]

HALMATURUS. [KANGAROO.]

HALO'DROMA, Illiger's name for a genus of Sea-Birds allied to the Petrels and Albatrosses. [LARIDÆ.]

HALO'NIA, a genus of Fossil Plants, allied to *Lepidodendron*, and occurring in the Coal Formation. [COAL PLANTS.]

HALORAGA'CEÆ, *Hippurids*. a small group of Exogenous Plants, many of which inhabit watery places, and all of which have minute inconspicuous flowers. In consequence of the calyx being superior, the embryo without much albumen, and some of them having four petals, they are often considered to form a peculiar section of *Onagraceæ*, or if separated from that order, are at least stationed in the immediate vicinity of it. Upon this supposition, they are looked upon as an imperfect coudition of the Onagraceous type, bearing the same relation to it as *Sanguisorbeæ* to *Rosaceæ*, *Chamælaucieæ* to *Myrtaceæ*, or *Mimoseæ* to other *Fabaceæ*. But in the present uncertainty regarding the true affiuity of many natural orders of plants, we must not consider this a settled point. On the coutrary, it is not improbable that *Haloragaceæ* constitute an imperfect form of the great Epigynous group of Exogens, of which *Onagraceæ* are only one of the members. What renders it peculiarly difficult to determine the real affinity of this little gronp is, that as it is now constituted, it offers striking modifications of development both in the organs of vegetation and those of fructification. While *Haloragis* has a stem with a complete vascular organisation, and regularly constructed leaves, *Myriophyllum* has its vascular system reduced to a rudimentary condition, and iu some of the species the leaves themselves appear only in the form of filiform ramifications ; and in *Hippuris*, the development of the vascular system of both stem and leaves is still further reduced. In like mauner in the flowers, *Haloragis* has four petals, eight stamens, four stigmas, aud four cells to the ovary ; *Proserpinaca* has no petals, three stamens, three stigmas, and three cells to the ovary; and *Hippuris* has no petals, one stamen, one stigma, and but one cell to the ovary. This latter genus is a common plant in the marshes and meadows of this country, where it is vulgarly called Mare's-Tail.

Common Mare's Tail (*Hippuris vulgaris*).

1, a single flower, with its bract, much magnified ; 2, a vertical section of the ovary, showing a single ovule hanging from the apex of a single cell ; 3, a vertical section of a ripe fruit, showing the seed suspended in the interior, and the dicotyledonous embryo.

Damp places, ditches, and slow streams in Europe, North America, Southern Africa, Japan, China, Australia, and the South Sea Islands are the resort of this order.

HALOSCIAS (Fries), a genus of Plauts belonging to the natural order *Umbelliferæ*, aud the tribe *Seselineæ*. It has a calyx of 5 small persistent teeth ; the petals ovate with an inflexed lobe aud short claw; the fruit elliptical, terete, or slightly dorsally compressed ; carpels with five sharp somewhat winged ridges; interstices and commissure with many vittæ; seed not cohering to the carpel, without vittæ. One species of this genus is a native of Great Britain.

H. Scoticum, Scottish Lovage, is found on rocks on the sea-coast of Scotland aud Northumberland. It has an herbaceous stem, tiuged with red, from 12 to 18 inches high.

(Babington, *Manual.*)

HALTICA, a genus of Insects belouging to the order *Coleoptera*, and to the tribe *Galerucitæ* of the family *Cyclica*. It includes the insects called Black Fleas, Turnip-Flea, or Turnip-Fly. The species of the genus *Haltica* are remarkable for their power of leaping, which is effected by means of the peculiar formation of their very thick hind legs. They are among the smallest of beetles, and are varionsly coloured with green, brown, or yellow, often brightly shining. Some destroy the cabbage, others flax, others tobacco, or hops ; but the turnip is the greatest sufferer from the ravages of these little creatures, which, though small in size, are many in number.

The species found on the turnips is the *H. Nemorum*. It is about one-eighth of an inch long, is rather flattened, and of a brassy-black colour, thickly dotted ; the wing-cases are grecuish-black, with a palo yellow broad line on each, the base of the autennæ and legs of a paler colour. The eggs are deposited on tho under side of a rough leaf from April to September. They hatch in two days, and the larva attain perfection in sixteen days. Tho chrysalis is fixed in the earth a fortnight. They lovo sunshine, warmth, aud fine weather, and eat away tho surface of the youug leaves of the plant with voracity. Tho larva feeds withiu the full-grown leaf, iu which tho egg has been laid and attached hy its parent, but does little or no mischief to the growth of the plant. It is the beetle which destroys the first smooth leaves or cotyledons of the turnip. It scents out the turnip crop from a great distance, and flies towards it even against the wind. It feeds by night, and during the day retires under the cotyledon. The parent insects are to be seen in the earliest fine days of February, and do not disappear before the end of October, but they do not feed much after the latter end of September. There are five or six broods of these in a summer. Besides the *H. Nemorum*, the *H. similis* and *H. flava* are also destructive to turnips.

The destruction caused by these insects may be conceived, when, so long ago as 1786, Mr. Young stated that the turnip crop destroyed in Devonshire alone was valued at 100,000*l.*; consequently, many entomologists have directed their attention both to the inquiry into the habits of the animal and the finding a remedy for the mischief it causes. Admirable essays on the subject have been published in the 'Entomological Transactions' by Mr. Le Keux, and in the 'Journal of the Agricultural Society of England,' by Mr. J. Curtis, which may be consulted with advantage by the farmer.

Among the remedies which have been proposed are fumigation, watering with weak brine, steeping the seed in brine, applying lime and soot to the land, and the application of wormwood decoction and road-dust. The last has been greatly recommended in Germany, and there is an essay on the subject, by M. Wundram of Dorste, Hanover, in the 'Transactions of the Royal Agricultural Society of Vienna.'

The rapid growth of the turnip plant is the best remedy, and in order to secure this, plenty of seed of the same age should be sown. Deep digging and burning the land when the chrysalides are in it are good practices. Sowing the surface of the soil with gas-lime two or three mornings after the seed has been sown has been recommended as the most effectual remedy.

HALYMENITES. Under this generic name Sternberg ('Flora der Vorwelt') and Bronn ('Lethæa Geognostica') include several species of Fossil Fucoid Plants, found in the slaty Oolitic rocks of Stonesfield and Solenhofen.

HALYSITES, the name given by Fischer to a genus of Fossil Corals, synonymous with *Catenipora* of Goldfuss. As having priority, it is adopted by Bronn in his 'Lethæa Geognostica.'

HAMAMELIDA'CEÆ, *Witch-Hazels*, a very small group of woody Exogenous Plants, characterised by having a superior calyx, a definite number of stamens half of which are usually sterile, a 2-celled ovary, and an embryo in the midst of horny albumen. There are only three genera in the gardens of this country, *Hamamelis*, *Trichocladus*, and *Fothergilla*. Some of the species are large forest-trees, affording good timber, but nothing is known of any other useful property in the order. The order is related to *Bruniaceæ*, *Cornaceæ*, and *Saxifragaceæ*. The species come from North America, Japan, China, and the central parts of Madagascar and South Africa. The kernels of *Hamamelis Virginica* are oily and eatable. The leaves and bark are very astringent, and also contain a peculiar acrid essential oil.

HAMBURGH WHITE. [BARYTES.]

HAMITES, a genus of Cephalopodous *Mollusca* proposed by Mr. James Sowerby. ('Mineral Conchology of Great Britain.') It includes only fossil species. According to the original views of Mr. Sowerby, only those chambered shells belong to *Hamites* which have the form of a hook or siphon bent in one plane, with parallel but unequal limbs, and sinuous septa. But the specimens having these characters appear always imperfect; and when Professor Phillips found in Yorkshire many fossils, in other respects perfectly resembling *Hamites* described by Mr. Sowerby, rolled in a plane spiral, the volutions in some species touching, in others free, and in a few terminating in a straight elongation (like *Spirula*), he extended the use of the term. Dr. Buckland has adopted this view in his 'Bridgewater Treatise.'

In the 'Transactions of the Geographical Society of France,' June, 11, 1837, M. Léveillé gives descriptions and figures of species of fossil *Cephalopoda*, which might be considered as the spiral part of *Hamites* (Phillips), and names them *Crioceratites*. Bronn adopts this genus. Mr. Sowerby has recently been led to very similar results, and has proposed to call the same group *Tropæum*. Now, as certain forms of ammonites in the Lias and Oolitic rocks (*A. fimbriatus*) have no very obvious difference from *Tropæum*, *Crioceratites*, or the spiral parts of *Scaphites* (e.g. *Scaphites Yvanii* in the British Museum), it is evident that the whole question of the true relations of these remarkable fossil genera to ammonites remains to be further examined.

Hamites of the typical forms occur at Folkstone, Hamsey, and other situations in the Gault, Greensand, and other cretaceous beds. *Crioceratites* and *Tropæum* belong chiefly to the same groups of rocks in England, France, Switzerland, &c. Fifty-eight species of *Hamites* have been described. D'Orbigny proposes the name *Hamulina* for the twenty species found in the Neocomian beds of France. [TROPÆUM.]

HAMSTER. [CRICETUS.]

HAND. [SKELETON; MAN.]

HAND-TREE. [CHEIROSTEMON.]

HA'PALE. [JACCHUS.]

HARBIN. [MERLANGUS.]

HARDNESS (in Mineralogy). The different degrees of hardness possessed by minerals of similar external characters will often serve to distinguish them from each other. Mohs has formed a scale which affords an approximation in estimating the hardness of minerals, and according to which it is expressed in numbers. The substances which he uses are such as are easily obtained in a state of purity. They are:—

1. Talc, white or greenish.
2. Rock-salt, pure and cleaveable; and gypsum, uncrystallised and semi-translucent.
3. Calcareous spar, cleaveable.
4. Fluor-spar, which cleaves perfectly.
5. Apatite, the asparagus-stone, from Salzburg.
6. Adularia.
7. Rock crystal, limpid and transparent.
8. Topaz.
9. Corundum, from Bengal, with smooth fractured faces.
10. Diamond.

Any mineral which neither scratches nor is scratched by any one of the substances above named, is stated to possess the degree of hardness expressed by the number opposite that mineral. Thus, supposing a body neither to scratch nor to be scratched by fluor-spar, its hardness is represented by 4; but if it should scratch fluor-spar, and not Apatite, then its hardness is stated to be from 4 to 5.

Another method of trying the hardness of minerals is passing them very gently over a fine hard file, and judging by the touch and appearance of the file as to the degree of hardness. [MINERALOGY.]

HARE. [LEPUS.]

HARE-BELL. [CAMPANULA.]

HARE'S-EAR. [BUPLEURUM.]

HARELDA. [DUCKS.]

HARFANG. [STRIGIDÆ.]

HARMODYTES, a genus of Tubular Stony Corals, proposed by Fischer and adopted by Bronn. The same species were afterwards designated by Goldfuss *Syringopora*, a name generally adopted.

HARMOTOME (*Andreolite; Ercinite*). This mineral occurs in attached crystals, generally intersecting each other lengthwise. Primary form a right rhombic prism. Cleavage parallel to the primary planes, and to both the diagonals of the prism. Hardness, 4·5. Colour, grayish-reddish, yellowish-white. Fracture uneven. Lustre vitreous, and sometimes pearly; streak white. Specific gravity, 2·35 to 2·4.

By acids, unless heated, Harmotome is scarcely acted upon. Before the blow-pipe it fuses into a clear glass. It occurs at Strontian in Scotland, and at Andreasberg and Oberstein in Germany.

The analyses of this substance do not greatly differ in general. The Harmotome of Strontian yielded, by the analysis of Mr. O'Connell—

Silica	47·04	
Alumina	15·24	
Barytes	20·85	
Lime	0·10	
Soda or Potash	0·88	
Water	14·92	
		99·03

HARPA. [ENTOMOSTOMATA.]

HARPAGON. [FALCONIDÆ.]

HARPAGUS. [FALCONIDÆ.]

HARPA'LIDÆ, an extensive family of Coleopterous Insects of the section *Geodephaga*, the species of which are distinguished by the tarsi of the two anterior pairs of legs being dilated in the male sex.

In these insects the tibiæ of the anterior pair of legs have always a deep notch on the inner side; the head is almost always short and rounded in front; the thorax is generally broader than long, somewhat convex, but slightly narrower behind than before, and nearly equal in width to the elytra. The body usually approaches more or less to a cylindrical form; the elytra are almost always rounded at the apex, and never truncated at this part. They are usually found under stones.

Of the family *Harpalidæ*, Dejean, in his 'Species Général des Coléoptères,' enumerates 27 genera: others however have been discovered since the publication of that work.

The number of species known is probably upwards of 500.

The most convenient way perhaps of grouping the genera of this family is to take, in the first place, the form of the mentum as a guide. We then find almost all the species divided into two great groups, those in which the mentum is simply emarginated, and those in which there is a small projecting process in the middle of the emargination. Besides these there are certain species (the natural situation of which is perhaps somewhat doubtful) which have the mentum trilobed, and there are others in which the mentum is bilobed.

The various genera described by Dejean are as follows:—

Section I.—Mentum trilobed.

Genus 1. *Pelecium* (Kirby), containing 2 species, both inhabiting the Brazils.

2. *Eripus* (Höpfner), containing 2 species, one of which is from California, the other inhabits Mexico.

Section II.—Mentum bilobed.

Genus 3. *Promecoderus* (Dejean), of which there is one species from Australia.

4. *Cyclosomus* (Latreille), containing 2 species, one from India, the other from Senegal.

Section III.—Mentum emarginate, and without central tooth.

Genus 5. *Daptus* (Fischer); 2 species. Found in North America.
6. *Cratognathus* (Dejean); 1 species. Probably from Buenos Ayres.
7. *Agonoderus* (Dejean); 5 species; three of which are from North America, one from India, and one from Senegal.
8. *Barysomus* (Dejean); two species from India, and one from Mexico.
9. *Amblygnathus* (Dejean); 5 species. All inhabitants of Cayenne.
10. *Platymetopus* (Dejean); 10 species. From Africa and India.
11. *Selenophorus* (Dejean); 59 species. From North and South America.
12. *Anisodactylus* (Dejean); 23 species. Chiefly from Europe and North America.
13. *Bradybænus* (Dejean); 3 species. From Senegal.
14. *Stenolophus* (Megerle); 22 species. Almost all European.

Section IV.—Mentum emarginate, and with a small projecting process in the middle.

Genus 15. *Cratocerus* (Dejean); 1 species. From Brazil.
16. *Somoplatus* (Dejean); 1 species. From Senegal.
17. *Axinotoma* (Dejean); 1 species. From Senegal.
18. *Acinopus* (Ziegler); 6 species. Chiefly European.
19. *Cratacanthus* (Dejean); 3 species. From North America.
20. *Paramecus* (Dejean); 2 species. From South America.
21. *Geodromus* (Dejean); 1 species. From Senegal.
22. *Hypolithus* (Dejean); 18 species; the greater portion of which inhabit Africa. Four are from South America.
23. *Gynandromorphus* (Dejean); 1 species. From Italy and South of France.
24. *Ophonus* (Ziegler); 45 species. Chiefly European.
25. *Harpalus* (Latreille); 134 species. From Europe, Asia, Africa, America, and Australia.
26. *Geobænus* (Dejean); 2 species. From the Cape of Good Hope.
27. *Acupalpus* (Latreille); 46 species. Chiefly European. There are however species found in all the other quarters of the globe.
28. *Tetragonoderus* (Dejean); Africa, India, and South America. One species is found in North America.
29. *Trechus* (Clairville); 22 species. Chiefly European.
30. *Lachnophorus* (Dejean); 4 species; three of which are from South America, and one from North America.

For the characters of the genera and species above alluded to, we must refer our readers to M. Dejean's work which has been quoted, and for the British species to Mr. Stephens's 'Illustrations of British Entomology.' We have followed Dejean in restricting the family *Harpalidæ* to such species only as will come under the definition given at the commencement of this article. Two very distinct groups are included in the family *Harpalidæ* as defined by Mr. Stephens.

(Stephens, *Illustrations of British Entomology;* Dejean, *Species Général des Coléoptères.*)

HARPES, a genus of Fossil *Crustacea* [TRILOBITES], from the Devonian Strata.

HARPY-EAGLE. [FALCONIDÆ.]

HARPYA. [CHEIROPTERA.]

HARPYIA. [FALCONIDÆ.]

HARRIER, the English name for the hound employed in hunting the Hare. The size and breed of the Harrier depend upon the taste of the owner, and that is most frequently regulated by the nature of the country in which the pack is to hunt. Mr. Beckford, a great authority in such cases, says, "The hounds, I think, most likely to show you sport are between the large slow-hunting harrier and the little fox-beagle; the former are too dull, too heavy, and too slow; the latter too lively, too light, and too fleet. The first, it is true, have most excellent noses, and I make no doubt will kill their game at last if the day be long enough; but you know the days are short in winter, and it is bad hunting in the dark. The other, on the contrary, fling, dash, and are all alive; but every cold blast affects them, and if your country be deep and wet it is not impossible that some of them may be drowned. My hounds were a cross of both these kinds, in which it was my endeavour to get as much bone and strength in as small a compass as possible. It was a difficult undertaking. I bred many years, and an infinity of hounds, before I could get what I wanted. I at last had the pleasure to see them very handsome; small, yet very bony; they ran remarkably well together, went fast enough, had all the alacrity that could be desired, and would hunt the coldest scent."

Hare-hunting, it has been said, is generally followed by sportsmen in the decline of life; though when the district is tolerably open, and the hare 'flies the country,' there is often opportunity for a good horse and bold rider to show themselves. But these capital runs come 'few and far between,' and the old fox-hunter can seldom brook the change. In a close or woody district, the constant repetition of the same scene, and the discovery that in consequence of a sudden double of the hare a rustic upon his galloway who knows the country is frequently as near the hounds as the man who is mounted on a first-rate hunter and has taken some daring leaps, prove rather disgusting both to the ardour of youth and the experience of age.

HARRIER (Ornithology), a name applied to certain Hawks (*Circus*). [FALCONIDÆ.]

HARRINGTONITE. [MESOLE.]

HARTITE, a Mineral occurring crystallised. Primary form an oblique rhombic prism. Cleavage imperfect. Colour white. Lustre somewhat greasy. Translucent. Hardness 1·0. Specific gravity 1·046. Found at Oberhart, in Austria. The following is an analysis, by Schrötter:—

Carbon	87·473
Hydrogen	12·048
	99·521

HART'S-TONGUE. [SCOLOPENDRIUM.]

HASSELQUISTIA, a genus of plants named by Linnæus in honour of Frederick Hasselquist, M.D., his pupil, who travelled in the Holy Land. It belongs to the natural order *Umbelliferæ*, and to the tribe *Tordylineæ*. The species closely resemble those of *Tordylium*, and are regarded by some botanists as monstrous forms of this genus.

HASSELTIA, a genus of Plants belonging to the natural order *Apocynaceæ*. It has a 5-parted permanent calyx; a corolla with the tube contracted in the middle; the throat naked; the limb campanulate, 5-parted, and contorted. The stamens are inserted in the throat. Anthers large, cuspidate, callous at the back, adhering to the stigma; the ovary double, surrounded by a fleshy ring; styles 2; stigma clavate; follicles 2, distinct, and long; seeds with a stipitate coma at the lower end.

H. arborea is found in Java, near Tjampiam. It is a handsome tree, with oval leaves, rather acute at each end, smooth above, paler and a little downy on the under side. The flowers are large, yellowish-white, in axillary fascicles. In Java the milk obtained from the trunk by incision, mixed with honey and reduced with boiling water, is employed as a powerful drastic for destroying the tape-worm; it is however apt to produce inflammation of the intestines, and in some cases has proved fatal.

(Lindley, *Flora Medica.*)

HASTINGS SANDS. The middle group of the Wealden Formation, which constitutes the uppermost part of the Oolitic system in England, is thus named from its characteristic development around Hastings in Sussex. In the Hastings Sands we may distinguish four divisions, which lie in the following order:—

The Horsham Beds . .	Fawn-coloured sand and friable sandstone: good flagstone occurs here.
The Tilgate Beds . .	Sandstones often calcareous, with various grits and conglomerates, resting on blue clay. These have yielded a considerable number of organic remains, plants, *Mollusca*, fishes, and reptiles of gigantic dimensions. [IGUANODON; HYLÆOSAURUS.]
The Tilgate Beds . .	White sand and friable sandstone, alternating with clay.
The Ashburnham Beds .	Nodules and beds of limestone, alternating with clays and sandstones.

The axis of elevation, or forest ridge of the Weald of Kent and Sussex, is chiefly formed of Hastings Sands, which rise in Crowborough Beacon to 804 feet above the sea. [GEOLOGY.]

(Mantell, *Tilgate Forest;* Fitton, *Geology of Hastings*, &c.)

HATCHETINE (*Mineral Adipocire*). This substance occurs in thin flakes in the cavities of the ironstone of South Wales. It is very soft, somewhat granular in appearance; translucent; colour yellowish-white or greenish; not elastic; inodorous; combustible. It melts at 170°, and is soluble in ether.

According to Professor Johnston it consists of—

One atom of Carbon	85·910
One atom of Hydrogen	14·624
	100·534

HATTERIA. [DRACONINA.]

HAUSMANNITE. [MANGANESE.]

HAÜYNE (*Latialite*), a Mineral occurring in detached rhombic dodecahedral crystals, also granular and massive. The primary form is the cube. Cleavage parallel to the diagonal planes of the cube, indistinct. Fracture uneven. Brittle. Hardness, 5·5 to 6·0. Specific gravity 2·68 to 3. Colour when opaque indigo-blue, when translucent blue or bluish-green; streak white; lustre vitreous. The massive varieties are amorphous; structure granular, compact. When heated in an acid it becomes gelatinous and transparent. Before the blow-pipe it fuses with borax into a clear glass, which becomes yellow on cooling. This mineral is found in the cavities of lavas and in the fragments of rocks ejected from Vesuvius, and also embedded in pumice and lava near Andernach on the Rhine, &c. According to Gmelin, the mineral from Marino yielded—

Silica	35·48
Alumina	18·87
Potash	15·45
Lime	12·00
Sulphuric Acid	12·39
Oxide of Iron	1·16
Water	1·20
	96·55

HAWFINCH. [COCCOTHRAUSTES.]
HAWK. [FALCONIDÆ.]
HAWK-MOTH. [SPHINGIDÆ.]
HAWK-WEED. [HIERACIUM.]
HAWKS'-BILL TURTLE. [CHELONIA.]
HAWTHORN. [CRATÆGUS.]

HAYDENITE, a Mineral resembling *Chabazite* in the appearance of its crystals, but is described as having an oblique rhombic prism. It occurs with *Heulandite*.

HAYESINE (*Borocalcite*), a Mineral occurring in globular masses of a fibrous structure, having externally a brown colour; when broken these masses appear to be formed of snow-white delicate fibres, interwoven, curved, and knotted. The lustre is satin-like, and the fibres so soft as to crush readily between the fingers. It incloses fragments of argillaceous slate, with brilliant and perfect crystals of *Glauberite*, which are sometimes penetrated by the fibres of this mineral. Found in the province of Tarapaca, Peru. The following is an analysis (after drying at 150° Fahr.):—

Boracic Acid	46·111
Lime	18·889
Water	35·000
	100·

HAY-TIT. [SYLVIA.]
HAZEL. [CORYLUS.]

HAZEL-NUT, the fruit of the wild bush of *Corylus Avellana*, unchanged and unimproved by cultivation. It differs from the domesticated varieties only in being smaller and rather more hardy. [CORYLUS.]

HEAD. [BRAIN; SKELETON.]
HEARING. [EAR.]

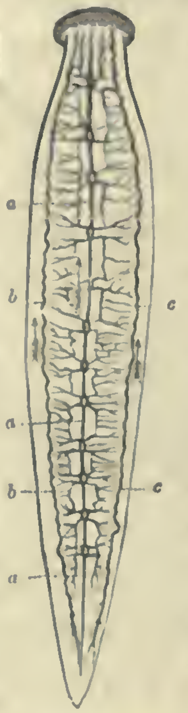
HEART is the central organ of the circulation, and by its alternate contractions and dilatations exercises the principal power by which the blood is moved through the bodies of the higher animals. Its anatomy and physiology will be made most easily intelligible by considering first the principal varieties of the circulation or other motion of nutritive fluid which occur in the animal kingdom; bearing in mind that the main objects for which such a motion is required are a constant supply of fluid adapted for their nutrition to all parts of the body, and its regular exposure to the influence of atmospheric air, that by the process of respiration it may be fitted for maintaining the life of the animal.

The simplest mode by which a distribution of nutritive fluid is effected is by means of ramifications proceeding from the stomach or intestinal canal to various parts of the body, which occurs in the polyps, *Infusoria*, intestinal worms, *Echini*, *Medusæ*, and other zoophytes. In all these the digestive canal and the circulating system form but one apparatus: the food, which in the higher animals requires a complicated process of assimilation before it is fitted to move with the blood, is in them already adapted for nutrition. In most of them currents can be seen passing in opposite directions along the canals opening into the digestive cavity, exactly like those well known to exist in the stems of *Charæ* and other plants, and probably produced by the motion of cilia which line the tubes, but are too minute to be discerned in all cases even with the microscope. In many instances however cilia have been observed, as in the case of *Grantia* among the sponges. Cilia have also been shown to exist and to cause the currents observed in many of the *Desmideæ*. ('Quarterly Journal of Microscopical Science,' vol. ii. p. 234.)

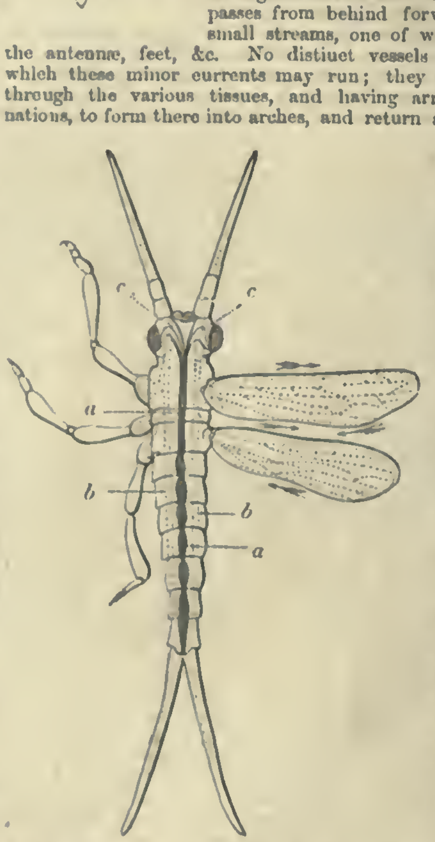
In the *Planariæ* and some of the *Trematoda* a separate vascular system has been discovered in addition to the ramified digestive tubes. In the former the main trunk has the shape of an oval loop (*a*, *b*, *c*, *d*), from which capillary networks arise and communicate freely together, and with a dorsal median vessel (*e*).

These vessels have been seen contracting and dilating, but no regular course of fluid has yet been discerned.

A more perfect form of circulation of this kind is found in the *Annelida*, and it has been closely observed by Müller in the leech, as shown in the next drawing. There are two main lateral vessels (*b*, *b*, *c*, *c*), communicating at their extremities and by transverse branches with each other, and with a third central vessel (*a*, *a*, *a*), which contains within it, bathed in its blood, the nervous cord, and presents knot-like swellings at the same situations as that cord does. Alternate motions of the blood may be seen in these vessels: at one moment the lateral vessel (*b*, *b*), and the central (*a*, *a*, *a*), with the communicating branches between them, are seen filled with blood; while the other lateral vessel (*c*, *c*) and its branches are empty. In the next moment *c*, *c* and its branches are filled, while *a* and *b* are empty; so that one lateral vessel, and the central one, are always opposed in action to the other lateral one. The central continues acting with one of the lateral for 20 or 25 pulsations, and then its relation changes and it acts in unison with the other. During the contraction of a lateral vessel the blood evidently flows from it through the middle transverse vessels over to the other side, and in the next moment returns. The contraction proceeds gradually from behind forwards, so that a wave (as it were) of blood is seen passing from one end of the lateral and of the central vessel to the other, and then returning in the contrary direction through the other lateral vessel. In this manner it is probable that a constant circulation is maintained along the sides of the animal, and its direction seems to be changed after every eight or thirteen pulsations. The same general type of circulating system is found in earthworms and all the other *Annelida*.

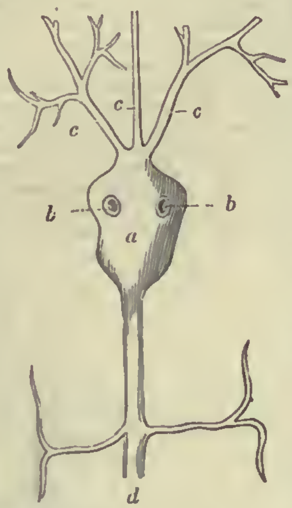


Hitherto nothing has been seen which could fairly be called a heart, nor have the vessels presented any characters by which they could be separated into systems of arteries and veins, for all alike seem to perform at different times the functions of both. A more distinct division of the parts of the circulating system is found in insects. They have a large vessel (*a*, *a*) running along the back, divided by numerous constrictions into a series of communicating cavities, between which there are lateral openings through which the blood is received, and which are guarded by valves to prevent the blood from flowing out. Through this, which is commonly called the dorsal artery, but which may rather be regarded as a series of ventricles, the blood passes from behind forwards, diverging into small streams, one of which flows to each of the antennæ, feet, &c. No distinct vessels can be detected in which these minor currents may run; they seem simply to pass through the various tissues, and having arrived at their destinations, to form there into arches, and return and empty themselves into abdominal vessels *b*, *b*, which may be regarded as veins, and through which the blood flowing from before backward is returned into the dorsal artery through the communications which exist between them and the posterior part. This is also the plan of the circulating system which with various modifications prevails in the *Arachnida* and the lower *Crustacea*.

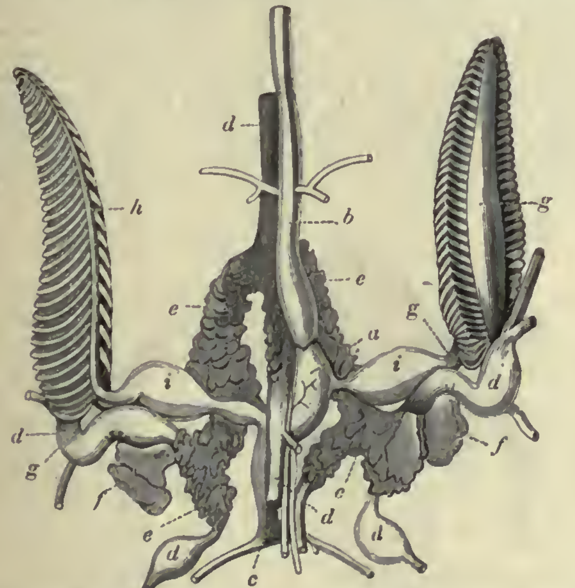


In the orders already mentioned no special arrangement of vessels has been found for the purpose of exposing the blood to the influence of the air. Either the whole or part of the blood undergoes respiration on the whole surface of the body, or at the tracheæ, or the vesicles arranged in especial systems for that purpose. In those which follow however, we shall observe a separate and complicated respiratory apparatus; and that the form of the heart and its large vessels are adapted in accurate correspondence with that of the gills or lungs, and according as the whole or part of the blood is required to be exposed at each round of the circulation to the influence of the air.

The simplest kind of a heart, forming a defined cavity, is found in the larger *Decapoda*, and some other *Crustacea*. The annexed sketch represents the heart and large arteries of the lobster. There is a single cavity or ventricle (*a*), into which the arterial blood flows from the gills by vessels which unite into two trunks, whose orifices (*b*, *b*) are protected by valves. Six main arteries proceed from the heart; the three anterior (*c*, *c*, *c*) go to the head; two from its inferior part to the liver; and the largest of all (*d*) from its posterior part. This last gives off a superficial and a deep artery to the tail, and then curving forwards under the sternum, gives branches to the feet and deep arteries to the head. From these the blood returns by veins into a number of venous sinuses which lie at the sides by the articulations of the legs with the chest, and all communicate together. From them branchial arteries proceed, which run on the outer edge of the gills, and pass through capillary vessels in them, terminating in branchial veins which unite into two trunks that open into the heart.

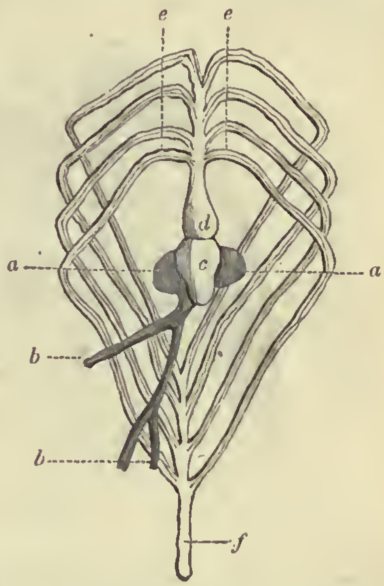


In most of the *Mollusca* the blood flowing through the branchial veins, instead of being poured directly into the ventrical, is received first into an auricle, presenting the first instance of a heart with more than one cavity. In most of the *Gasteropoda* and *Pteropoda* the auricle is single; in the bivalves the auricle is mostly double. In the latter division, the blood, collected from the systemic veins into one venous reservoir, before going to the gills passes by numerous branches into a spongy tissue consisting of lacunæ, which Bojanus calls a lung, and others a kidney. From this a few branches pass at once into the auricles, but the greater number go as branchial arteries to the gills. In the brachiopods the systemic ventricle is also double, each cavity giving rise to an aorta. In these cases, although the auricle is double, it is not to be regarded as representing the two auricles of warm-blooded animals, of which one receives the blood from the system, the other from the lungs, since here the two auricles have the same function, and there are two for the sake of convenience. In the oyster they are united into one cavity. But the most singular form of heart in this class, and one of much interest as presenting all the cavities separated, which in higher classes are united in one body, is that of the cuttle-fish. The blood passes in it from a systemic or central ventricle (*a*), through the aorta superior (*b*), and inferior (*c*), and is thence

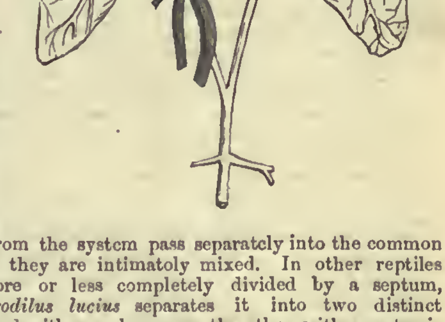


distributed throughout the body, whence it is collected into six venæ cavæ (*d*, *d*, *d*, *d*, *d*, *d*), which open into two branchial auricles (*e*, *e*), conducting into two branchial ventricles (*f*, *f*) by which it is forced through branchial arteries (*g*, *g*, *g*). From the extremities of these it is received into branchial veins, of which that of the left side (*h*) is here shown, which open into the two systemic auricles (*i*, *i*), conducting again into the systemic ventricle (*a*). Here then we have the first appearance of a separate heart for the respiratory circulation, and the elements of all the compound forms which we have now to notice.

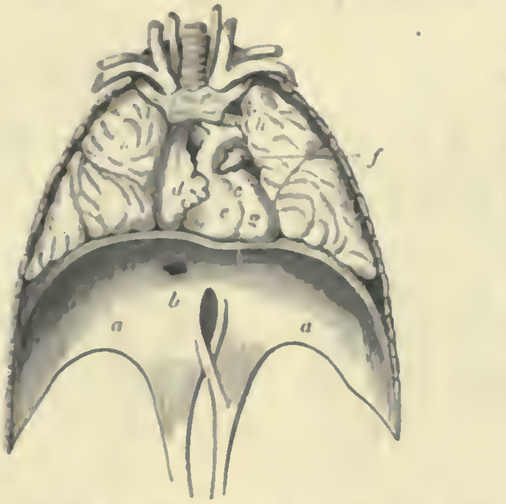
Among vertebrate animals the simplest form of heart is found in Fish. They have a single auricle (*a*, *a*), which receives the blood from the trunks of the veins of the whole body (*b*, *b*), and communicates with a single ventricle (*c*), which forces the blood into an arterial trunk with a contractile bulb (*d*). From this trunk all the branchial arteries (*e*, *e*) arise, and passing on each side in arches to the gills, divide there into capillary branches. The blood thus aerated passes on, and the arches again unite into a common trunk (*f*), the true aorta, which runs along the under surface of the spine, and sends the blood to all parts of the body. From these it collects again into the systemic veins (*b*, *b*), by which it is carried back to the auricle. The same type of formation is found in the reptiles which have gills, as in the *Proteidæ* in their adult state, and in the larvæ of many which at that period also breathe by gills.



In Fish all the blood is subjected to the respiratory process before it passes to the body: in the Reptiles, which breath in air, and have therefore a much more complete exposure of the blood to it than fish, who breathe only the air that is dissolved in the water, only a part is exposed before entering the general circulation, but the modes in which this is effected vary greatly. The annexed sketch represents the circulatory system of the Frog in its perfect state. It has a single ventricle (*a*), from which arises a single aortic trunk (*b*), from which proceed the two pulmonary arteries (*c*, *c*), conveying that part of the blood which is to undergo respiration to the lungs (*d*, *d*), whence it is returned by pulmonary veins (*e*, *e*). From the same aortic trunk four other arteries arise, two of which, forming arches, unite to form the dorsal aorta, while the two uppermost are distributed to the head and upper extremities. From the terminations of these arteries in all parts of the body the blood is collected into large venous trunks, which open into the double auricle (*f*, *f*), from which the aerated blood from the lungs and the impure blood from the system pass separately into the common ventricle, in which they are intimately mixed. In other reptiles the ventricle is more or less completely divided by a septum, which in the *Crocodilus lucius* separates it into two distinct cavities, one connected with a pulmonary, the other with a systemic aorta; in some others the septum is nearly complete, and the mixture of the two kinds of blood is supposed to be prevented by a valve; but in the rest of the order the septum is so small that the blood must necessarily be mixed. In all of this order however the abdominal aorta, which runs along the spine, is formed, as in the frog, of two arches, and in those which have separate ventricles a branch proceeds from each to form it, so that while the head and upper extremities are supplied with pure arterial blood from the left side of the heart, the lower portion of the body receives a mixed blood from the left side and the right.



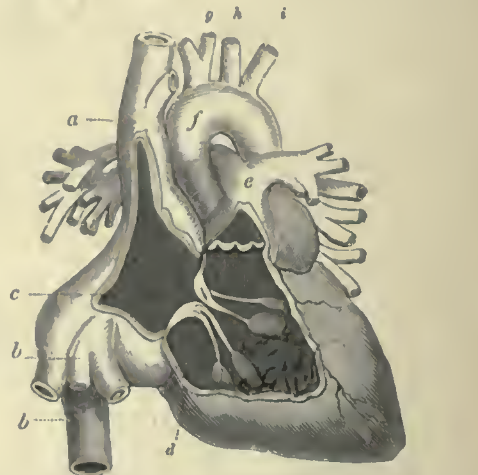
Lastly, we arrive at the complete double circulation of Man (*Mammalia*) and Birds, to which some of the forms just described make very close approximations. In all of them the blood arrives at the heart from the veins of all parts of the body by two large trunks, the venæ cavæ, superior and inferior, from which it is received into the right auricle, and thence passes into the right ventricle. The right ventricle, by contracting, forces it into the pulmonary artery, in whose branches it is exposed to the air, and passes from them to



the pulmonary veins, which open into the left auricle, from which it proceeds to the left ventricle, thence through the single aorta into all parts of the system, and again into the veins and right auricle.

We may now consider the anatomy of the heart, and the chief phenomena of the circulation, in Man.* The heart is of a somewhat conical form, having its base directed backwards towards the spine, and its point forwards, downwards, and to the left side, so that at each contraction it may be felt striking between the fifth and sixth ribs, about four inches from the middle line. It rests upon the diaphragm (*a*, *a*), the muscular partition between the chest and abdomen, and the surface upon which it lies is much flattened. It is firmly attached to the diaphragm at its right side and behind by the inferior cava, which passes through that muscle at the aperture *b*; and above and behind it is fixed, though more loosely, to the upper and back part of the chest by the rest of its great vessels, which there pass out of the pericardium, and are united to the surrounding cellular tissue and organs. Everywhere else it is quite free and moveable, though the range of its motions is limited by the pericardium, or membranous bag in which it is contained, and which closely surrounds it at all times. When the heart is exposed by cutting open the front of the pericardium, it is seen to be divided along its front and most convex surface by a line running from the middle of its base downwards to the right side of its apex. This line and a similar one on the under and flatter surface, both of which are traced out by two vessels, the principal trunks of the coronary arteries and veins by which the walls of the heart itself are supplied with blood, indicate the position of the septum or partition by which the ventricles are divided from each other. At the base, above and on each side, two other divisions will be seen, each having a little fleshy pendulous appendage at its corner; these are the auricles. Thus may be seen at once a right auricle (*d*) and ventricle (*c*) on the right side and front of the heart, and a left auricle (*f*) and ventricle (*g*) on its left side and behind. From the greater thickness of the walls of the latter they form the larger portion of the whole heart, but the cavities will be found to be nearly of the same size. The right anterior, or pulmonary, side of this double heart is exclusively for the circulation through the lungs (*h*, *h*); the left posterior, or systemic, for that through the body.

To examine the interior of the heart it should be removed from the pericardium, and an incision should be made into the front of the right or front auricle, so that an angular flap may be cut out of its walls, and the whole view of the back part and sides of its interior may be exposed. There will then be seen, behind and to the right side, two large apertures—the upper leading to the vena cava superior (*a*), through which all the blood is returned from the head and upper extremities; and the lower leading to the vena cava inferior (*b*, *b*), by which all the blood is conveyed from the abdomen and lower extremities. These apertures will be seen to be surrounded by a few muscular fibres continuous with those of the auricle itself, and that of the inferior cava is partially guarded by a thin semilunar membranous fold called the Eustachian valve, varying much in size and often much torn. The left side of the cavity, on the partition which separates it from that of the right auricle, presents an oval depression (the fossa ovalis) surrounded by an elevated border, indicating the situation of the foramen ovale, through which during the fœtal state the blood, which was prevented by the Eustachian valve from passing into the ventricle, was conveyed directly from the right into the left auricle, and thence into the left ventricle. Lastly, at the anterior and left angle of the cavity another and the largest aperture (c) is seen, which leads into the right ventricle, and has attached to its sides a membranous curtain (*d*), by which it is occasionally closed, and which is called the tricuspid valve. The general form of the cavity of the right auricle is that of a quadrangular sac, from the right and interior part of which a small flattened triangular process stands out, from the remote similarity of which to the ear (auris) of a dog the cavity has received its name. Its interior is tolerably smooth behind, by the orifice of the superior cava, on the partition, and about the opening into the ventricle; but to the right and front side, about the auricular appendage and the inferior cava, it is rendered uneven by prominent bands of muscular fibres (the musculi pectinati) which seem to radiate from the auricles.



Proceeding in the course of the circulation, a cut should be made from the right auricle through the aperture leading from it into the right ventricle, and along the front of the heart nearly to its apex; and then another from the end of the first upwards into the pulmonary artery, as it arises from the front and upper part of the ventricle. By raising the portion thus cut out, a complete view of the cavity of the right or pulmonary ventricle, and of its communication with the auricle, will be seen. The cavity of the right ventricle has a somewhat conical form, with its base uppermost; that part of its walls which is formed by the septum projecting somewhat into it. Its walls are rendered extremely irregular by prominent bands of muscular fibres crossing each other in every direction, and inclosing spaces of various size and form, which after death are generally found filled with coagulated blood entangled in and adhering to them. Here and there stand out short columns of muscle projecting into the interior, and pointing towards the right auricle; these are called columnæ

a, *a*, *a*, *a*, the columnæ carneæ; *b*, *b*, *b*, *b*, chordæ tendineæ; *c*, *c*, *c*, *c*, valves.

carneæ, and they have attached to their summits fine tendinous cords (chordæ tendineæ), which pass thence to be attached to the edges of the curtain-like membrane (the tricuspid valve) which guards the orifice between the auricle and ventricle. This orifice is of a broadly oval form, surrounded by a ring of firm dense tissue, to the whole interior circumference of which is attached the fold of membrane, strengthened by tendinous fibres, forming the valve. The edges of

* The heart and large vessels of any of the larger of our domestic quadrupeds may be used for popular dissection; their structure differs so little from that found in man, that the present description will almost exactly apply to them.

this valve are very irregular, but it may be roughly divided into three principal portions (whence its name), the largest of which lies so as to separate this orifice from that leading into the pulmonary artery. If this valve be pushed inwards towards the cavity of the ventricle, as in the larger of these figures of the mitral valve, of which the construction though similar is more simple, it will lie nearly flat against the walls, and would in this positiou present no obstacle to the passage of a fluid from the auricle into the ventricle; but if, on the coutrary, it be pushed from the ventricle towards the auricle, its edges will be found to meet so as to close the orifice as in the smaller figure. This we shall see is the mode in which it acts duriug life.

From the front and upper part of the ventricle a smooth short passage leads to the origin of the pulmonary artery (*e*), which is attached firmly to the deuse ring to which many of the muscular fibres of the ventricle are affixed. At their union, and at the very orifice of the pulmonary artery, three little valves (the semilunar, sigmoid, or pulmonary valves) are seen, of a semilunar form, attached by the whole length of their convex edges to the walls of the artery, and hanging loosely in it with their free festooned edges directed upwards, inclosing behind them three small spaces, where the artery bulges somewhat outwards. If one looks from the cavity of the ventricle along the interior of the artery, and blows gently into it, the valves will be seen to lie nearly flat against its walls, and will offer no obstacle whatever to tho passage of any fluid in that direction; but if one looks and blows in the opposite direction, from the artery down into the ventricle, the valves will fall inwards, so that their edges will meet, and they will completely close the tube of the artery, so that, unless driven with force sufficient to rupture them, no fluid could pass into the ventricle. It is evident that if the artery be circular the edges of these semilunar membranes could not exactly meet to close it, but would leave a little space of a triangular form between them. This is filled by three little bodies, the corpora arantii, one of which is attached to the middle of the edge of each valve, and which at the same time that they effect this afford a strong point of attachment for the tendinous fibres by which the valve is strengthened. The pulmonary artery proceeds upwards, and to tho left, in front of the other vessels; and after a course of about an inch divides into two branches, one of which turns sharply round to go to the right lung, while the other goes straight onwards to the left. Iu these organs each artery divides into numerous branches, which become smaller as they become more numerous, and terminate in a most delicate network of vessels, ramifying on the walls of the air-cells, from which, after the blood which they contain has been exposed to the air, it is received into equally delicate pulmonary veins, and through them conveyed in gradually increasing branches to the four main trunks of the pulmonary veins, which open into the left auricle.

It would be useless repetition to describe in detail the left posterior or aortic ventricle and auricle, which differ in no important particular from the right. The walls of both cavities on the left side, and all the parts contained in them, are thicker and stronger than those on the right; the orifice between them is guarded by a valve which has only two principal divisions, and is therefore called the mitral valve; and the aortic semilunar valves have larger aud more prominent bodies (corpera arantii) on their edges. The aorta (*f*) proceeds upwards, and to the right side, then arches backwards and to the left, and, turning over the main air-tube of the left lung, passes down along the spine, at the lower part of which it divides into two large arteries (the common iliacs), which supply the pelvis and lower extremities. From the upper part of its arch it gives off the main trunks of the head and upper extremities in three large trunks—that most to the right, called arteria innominata (*g*), is the common trunk which divides into the right carotid for the right side of the head, and the right subclavian for the right arm and side of the neck and chest. Next to it is the left carotid (*h*), and next the left subclavian (*i*), of which the distribution is similar to that of those on the right side.

During life, the blood, returning from the whole body by the veins which unite to form the two venæ cavæ, enters the right auricle and gradually distends it, at tho same time that the blood returning from the lungs by the pulmonary veins enters the left auricle and distends it; when completely filled, a kind of vermicular motion is seen commencing at the point of each auricle, which is rapidly propagated along their walls, and simultaneously empties the contents of the one into the right and of the other into the left ventricle. The ventricles are no sooner completely filled than they contract suddenly and with much greater force than the auricles, and propel the blood into the pulmonary artery and aorta. They drive it indeed in all directions, but in each ventricle there is but one orifice into which it can find a passage, for that by which it entered is closed by the valve surrounding it. The same contraction of the walls of the heart which propels the blood serves to raise and fix the valves by which its regurgitation into the auricle is prevented; for as soon as any blood is forced under their edges they are lifted up and pressed towards the auricles; and they would be forced iuto them, but that when they have arrived at such an elevation as to close the orifice they are restrained from passing farther by the chordæ tendineæ, which are attached at one end to the edges of the valves, and at the other to the summits of the columnæ carneæ—those muscular pillars which we have described as standing out into the cavity of each ventricle. The length of these little teudons is exactly measured to the distance to which the valves may be allowed to flap back, and as the columnæ carneæ contract so as to narrow the cavity of the heart, and force the blood out of it, they tighten and fix the edges of the valves against which some of the blood is forced, and thus keep them steady, till the ventricles being emptied their walls relax and permit the valves to be forced down again by the next current coming from the auricles. The blood forced into the artery pushes on that which was already there (for the whole circulating system is throughout life completely filled), and distends the lower part of the vessel, which by its elasticity recoils, and contracting would tend to force the blood as well back into the ventricle as forward into the branches. It would accomplish both, and half the power of the ventricles would be thus wasted, but that the semilunar valves, which are prevented from adhering to the walls of the arteries as well by their form as by the little projecting bodies on their edges, as soon as any blood gets behind them, are pushed dowu and close the passage into the veutricle. The whole of the blood is therefore driven on along the arteries, displacing that which had just before been thrown into them by the ventricles, and itself in turu displaced by the next succeeding wave.

Through the arteries it is distributed to all the body, and returned by the veins; but the veins of the iutestiual canal and the organs connected with it unite into a large trunk, the vena portæ, which, instead of at once entering the heart with the others, passes into the liver, and there again divides into minute capillary vessels, from which the bile is secreted, and which pass into the ultimate divisions of a series of hepatic veins, which collect into three or four large trunks which open into the vena cava inferior just before it passes through the diaphragm to enter the right auricle.

A point of much interest is the cousideration of the changes which the circulating system of man and the higher animals undergoes in the various periods of their life in the fœtal and in the perfect state. At the very earliest periods it has been clearly proved that in the embryoes of both man and the higher animals the first appearance of the motion of any nutritive fluid is iu the form of a circular canal running rouud the edge of the area in which the future development of the animal is to be effected—an arrangement in some measure analogous to that of the *Planariæ*, and those of the lowest animals, in which a circulating system is first added to the digestive. The first appearance of a heart is in the form of a long tubular pouch, lying beneath the spinal cord, analogous to the dorsal vessel of the insects. The first trace of a separate respiratory system is iu that of gills, for at very early periods of fœtal life fissures may be seeu by the sides of the neck, in birds and many *Mammalia*, and therefore in all probability they exist iu man, beneath which arches of vessels run from the anterior part of a single heart, and collect at their opposite extremities into a single aortic trunk; au arrangement most closely analogous to that of fish. After this, and to the end of fœtal life, the arrangement is adapted to the respiration by a placenta, previous to the possiblility of the action of the lungs, which are only formed for respiratiou in open air. The purified blood coming from the placenta circulates in great measure through the liver before it enters the right auricle by the inferior cava; from this cavity it passes straight through the foramen ovale, over the Eustachian valve, into the left auricle, whence it is conveyed into the left ventricle, aud by it forced through the aorta and its three principal branches to the head and upper extremities, wheuce it returns by the superior cava to the right auricle, and passes through it (without mingling with the other current going through it from the inferior cava to the left auricle) to the right ventricle. From this it is carried into the trunk of the pulmonary artery; but as the lungs are at present incapable of performing their functions, it is couveyed through a direct passage, the ductus arteriosus, from the pulmonary artery into the aorta, just below the origin of the left subclavian artery; and from this part it passes along the aorta through the chest and abdomen, aud is conveyed through the trunks of the iliac arteries to the placenta, to be again purified. Thus there is a single auricle, but through the right side of it two currents are constantly running in opposite directions; and two ventricles, one forciug the blood to the head and upper extremities, of which the former is at this time peculiarly active iu development, while the other forces the blood through the ductus arteriosus to the placenta, and therefore now, as during perfect development, may be regarded as tho respiratory portiou of the heart. At this time the two ventricles, haviug uearly equal extents to force the blood through, are of nearly equal size. After birth the left becomes much larger, and is thus enabled to accomplish the more exteusive purpose of propelling the blood through the whole body. Directly after birth changes commence which in a few days convert the arrangements for the fœtal circulation into those adapted for the circulation of the completely-formed animal: the foramen ovale is completely closed; the ductus arteriosus becomes consolidated; the branch of the umbilical vein, which had passed directly into the inferior cava, is obliterated; and the terminations of the iliac arteries which had carried the blood to the placenta contract, gradually close, aud are ultimately traceable only in the form of dense solid cords.

We may now consider the powers by which the motion of the blood is effected in man, and the chief phenomena of the circulation in the various parts through which it takes place.

When the ventricles of the heart contract they are shortened, and become narrower, harder, and firmer. The heart lying loosely in its pericardium, and fixed only where the great vessels pass out of that cavity, recoils from the blood which the ventricles force out; its point is tilted up, and strikes at each ventricular contraction, or systole, as it is called, against the wall of the chest, producing that impulse which may be felt by the finger or hand placed just beneath the left breast, and which is almost exactly coincident with the pulse felt at the wrist. At the relaxation, or diastole, of the ventricles they regain suddenly and forcibly their previous conditions. These actions are accompanied with certain sounds. If the ear be placed directly, or on a stethoscope, on or near the part where the heart is felt beating, a sound like that of a gentle breathing is heard coincidently with the impulse of the heart. This is immediately followed by a second sound, which is shorter, sharper, more defined, like the falling back of a light valve, coincidently with which the heart seems to fall back from the wall of the chest. A short pause of perfect silence succeeds, and then the first long sound is again heard. They take place in regular rhythm. Dividing the whole period occupied between each two impulses of the heart into four parts, the first sound would occupy two, the second one, and the pause one.

It is unnecessary to allude to various explanations given of those sounds. They were made the subject of an extensive series of experiments by a committee of the British Association, which were reported at the meetings in 1836 and 1837. From these and other experiments we may conclude that the first sound is produced by the vibrations of the muscular fibres of the ventricles during their contraction, and by the rush of the blood through the narrow passages leading to the aorta and pulmonary artery, assisted in a very slight degree by the vibration of the heart striking against the chest. The second sound is in all probability the result of the falling back and consequent tension of the semilunar valves when the blood just expelled from the ventricles regurgitates. The succession of actions in the heart has been described: the contraction of the auricles is coincident with the pause, for their vermicular and slight contraction does not produce any audible vibrations; the pause lasts till the ventricles are completely distended by the contraction of the auricles: then comes the first sound coincidently with the ventricular contraction, the forcing of the blood into the arteries, the elevation of the valves to prevent the blood from going into the auricles, and to permit it to go into the arteries, the impulse of the heart against the wall of the chest, the pulsation of the great arteries, and followed after a scarcely appreciable period by the pulse at the wrist and other parts distant from the heart. Lastly, the second sound is heard coincidently with the relaxation of the ventricles, the falling down of the valves to permit the blood to pass from the auricles into the ventricles, and to prevent its passing from the arteries back into the ventricles; and the rush of blood from the auricles into the ventricles, which continues through the whole time of the second sound and the pause.

At each contraction of the ventricles a very large proportion of the blood which they contained is expelled into the arteries, and a very little may flow back into the auricles, especially the right, before the valves are completely closed, producing the slight dilatation of the venæ cavæ which may often be seen at each contraction of the ventricles. At each contraction of the auricles also it is probable that some blood flows back into the cavæ and pulmonary veins, for they are seen distended rather more suddenly at this time than can be explained by the mere arrest and consequent accumulation of blood in them. However, so large a portion of the heart's power is exerted in propelling the blood into the arteries that these slight influences in the contrary direction need scarcely be taken into account in calculating its amount. At each contraction of the ventricles about an ounce and a half of blood is forced into each artery, with such force, that Hales found that the blood as it rushed from the open main artery in the thigh of a horse would rise 8 or 9 feet in a glass tube of the same size as the vessel, while in the temporal artery of a sheep it rose 6½ feet, and in those of dogs from 4 to 6 feet. Poiseuille (Magendie's 'Journal de Physiologie') also calculated, by deductions from accurate experiments on animals, that the force of the blood as it streams in the human aorta was sufficient to support a weight of 4 lbs. 3 dr. 43 grs. Now, if the quantity of blood in the whole body be assumed to be 30 pounds (troy weight), which is probably about an accurate average, and if an ounce and a half be forced from the ventricle at each pulsation, of which, on an average, there are 70 per minute, a portion of blood will go the complete round of the circulation in about 3½ minutes, which is however a somewhat slower rate than we might deduce from the experiments of Hering (Tiedemann's '*Zeitschrift*,' t. 3), who found that substances injected into the veins of horses could be detected in distant arteries in half a minute.

Harvey considered the heart to be the sole agent by which the circulation is effected, but it is certain that several other agents exercise auxiliary powers. That the heart has however an influence on all parts of the circulation is quite evident. In the larger arteries its effect is seen in the increase of the current which it had set in motion, in exact coincidence with the contraction of the ventricles; in the smaller ones, by the same increase at a scarcely appreciable interval; in the capillaries, by the occasional pulsatile motion which may be seen in them, when, after an animal has been largely bled, its transparent parts are examined with the microscope, and this though the heart is acting very weakly. Lastly, in the veins we find its influence still exerted; for if the main artery and vein in a limb be exposed and isolated, and the latter be wounded, the flow of blood from the orifice may be exactly regulated by compressing the artery, that is, by preventing, to a greater or less extent, the blood from flowing to the vein with the impulse given to it by the heart. There are cases again in which the veins have distinctly pulsated, and the pulsations have been clearly proved to have been communicated from the heart through the capillaries. To these we may add that the rapidity of the current in the arteries, veins, and capillaries, is always in direct proportion to the strength and frequency of the ventricular contraction, and always more rapid in the parts near them than in those remote from the heart; that it ceases in all the instant the heart is removed, or its influence on a part cut off by dividing the main artery; that in old persons, in whom the whole arterial system of the lower extremities is sometimes ossified and rendered incapable of contraction, the heart alone is sufficient to maintain the circulation through the affected parts; while, on the contrary, when the heart's power is by any cause weakened or interfered with, partial stagnation and an extremely languid motion of the blood is found in all the organs. In cases of suspended animation no motion of blood can be produced till the heart begins to act; but when this is the case, it has of itself sufficient power to set all the blood of the body in a current.

There are so many proofs that the contraction of the ventricles has a share in propelling the blood throughout the whole course of the circulation; but the heart also assists, by the enlargement of its cavities after their contraction, which, whether it be the effect of mere elasticity, or of an active power of dilatation, certainly takes place with great force. The heart, in short, acts at once as a forcing and as a sucking-pump. The proofs of this are, that the auricles, and still more the ventricles, dilate, not gradually, but suddenly, and with more force than they could be distended by the blood being impelled into them; that the currents observed in living animals are often seen to be increased coincidently with the dilatation of the auricles; by the velocity of the flow of blood from the auricles into the ventricles being disproportionate to the degree of contraction of the former.

1, trunk of the artery; 2, large branches into which it subdivides; 3, small branches, successively becoming smaller and smaller until they terminate in 4, the capillary branches.

From the heart the blood is poured into the arteries, a series of ramifying tubes through which the current is distributed, divided into a gradually increasing number of streams, which progressively diminish in size, till it arrives at a network of the most minute canals, the capillaries. As a general rule, when an arterial trunk divides, the sum of the diameters of the branches is greater than the diameter of the trunk—thus in the annexed diagram (in which the arrows indicate the course of the blood), the sum of the diameters of the branches 2, 2, is greater than that of 1, and the sum of these of 3, 3, 3, greater than that of 2, from which they arise. Hence the arterial system has been compared in form to a cone, of which the heart is at the apex—and the stream of blood will be like a current gradually growing wider, so that if no additional impulse be given to it, it will become slower as it becomes more distant from the heart, an effect to which the friction of the blood against the walls of the vessels will also contribute. The effect of both these causes however is so slight that M. Poiseuille has found that the force of the current of blood in all arteries sufficiently large to be experimented on is relatively the same; that in the aorta, for example, bears the same relation to its diameter as that in the artery at the wrist does to its diameter. Thus the diameter of an artery may be taken a measure of the force of the current of blood in it. It does not appear moreover that the direction in which a branch is given off from the trunk has any appreciable influence on the velocity of the current in it—most frequently the branches of arteries are given off so as to form an acute angle with the continued trunk as 2, from 1, 2,—but often they separate at right angles, and less frequently so as to form obtuse angles. Neither can the effect of the tortuosity of an artery be calculated, though there can be little doubt that, cæteris paribus, the current in it will be slower. An important point in the arrangement of arteries is the frequent union, or anastomosis, of branches with each other. The purpose of this is evidently to prevent any part being cut off from its supply of blood, by the compression or obliteration of one of its arteries. Hence it is that even when the main artery of a limb has been tied, the nutrition has still been amply effected by the current of blood being diverted into the collateral channels, which subsequently become enlarged. [ANEURISM, in ARTS AND SC. DIV.]

The chief property of the arteries by which they affect the circulation is their extreme elasticity. It is by this that when dilated they contract on the blood that had been forced into them, and propel it in every direction—and that when elongated they again shorten, and that when empty they remain open and tubular. The chief effect of the action of this elasticity is the gradual conversion of the jetting pulsatile motion which the blood receives from the forcible and successive contractions of the ventricle into an even and steady current. The elastic contraction of any part of an artery after its distension can have no general influence to accelerate the blood, for it would press that fluid equally in all directions, and thus would retard the current coming from the heart to any part to exactly the same degree that it accelerated that passing from that part towards the veins—the one influence exactly nullifying the other.

To convert the pulsatile motion however into a uniform one no more admirable property could have been imagined than this elasticity, which by continually acting to contract the arteries (which are always during health in a state of slight distension) maintains a propelling force upon the blood during the intervals in which the ventricles are at rest. If the elastic power were not exercised, we should see, on opening an artery, a jet of blood, and then a pause, then another jet, followed by a second stoppage of the current, just as when by the successive strokes of a piston we force water through a rigid tube—the jets of blood being coincident with the contractions of the ventricles, and the pauses with the intervals of their dilatation and rest. But the arteries being elastic, when the impulse of the ventricles, which at the same time distends them and forces a jet of blood through an orifice in them, ceases, their elasticity, making them contract, forces some more blood out of the orifice, and thus makes the stream from it continuous. In the arteries near the heart indeed the force of the ventricular contraction is so great that it predominates over that of the elastic contraction; and the current, though continuous, is irregular, presenting a succession of jets—but as we recede from the heart, this predominance becomes less, the succession of jets becomes less distinguishable, and in the veins we find a perfectly equable stream. An artificial contrivance for effecting the same object, namely, the conversion of a series of motions of a fluid into a continuous one, may be seen in an organ. The air is forced into the wind-chest by a series of strokes of the bellows, and if the walls of that chest were fixed it would issue from it into the organ-pipes in the same intermitting manner; but the top of the chest is moveable, and is loaded with weights (proportioned to the size of the instrument), so that it maintains a constant and steady pressure on the air below it, which therefore, though driven in by a succession of small forces, passes out into the organ-pipes under the influence of the single force from the top of the chest in a continuous steady current. A similar arrangement is employed in fire-engines, where the elastic power is the air which partly occupies the chest into which the water is forced. [FIRE-ENGINE, in ARTS AND SC. DIV.]

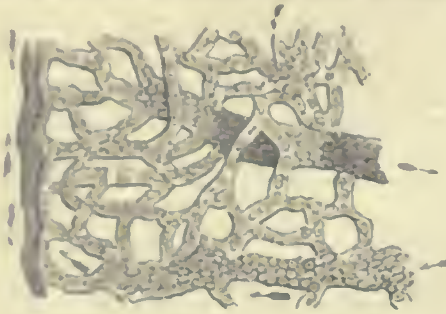
We have said that the arteries are dilated slightly by each column of blood poured out by the ventricles: from this arises their pulse, which may be said to be owing to the dilatation of the arteries produced by the wave which is propagated along the column of blood contained in them. One may form an idea of what is here called the wave by observing a ripple in a running stream. There are in that case two different motions of the particles of the fluid: they move all together, with an absolute change of place, and this constitutes the stream; but again, they move separately; one particle or series of particles rises, and the next falls, and as the first falls again, the second rises—this constitutes the ripple or wave. In it the particles undergo only a relative and temporary change of position, for they all return to rest in their former places, as is shown by any light body that may be floating in them, which merely rises to the top of the wave, and again descends to precisely the same place as it had before the wave arrived. So in the circulation there is a constant stream running through the vessels, and at every contraction of the ventricle an impulse is given to that part which is next the heart, producing a wave which is propagated with incalculable rapidity through all the arteries, and causes at each part of them a slight dilatation as it passes within them. The repeated contractions produce a series of such impulses, waves, and dilatations, and when a finger slightly compresses an artery, it feels the tendency to dilatations, in what is called the pulse. The degree of dilatation is so slight that its existence was much disputed; but M. Poiseuille has proved that in the larger arteries it is equal to about 1-11th of their average diameter. In feeling the pulse however we perceive a greater impulse than so slight a dilatation could produce, because the finger flattens the artery, and therefore we feel the force of the wave over a large part of its circumference, and we increase its velocity by diminishing the size of the channel. From this description it will be evident that the characters of the pulse by which the conditions of health or disease in any person are decided will depend on two circumstances—the state of the heart, and that of the artery itself. The frequency of the pulse will depend entirely on the number of contractions of the left ventricle in a certain time, and hence the varieties of frequent, slow, irregular, and intermitting pulses are entirely referrible to the heart. The size and degree of contraction of the artery will produce the fullness or smallness, the hardness or softness, and all the other characters which are determined by the touch rather than by mere counting.

But the arteries have another power besides that of their elasticity, by which they influence the circulation, though the mode and extent of its operation are less clear. This is the power of contraction which they possess during life, and which is sometimes, but erroneously, called muscular. The vital contraction of the arteries differs from the muscular contraction, in being slow and gradual, in not being at all times excitable by any of the stimuli that excite the muscles to contract, as mechanical irritation, electricity, &c., but following generally some peculiar influence, as that of cold, or some particular local excitement, as inflammation, &c. From elastic contraction it is distinguished by being exercised only during life, and then tending to reduce the artery often to a smaller calibre than its elasticity would, so that on the complete cessation of life the artery dilates to the size which its elasticity, the consequence of its mechanical structure, would in any circumstances tend to give it. It must be regarded as an instance of that vital contractility which is observed in many tissues quite distinct from the muscular, as in the skin, the dartos, &c. It is best seen by exposing an artery during life, and cutting it directly across; the orifice will then contract slowly, but powerfully, till it is completely closed, either at its very extremity or at a short distance within the tube; if the animal be killed the artery will remain closed for some time, but will then again gradually dilate under the influence of its elasticity.

It does not appear certain that this vital contractility of the arteries exercises any constant influence on the circulation; but, on the contrary, the immediate cessation of the flow of blood from a vein and in the capillaries, when the influence of the heart is cut off by tying the main artery (after separating the collateral vessels), or by removing the heart, and the possibility of exactly regulating the velocity of the current in the vein of a part by permitting or preventing the supply from the heart, seem sufficient to prove the reverse. There are many occasions however in which it evidently acts, and in none more importantly than in cases of wounded arteries, in which it is among the most effectual means of arresting hæmorrhage. [HÆMORRHAGE, in ARTS AND SC. DIV.] It is shown also in the paleness and shrinking of a part when exposed to cold, and in the smallness of the pulsations then felt in the main artery; and Schwann has seen the diminution in size of the arteries in the mesentery of a frog, when cold was applied. It is probably the principal cause of the emptiness of the arteries after death; for as they will contract long after the heart has ceased to act and to force blood into them, they will pour much of that which they contained into the veins, in which it will be retained by the valves. Hales found that this power of contraction resisted the passage of stimulants during life through the arteries; for a much larger quantity of water could be driven with a given force through the vessels of a part than of brandy, though the latter passed most easily after death. For some time too after the heart has ceased to act, this power is sufficient to resist the injection of fluids into the vessels, and hence in making preparations it is advisable to wait a few hours after death, that the fluids may run with more ease along the arteries.

It is probable that the vital contractility of the arteries is principally useful by regulating, according to their need, the supply of blood to certain organs, for it seems to exist in the greatest degree in arteries which run most tortuously and which are distributed in parts requiring occasionally increased supplies or velocity of blood, as the spleen, &c.; perhaps too it is exerted in maintaining the portal circulation, which can receive but little assistance from the heart, whose influence must be nearly expended in forcing the blood through the capillaries of the digestive apparatus. However, it must be acknowledged that at present we only know that such a power exists; the amount and manner of its action are quite problematical.

Much is undoubtedly due to the influence of the capillaries on the circulation. They form a dense network of extremely minute tubes, in which the arteries seem to terminate and the veins to arise; for their delicacy prevents the possibility of discovering any such structure as could decide to which set of vessels they belong, and indeed it is only by observing that the currents of blood-globules pass in regular directions, that we can prove that they are canals with definite membranous walls. [BLOOD.] When the circulation is examined in the web of the foot of a frog (from which the annexed highly-magnified sketch is taken), or in the transparent parts of other animals, as the fins, tails, or lungs of fish, frogs, lizards, &c., we see



a number of minute globules coursing along in little streams, in some parts in a confused multitude, as in the vessels which are sufficiently large to admit several to pass together, at others in only a single line, where the vessel is but little larger than the globule itself. Here and there a globule is seen to be checked in its course, as if the canal were too narrow for its passage; then it turns a little, and again rolls on. The currents run generally in the same direction in the same vessels, all tending to a larger branch, which may be regarded as the commencement of a vein, and setting out from the minutest termination of the artery. The capillaries are the most delicate of all organic tissues, measuring from 1-2000th to 1-5000th of an inch in diameter; they exist in all tissues of the body, varying in arrangement only in the greater or less closeness of the network which they form, and of which the meshes are in some organs so fine as not to exceed in width the diameter of the capillaries themselves, as is the case in the iris and lungs. It is through these vessels that all the important processes of secretion, nutrition, and absorption are effected, for there is no sufficient evidence for believing in the existence of a still more minute series traversed only by the colourless parts of the blood, and which some have described as vasa serosa, vasa exhalantia, &c. But hitherto no precise observations have been made on the manner in which these processes are performed; no pores can be discovered at the sides of the capillaries for the passage of fluids, which it is therefore probable is effected by simple transudation; nor can any open terminations be seen, for all appear to arise from arteries and terminate in veins.

The influence of the minutest arteries and veins, and of the capillaries, on the circulation, is best seen in the phenomena of local action, as inflammation, blushing, turgescence, &c. If the web of a frog's foot placed in a microscope be irritated, the capillaries are seen slowly contracting, so as sometimes to prevent the flow of blood through them, and if the stimulus be so great as to produce inflammation, then they dilate, and a larger number of globules is seen passing along them with great rapidity. The same may be seen in the human eye, the vessels in the front of which are so minute that they give no colour to it; but if they be irritated by a particle of dust, at once they dilate, and more blood-globules entering them, they are seen as tortuous canals filled with blood. On a larger scale one sees, after a wound or other injury, the parts around grow redder, and swell from the afflux of blood to its capillaries; and if the inflammation arise in a part which can be compared with another similar one, as in the hand, one feels that the pulse is fuller and stronger on the injured than on the sound side, indicating that a larger quantity of blood is passing through it. A still more evident accumulation of blood is shown in blushing, in which, from a mental impression, in an instant all the minute vessels of the face, neck, head, &c., become distended with blood. The paleness of fear is produced by the opposite condition, and we have other cases in which a decrease of the quantity of blood in a part is seen in the deficient nutrition and shrinking of parts which have become useless, as in the gills of tadpoles, the horns of deer, &c. All these circumstances are clearly sufficient to prove that, independent of any influence extending from the heart or arteries, there is in the very minute vessels of all parts a power by which the supply of blood passing through them may be either increased or diminished, whether it be effected by an alteration in the propelling power of the vessels themselves, or, as some imagine, by an increased attraction or repulsion between the tissues and the blood. An explanation of the phenomena which attend this circulation, independent of the heart, has been offered by Professor Draper of New York:—

"It is capable of being shown, by experiments on inorganic bodies, that if two liquids communicate with each other through a capillary tube, for the walls of which they have both an affinity, but this affinity is stronger in one liquid than in the other, a movement will ensue; the liquid which has the greatest affinity being absorbed most energetically into the tube, and driving the other before it. The same result occurs when the fluid is drawn, not into a single tube but into a network of tubes permeating a solid structure; for if this porous structure be previously saturated with the fluid for which it has the less degree of attraction, this will be driven out and replaced by that for which it has the greater affinity, when it is permitted to absorb this. Now if in its passage through the porous solid the liquid undergo such a change that its affinity be diminished, it is obvious that, according to the principle just explained, it must be driven out by a fresh supply of the original liquid, and that thus a continual movement in the same direction would be produced. Now this is precisely what seems to take place in an organised tissue which is permeated by a fluid, between whose particles and those of the tissue which it penetrates, affinities exist which are concerned in the formative changes that have already occurred, and thus in the circulation of the nutritive fluid there is a constant attraction of its particles towards the walls of the vessels, and a continual series of changes produced in the fluid as the result of that attraction. The fluid which has given up to a certain tissue some of its materials, no longer has the same attraction for that tissue; and it is consequently driven from it by the superior attraction then possessed by the tissue for another portion of the fluid which is ready to undergo the same changes, to be in its turn rejected for a fresh supply. Thus, in a growing part there must be a constantly renewed attraction for that portion of the nutritive fluid which has not yet traversed it; whilst, on the other hand, there is a diminished attraction for that which has yielded up the nutritive materials required by the particular tissues of the part; and thus the former is continually driving the latter before it. But the fluid which is thus repelled from one part may still be attracted towards another, because that portion of its contents which the latter requires may not yet have been removed from it, and in this manner the current may be maintained through the whole capillary network until the liquid has been entirely taken up by the tissues which it permeates."

"The source of the movement being thus attributable to the formative actions to which it is subservient, it is obvious that it must be effected by any external agencies which quicken or retard these; and it is thus that the influence of heat, cold, and electricity upon the rate of the flow seems most readily explicable." (Carpenter, 'Principles of Physiology.')

It will be seen that these elementary facts may be employed to explain the nature of the capillary circulation, and here again we may quote Dr. Carpenter's explanation of the phenomena:—

"It will be convenient to take the respiratory system as an example of its application; since the changes to which this is subservient are more simple than those which take place elsewhere. The venous blood transmitted to the lungs, and the oxygen in the pulmonary cells have a mutual attraction, which is satisfied by the exchange of oxygen and carbonic acid that takes place through the walls of the capillaries; but when the blood has become arterialised, it no longer has any such attraction for the air. The venous blood therefore will drive the arterial blood before it in the pulmonary capillaries, whilst respiration is properly going on; but if the supply of oxygen be interrupted, so that the blood is no longer aerated, no change in the affinities takes place while it traverses the capillary network; the blood continuing venous still retains its need of a change, and its attraction for the walls of the capillaries and its egress into the pulmonary veins is thus resisted rather than aided by the force generated in the lungs. In the systemic circulation the changes are of a much more complex nature, every distinct organ attracting to itself the peculiar substances which it requires as the materials of its own nutrition; and the nature of the affinities thus generated will be consequently different in each case. But the same law holds good in all instances. Thus, the blood conveyed to the liver by the portal vein contains the materials at the expense of which the bile-secreting cells are developed; consequently, the tissue of the liver which is principally made up of these cells possesses a certain degree of affinity or attraction for blood containing these materials, and this is diminished so soon as they have been drawn from it into the cells around. Consequently, the blood of the portal vein will drive before it into the hepatic vein the blood which has already traversed the capillaries of the portal system, and which has given up, in doing so, the elements of bile to the solid tissues of the liver. We are now prepared, therefore, to understand the general principle that the rapidity of the local circulation of a part will depend in great measure upon the activity of the functional changes taking place in that part—the heart's action, and the state of the general circulation remaining the same. When, by the heightened vitality, or the unusual exercise of any organ, the changes which the blood naturally undergoes in it are increased in amount, the affinities which draw the arterial blood into the capillaries are stronger, and are more speedily satisfied, and the venous blood is therefore driven out with increased energy. Thus, a larger quantity of blood will pass through the capillaries of the part in a given time without any enlargement of their calibre, and even though it be somewhat diminished; but the size of the arteries by which it is conveyed soon undergoes an increase in the supply of blood, alogether irrespective of any change in the heart's action. This principle has long been known, and has been expressed in the concise adage, 'Ubi stimulus ibi fluxus,' which those physiologists who maintain that the circulation is maintained and governed by the heart alone, cast into unmerited neglect."

Following the course of the circulation, we come now to the veins, which may be regarded as the most passive of the parts engaged in it, though they are constructed so as to permit many important external agencies to act upon the motion of the blood. While the arteries form a series of branching canals in which the main current is diverted into streams whose number increases as their individual size decreases, the veins are made up of a series in which a vast number of currents gradually unite into others whose number decreases as their size increases (as shown in the annexed figure), and which all at last meet in two great trunks — the venæ cavæ. In addition to other peculiarities of structure, the veins have valves (5, 5, 5), very similar to those at the origins of the arteries, which are arranged in pairs, or in threes, at different distances, in the course of nearly all those veins in which the blood has to rise against the power of gravitation. Their simple use is evident: the blood, returning slowly through the capillaries, and much of the force of the heart being expended in propelling it so far, would be apt to retrograde, or remain stationary, if the weight of the whole column in the veins bore down upon the arteries, and through them on the heart. As soon however as a portion is raised into a vein, when it tends to return to the arteries it forces down the valves, which close the canal of the vein and support the blood above them, till another portion rising sends it onwards. Thus, while they permit the blood to pass without obstacle towards the heart, they entirely prevent it from retrograding; and if it were stationary, the column of blood would be like a stream branching out, and divided by a number of closed locks in which the portion of fluid between any two is prevented from exercising any influence on the portions adjacent to it.

1, capillary venous branches; 2, small branches formed by the union of the capillary; 3, larger branches formed by the union of the smaller and gradually increasing in size, to form the great trunk, 4, a portion of which is laid open to show its inner surface and the arrangement of the valves, 5, formed by its inner coat.

The veins, like the arteries, are elastic, and this power is occasionally exerted in recovering them from too great distension; they too have a vital contractility whose influence is remarkably shown in their shrinking when cold is applied; but its effects have been even less calculated than in arteries.

We have seen that pressure exerted equably on all parts of the walls of an artery would force the blood as much in one direction as the other, so that it could be of no use in accelerating the circulation; but from the arrangement of the valves equal pressure on the veins has a very different effect, for it will be prevented by them from producing any retrograde current towards the extremities of the arteries, and thus the greater part of the power exerted will be gained in favour of the flow of blood towards the heart. Such pressure is exercised by the muscles surrounding the veins; as they contract they compress the veins, and thus force the fluid to flow in the only possible direction, namely, towards the heart. Their influence in this way is shown in the greater tendency to diseased and permanent dilatation of the veins immediately under the skin and other parts remote from the muscles, than in the deep-seated branches in which this varicose state (as it is called) very rarely occurs, although the number of valves in the former is always much greater; in the benefit derived by supplying the place of muscles by artificial pressure on the veins by bandages, &c.; by the increased fullness of the veins, and velocity of the current commonly seen in bleeding when the bleeding-staff is compressed and moved about in the hand; by the general acceleration of the circulation by muscular exertion; and, on the contrary, by the tendency to stagnation and swelling of the veins in the indolent, or those whose muscular systems are greatly debilitated.

But a still more important influence which is permitted by the presence of the valves is that of atmospheric pressure. It acts principally in respiration. When the chest is expanded for the purpose of inspiration, it is evident that the atmosphere will press with equal weight on all parts to fill up the vacuum thus produced. From without it will pass at once into the most open course through the trachea into the lungs, which it distends; but at the same time the blood will be forced towards the heart and the great vessels contained in the chest, and will assist in filling up the vacuum to a degree directly proportionate to their volume as compared with that of the lungs. An experimental proof of this influence in the veins (for in the arteries its effect is prevented by the valves at their origins) is afforded by introducing a tube into the jugular vein of an animal, and placing its opposite extremity in a vessel full of fluid. At every inspiration the fluid will be seen to rise, and at every expiration to descend a little, indicating first a suction towards the heart, and next a slighter expulsion of fluid from it. It is seen also in cases in which the brain is exposed by removing a portion of the skull; and in cases of Hernia Cerebri [Head, Injuries of, in Arts and Sc. Div.], in which, in addition to its slight elevation by the pulsation of the arteries at its base, the brain is seen to enlarge and rise at every expiration, and to become flattened at every inspiration. All these phenomena are still more evident when a strong inspiratory effort is made, as in sighing.

As inspiration draws the blood into the chest, so expiration acts by compressing all the large vessels to force it out of that cavity away from the heart. Its principal influence must be exerted on the arteries, for the blood would be prevented from passing far along the veins by their valves. In the arteries (and to a less extent in the veins) it is seen to act in the increased velocity of the current that issues from a wound; in the fullness of the vessels of the face and other parts during a strong expiration, or when holding the breath, coughing, or sneezing, actions which are sometimes the causes of rupture of the smaller vessels, and produce an evident alteration in the pulse.

Atmospheric pressure on the veins must also act to some extent in filling up the vacuum which the sudden contraction of the ventricles must produce in the pericardium. Of course the lungs will expand, and in part effect this by pressing the pericardium towards the heart; but at the same time the blood will tend to rush towards the auricles and dilate them, so that they may fill up the vacant space. Dr. Barry proved this further, by showing that if a tube be introduced into the sac of the pericardium, without allowing any air to enter with it, a fluid placed in it will be seen to be drawn towards and driven from the sac at each contraction and dilatation of the ventricles.

Such are the powers concerned in the circulation, and the principal effects which they produce. The influence of each is certain, but what is its extent, and what are the circumstances under which it is chiefly exercised, cannot be accurately determined. In order of importance, the contraction of the ventricles must undoubtedly be placed far highest; then would come the auricular contraction, the ventricular dilatation, the auricular dilatation; then inspiration, expiration, and the cavity in the pericardium when the ventricles contract. All these assist at all times in moving the blood; the elasticity of the arteries tends at all times to equalise the velocity of the current, while their vital contraction and that of the veins, the action of the contents of the capillaries, and the muscular pressure on the veins, would also seem to exercise an important influence.

One of the most interesting enquiries in connection with the heart is its development, to which we have before alluded, and on which considerable light has been thrown by modern research. The circulating system which has been described is not perfected until the moment of birth; and, as before observed, in its several transitory stages of growth it resembles permanent forms of the circulating apparatus amongst the lower animals. As the egg of the bird affords the best means of studying these changes, we give an outline of them, from Dr. Carpenter's 'Physiology:'—

"At an early period of incubation the yolk is found to be enveloped by a germinal membrane, composed of distinct cells, which is divisible into three layers; and a thickened portion of this is easily distinguishable, at which the embryo will be subsequently evolved.

"The middle layer gives origin to the circulating system, and is therefore termed the 'vascular' layer. The thickened portion of this that surrounds the germ soon becomes studded with numerous irregular points and marks of a dark yellow colour; and as incubation proceeds these points become more apparent, and are gradually elongated into small lines, which are united together, first in small groups, and then into one net-work, so as to form what is called the 'vascular area.' A large dark spot of a similar kind is seen in the situation to be subsequently occupied by the heart. These dark points and lines are formed by collections of blood-corpuscles, which originate in the transformation of the cells of the embryo and of the germinal membrane; and the rows and masses of blood-discs seem at first to lie in mere channels, the walls of the heart and blood-vessels that subsequently inclose them being of later formation.

"From the first however a definite plan is perceptible; the network of capillaries that is formed over the vascular area being supplied with blood by the ramifications of a pair of arterial trunks, whilst the blood is collected from them by the circular venous sinus which bounds the area, and is returned to the embryo by the venous trunk. In the blood-vessels which are first observed in the body of the embryo, as well as in the vascular area, no difference is at first perceived between the characters of the arteries and those of the veins, and these are only to be distinguished by the direction of the currents of blood circulating through them.

"But at about the fourth or fifth day of incubation the coats of the arteries begin to appear thicker than those of the veins, and the distinction between them soon becomes evident. After the principal vessels are formed, the development of new ones appears to take place in two modes, according as they are to occupy the interspaces existing among those previously formed, or are to extend themselves into outgrowing parts. In the first of these cases the new capillaries appear to be formed, like the original ones, from stellate cells [CAPILLARIES], whose prolongations meet the vessels in which the blood is already circulating, coalesce with them, and thus receive the current into their own cavities, to transmit it to some other vessel. But in the second, the new vessels are formed entirely by extension from those already existing. This takes place in the following mode:—Suppose a line, or arch, of capillary vessels passing below the edge, or surface, of a part to which new material has been superadded; the vessel will at first present a slight dilatation in one, and coincidently, or shortly after, in another point, as if its walls yielded a little near the edge or surface. The slight pouches thus formed gradually extend, as blind canals, or verticula, from the original vessels still directing their course towards the edge or surface of the new material, and crowded with blood-corpuscles, which are pushed into them from the main stream. Still extending, they converge, and meet; the partition wall that is at first formed by the meeting of their closed ends clears away, and a perfect arched tube is formed, through which the blood, diverging from the main or former stream, and then rejoining it, may be continuously propelled. This last process may be seen in the growing parts of the tail of the tadpole, in the development of the filamentous gills and legs of the water-newt, in the first evolution of the extremities of the embryoes of higher animals, and in the formation of new structures in the fully-developed organism, either for the repair of injuries or as the result of morbid processes. In some instances it would appear that the wall of the newly-forming vessel gives way, and that the blood-corpuscles escape from it into the parenchyma, at first collecting in an undefined mass, but soon manifesting a definite direction, and coming into connection with another portion of the arch, or with some adjacent vessel. Thus, then, a channel, and not a vessel, is formed; and it is probably in this way that those passages are excavated, which take the place of distinct vessels in many of the lower tribes of animals, and also, according to Mr. Paget, in some of the softer and least organised growths in man.

"The first rudiment of the heart appears about the 27th hour, and is a mass of cells, of which the innermost soon break down, so as to form a tubular cavity; for some time it is simple and undivided, extending however through nearly the whole length of the embryo; but the posterior part may be regarded as corresponding with the future auricle, since prolongations may be perceived extending from that part into the transparent area, which indicate the place where the veins subsequently enter. Although the development has proceeded thus far at about the 35th hour, no motion of fluid is seen in the heart or vessels until the 38th or 40th hour. When the heart, which may be considered as analogous at this period to the dorsal vessel of the *Annelida*, first begins to pulsate, it contains only colourless fluid mixed with a few globules. A movement of the dark blood in the circumference of the vascular area is at the same time perceived; but this is independent of the contractions of the heart, and it is not until a subsequent period that such a communication is established between the heart and the distant vessels, that the dark fluid contained in them arrives at the central cavity, and is propelled by its pulsations. This fact, which we have just seen to possess a very important bearing on the theory of the circulation, and which has been denied by some observers, appears to have been positively established by the latest researches of M. Von Baer.

"The contraction of this dorsal vessel (for so it may be termed) begins, as in the *Annelida*, at its posterior extremity, and gradually extends itself to the anterior; but between the 40th and 50th hours a separation in its parts may be observed, which is effected by a constriction round the middle of the tube; and the dilatation of the posterior portion becomes an auricular sac, and that of the anterior a ventricular cavity. Between the 50th and 60th hours the circulation of the blood in the vascular area becomes more vigorous, and the action of the ventricle is no longer continuous with that of the auricle, but seems to succeed it at a separate period. At the same time the tube of the heart becomes more and more bent together until it is doubled, so that this organ now becomes much shorter relatively to the dimensions of the body, and is more confined to the portion of the trunk to which it is subsequently restricted. The convex side of the curve which the tube presents is that which subsequently becomes the apex or point of the heart, and between the 60th and 70th hours this is seen to project forward from the breast of the embryo, much in the situation it subsequently occupies. About the same time the texture of the auricle differs considerably from that of the ventricle, the auricle containing the thin and membranous walls which it at first possessed; while the ventricle has become stronger and thicker, both its internal and external surfaces being marked by the interlacement of muscular fibres, as in the higher *Mollusca*. About the 65th hour the grade of development of the heart may be regarded as corresponding with that of the fish, the auricle and ventricle being quite distinct, but their cavities are as yet quite single. The heart of the dog at the 21st day bears a great resemblance to that of the chick at the 55th or 60th hour; it consists of a membranous tube twisted on itself, and partially divided into two principal cavities, besides the bulb or dilatation which at this period is found at the commencement of the aorta, and which corresponds with the bulbus arteriosus of fishes.

"Having thus traced the evolution of the heart of the chick up to the grade which it presents in fishes, we may now inquire what is the condition of the other parts of the vascular system at the same time. At the end of the second day the primitive arterial trunk is seen to have divided into two canals, which separate from one another to inclose the pharynx, and then unite again to form the aortic trunk, which passes down the spine. During the first half hour of the third day a second pair of arches is formed, which encompasses the pharynx in the same manner; and towards the end of the third day two other pairs of vascular arches are formed, so that the pharynx is now encompassed by four pairs of vessels, which unite again to supply the general circulation. These evidently correspond with the branchial arteries of fishes, although no respiratory apparatus is connected with them; and in fact the distribution of the vascular system of the bird on the fourth and fifth days exactly resembles that presented by many cartilaginous fishes, as well as by the tadpoles of the *Batrachia*. The first pair of arches is obliterated about the end of the fourth day, but a pair of vessels which is sent from it to the head and neighbouring parts, and which afterwards remains as the carotid arteries, continues to be supplied through a communicating vessel from the second arch. While the first pair is being obliterated a fifth is formed behind the four which had previously existed, and proceeds in the same manner as the fourth from the ascending to the descending aorta. On the fourth day the second arch also becomes less, and on the fifth day is wholly obliterated, whilst the third and fourth become stronger. From the third arch, now the most anterior of those remaining, the arteries are given off which supply the upper extremities; and the vessels of the head are now brought into connection with it by means of the communicating branches, which previously joined the third with the second arch. When these vessels are fully developed, the branches by which these arches formerly sent their blood into the aorta shrink and gradually disappear; so that about the thirteenth or fourteenth day the whole of the blood sent through the two anterior arches is carried to the head and upper extremities, instead of being transmitted to the descending aorta as before. There now only remain the fourth and fifth pair of branchial arches, the development of which into the aorta and pulmonary arteries will be described in connection with the changes which are at the same time going on in the heart. During the fourth day the cavities of the heart begin to be divided for the separation of the right and left auricles and ventricles. About the 80th hour the commencement of the division of the auricle is indicated externally by the appearance of a dark line on the upper part of its wall, and this after a few hours is perceived to be due to a contraction which, increasing downwards across the cavity, divides it into two nearly spherical sacs. Of these the right is at first much the larger, and receives the great systemic veins; the left has then the aspect of a mere appendage to the right, but it subsequently receives the veins from the lungs when these organs are developed, and attains an increased size. The septum between the auricles is by no means completed at once: a large aperture (which subsequently becomes the foramen ovale) exists for some time at its lower part, so that the ventricle continues to communicate freely with both auricles. This passage is often closed by the prolongation of a valvular fold, which meets it in the opposite direction; it remains pervious however until the animal begins to respire by the lungs, and sometimes is not completely obliterated even then. The division of the ventricle commences some time before that of the auricle, and is effected by a sort of duplicature of its wall, forming a fissure on its exterior and a projection on its interior; and thus a septum is gradually developed within the cavity, which progressively acquires firmness, and rises higher up, until it reaches the entrance to the bulb of the aorta, where some communication exists for a day or two longer. At last however the division is complete, and the inter-ventricular septum becomes continuous with the inter-auricular, so that the heart may be regarded as completely a double organ. The progressive stages presented in the development of this septum are evidently analogous to its permanent conditions in the various species of reptiles; but it must not be lost sight of that in all reptiles the inter-auricular septum is first developed, and that it is completely formed in many instances in which the inter-ventricular septum is absent or imperfect. The changes which occur in the heart of the *Mammalia* are of a precisely similar character, and as they take place more slowly they may be watched with greater precision. Soon after the septum of the ventricles begins to be formed in the interior a corresponding notch appears on the exterior, which as it gradually deepens renders the apex of the heart double. This notch between the right and left ventricles continues to become deeper until about the eighth week in the human embryo, when the two ventricles are quite separated from oue another except at their bases; this fact is very interesting from its relation with the similar permanent form of the Dugong. At this period the internal septum is still imperfect, so that the ventricular cavities communicate with each other, as in the chick on the fourth day. After the eighth week however the septum is complete, so that the cavities are entirely insulated; whilst at the same time their external walls become more connected towards their bases, and the notch between them is diminished; and at the end of the third month the ventricles are very little separated from one another, though the place where the notch previously existed is still strongly marked."

We may now finally trace the distribution of the arterial trunks to their final modifications, by which the creature is enabled to become an air-breathing animal. The first, second, and third branchial arches are replaced by the brachial and carotid arteries, and loose all communication with the primitive arterial trunk except at its commencement, when the third pair of arches arises with the other trunks from its dilated bulb. This remains as a single cavity even after the ventricles have been separated. About the fifth or sixth day the bulb in the chick becomes flattened, and its opposite sides adhere together, so as to form two tubes running side by side; one of which unites with the left, the other with the right ventricle. The one on the left becomes the ascending aorta, that on the right the pulmonary artery.

A knowledge of the changes which go on in the development of the heart enables us to explain some of the malformations to which it is subject. For an account of these see CYANOSIS; and HEART, DISEASES OF, in the ARTS AND SC. DIV. For further information on subjects connected with the structure and functions of the heart, see ARTERY; CAPILLARY VESSELS; BLOOD; BLOOD-VESSELS; VEIN; HEAT, ANIMAL; RESPIRATION; LUNGS; and FOOD.

HEART'S-EASE. [VIOLA.]

HEARTWOOD. [ALBURNUM.]

HEAT, ANIMAL. The conversion of the food of man and the higher animals into nutriment for the body is attended with changes which produce an evolution of heat, which constantly maintains the temperature of an animal at a point above or below, according to circumstances, the temperature of the medium in which it exists. The degree of heat possessed by animals not gifted with the power of locomotion is very small above that of surrounding media, and in this respect resembles the heat given off by plants. [HEAT, VEGETABLE.] In proportion as animals possess the power of locomotion they evolve heat from their bodies. This arises from the fact that where the muscular system is most exercised there is greatest demand made upon the nutritionary processes going on in the system. We should therefore expect to find that the quantity of heat developed in the invertebrate animals was less than that in the vertebrate class. Infusoria are for a time capable of resisting cold; for when the water in which they are contained is frozen, the animalcule is observed to live for a time in a little uncongealed space which the caloric from its body prevents freezing. John Hunter found that various forms of *Annelida*, as leeches and worms, and several of the *Mollusca*, exhibit temperatures higher than the surrounding media. As might have been anticipated from their activity, the Insects of all the invertebrate animals exhibit the highest temperature. They have been lately the subject of experiment by Mr. Newport. He found that they possessed a temperature above that of the medium in which they lived, varying from 2 to 9 degrees. With respect to the temperature of the different tribes, Mr. Newport observes, "Our previous observations lead us to anticipate the fact, that the volant insects, in their perfect state, have the highest temperature, while, on pursuing the inquiry, it is found that those species which have the lowest temperature are located on the earth. Among the volant insects, those hymenopterous and lepidopterous species have the highest temperature which pass nearly the whole of their active condition on the wing in the open atmosphere, either busily engaged in the face of day despoiling the blossoms of their honied treasures, or flitting wantonly from flower to flower, and breathing the largest amount of atmospheric influence. Of these the hive-bee, with its long train of near and distant affinities, and the elegant and sportive butterflies, have the highest. Next to these are probably their predatory enemies the hornets and wasps, and others of the same order; and lastly, a tribe of insects which have always attracted attention, and in general are located on the ground, but sometimes enjoy the volant condition—the ants, the temperature of whose dwelling has been found to be considerably above that of the atmosphere. Next below the diurnal insects are the crepuscular, the highest of which are the sphinges and moths; and almost equal with them are the *Melolonthæ*." In Insects which live in societies the temperature is still greater. Mr. Newport found that a bees'-nest in a chalk bank had a temperature 14 to 16 degrees above that of the atmosphere, and 17 to 19 degrees above that of the bank.

Amongst the vertebrate animals, Fishes and Reptiles have the lowest temperature. Dr. Davy, John Hunter, and others, have found that fishes have a temperature of from 0·7 to 2·7 degrees above the surrounding medium.

In man the temperature of the accessible parts of the body, as the mouth, axilla, &c. is usually between 97·7° and 98·6°. The human blood is said to have a temperature in health varying from 100·6° to 101·75°; in disease it rises from 106° to 109°. In healthy persons the temperature is said to attain its maximum during the day, and to fall from 1·1 to 2·7 degrees during sleep. Dr. Davy found that the temperature of the interior of the body is 2·7 to 3·6 degrees higher in tropical than in temperate climates. Most of the *Mammalia* have a higher temperature than man, and Birds develop a greater quantity of heat than any other class of animals. This arises from the nutritionary changes going on in the bird in order to support the enormous muscular power which it is compelled to exert during flight. The following is a table of temperatures, as given by Rudolphi and Tiedemann, for several Birds and *Mammalia*:—

Birds.

	Degrees.
Great Titmouse	111·25
Swallow	111·25
Fringilla, different species	111·25 to 107
Anas, different species	111 to 106
Common Hen	109·94 to 102·99
Falco, different species	109·74 to 104·5
Pigeon	109·58 to 106·7
Raven	109·23 to 105·99
Vulture	107.49
Common Cock	103·78 to 102·99
White Game	102
Gull	100

Mammalia.

	Degrees.
Bat (*Vespertilio pipistrellus*)	106 to 105
Squirrel	105
Sheep	104 to 100·4
Ox	104 to 99
Rabbit	104 to 99·46
Ape	103·86
Cat	103·6 to 98·6
Bat (*Vespertilio noctula*)	102
Dog	101·3 to 99·3
Guinea Pig	100·4 to 96·37
Hare	100
Elephant	99·25
Horse	98·24 to 97

There is now no question that the cause of animal heat is the chemical changes which are going on in the nutrient fluid of the body. During the act of respiration a large quantity of oxygen gas is taken into the lungs, which is absorbed by the blood. In this fluid it meets the various compounds of carbon which have been taken in with the food; and the consequence is a union of the oxygen with the carbon, and the formation of carbonic acid gas, which gas is given out when the blood again reaches the lungs during expiration. [FOOD; RESPIRATION.] When carbon and oxygen unite out of the body, heat is the result, and the same thing occurs when they unite in the body; and it is through the medium of this change that the bodies of animals are raised to a given temperature by the circulation of the blood through the system. It has been calculated that there is more oxygen absorbed than is given out of the system in the form of carbonic acid gas: it is probable that this enters into combination with hydrogen, forming water and other compounds of hydrogen, nitrogen, and carbon, and thus contributes to the raising of the animal heat.

This theory of animal heat explains many well-known phenomena; as for instance, the slight independent warmth of the fœtus, and of those young animals which are born in an imperfectly developed condition. The low temperature of persons with morbus cœruleus, where the blood is only imperfectly oxygenated, and the cold experienced by aged and debilitated persons in whom a small quantity of blood circulates slowly; as also the increased temperature observed in persons labouring under attacks of inflammatory disease where the blood circulates rapidly, are also confirmatory facts. The phenomena also exhibited by the hyberuation of animals are explained by this theory. During the period of hybernation, when the blood is circulating only slowly and respiration is almost suspended, and the oxygenation of the blood is feebly performed, the temperature of the animal is low. The observations of Pallas and others show that hybernation is prevented by a temperature of from 50° to 80°, whilst it is induced in those animals which exhibit it even in summer by the application of artificial cold.

The production of heat is also dependent on the mass of the globules of the blood and the rapidity with which they circulate. When there are few blood-globules the necessity for the absorption of oxygen is diminished in the same ratio, and the circulation becomes slower, and the consequence is that there is less heat developed. On the other hand, blood containing an excess of globules, but which is circulated less slowly, developes less heat than blood which contains a smaller proportion of globules but which is more rapidly circulated, for more oxygen may be consumed in the latter than in the former case.

"The metamorphosis of the blood and the general change of matter lead to still another secondary source of heat. It has been shown by Pouillet that all solid bodies, organic and inorganic, undergo an elevation of temperature when moistened with different fluids. In organic substances it may amount to from 11° to 18°. Since the act of metamorphosis is always effected through humid membranes, this source of heat must be regarded as of great importance, even if it be not actually identical with the catalytic metamorphosis of the cells themselves." (Simon.)

(Carpenter, *Principles of General and Comparative Physiology*; Simon, *Medical Chemistry*, translated by Day.)

HEAT, VEGETABLE. That plants possess a temperature higher in winter than that of the air which surrounds them is known by the obvious fact that snow melts at the foot of a tree sooner than at a distance from it; that the temperature is lower in summer is equally well proved by the coldness of the fluid which is discharged from many vines and vine-like plants when cut across. These phenomena have been examined with care by several observers: John Hunter found that a thermometer whose bulb was plunged 11 inches deep in the trunk of a walnut-tree generally indicated in the autumn a higher temperature than that of the external air by 2 or 3 degrees; Schöpf at New York, and Bierkander in Sweden, Pictet, and Maurice, and various other observers, have obtained similar results; they have found even tubers and bulbs with a temperature higher in winter than that of the external air by 6 or 7 degrees Réaum., while on the other hand from the spring to the autumn it is lower.

The former fact accounts in some measure for the power possessed by some plants of resisting cold in winter, and for the protection given to the upper parts of trees by heaping straw up against their trunks in winter. During every season of the year trees are absorbing water from the earth; water when absorbed parts with its heat very slowly through the carbonated matter of a trunk; in winter the temperature of the earth, which determines that of the water it contains, is uniformly higher than that of the atmosphere, and consequently the temperature of the interior of a tree is also higher, in proportion to the difference between the heat of the soil and that of the air. In the spring and summer, on the contrary, the earth is cooler than the air, and the temperature of trees is cooler also.

These considerations throw some light upon the effects of frost upon trees. A young tree is, cæteris paribus, affected more than an old one of the same species; either because its roots derive their food from a smaller distance under the soil, or because the heat obtained from the soil is sooner parted with on account of the thinness of the bark and the smallness of the whole mass. Unhealthy trees, which also suffer in like manner, may be supposed to do so in consequence of the weakness of their power of pumping warmer fluid up from the soil in winter.

Independently of this source of heat in vegetables, there is another that deserves attention. Whenever oxygen combines with carbon to form carbonic acid, an extrication of heat takes place, however minute the amount; such a combination occurs much more extensively during the germination of seeds and the impregnation of flowers than at any other time. At the first of these periods extrication of heat takes place to a considerable amount, as is remarked in the germination of barley heaped in rooms, previously to being manufactured into malt: in the latter it also occurs, but in consequence of flowers not being confined in close cases, the heat is lost as soon as it is disengaged, and never accumulates, except in a few special instances. Saussure found the temperature of the male flowers of the common gourd, at between 7 and 8 o'clock in the morning, half a centigrade degree higher than that of the air; and those of the tuberose 9-10ths of a similar degree. It is however only when large quantities of flowers expand within close cases that this phenomenon is particularly remarkable. Accordingly, in the spathe of araceous plants it has been remarked at its greatest intensity. Lamarck, Senebier, and De Candolle, found the flowers of *Arum maculatum*, between 3 and 7 o'clock in the afternoon, as much as 7 degrees Réaum. warmer than the external air. Schultz found a difference of 4 to 5 degrees between the heat of the spathe of *Caladium pinnatifidum* and the surrounding air from 6 to 7 o'clock, p.m. Hubert and Bory de St.-Vincent assert that at sunrise the spathe of *Arum cordifolium* acquires in the Isle of France an elevation of 30 degrees Réaum. above the atmosphere. Finally, Messrs. Vrolik and Vriese at Amsterdam, and Adolphe Brongniart at Paris, have confirmed the fact by new observations in the hothouses of those cities.

The following tables of experiments on this subject by Dutrochet are given by Professor Balfour in his 'Classbook of Botany':—

TABLE I.

Observations made on the diurnal variations of heat in the stems of *Euphorbia Lathyris*.

Hour of Day.	Deviation of Thermo-electric Needle.	Proper heat of Plant above the Atmosphere.	Temperature of the Atmosphere.
5th June, 6 a.m.	1¼	0·160° Fahr.	62·24° Fahr.
7 a.m.	1½	0·198° Fahr.	62·24° Fahr.
8 a.m.	2	0·324° Fahr.	62·24° Fahr.
9 a.m.	3	0·324° Fahr.	62·42° Fahr.
10 a.m.	4	0·450° Fahr.	62·60° Fahr.
11 a.m.	4	0·500° Fahr.	62·96° Fahr.
12 noon.	5¼	0·558° Fahr.	63·14° Fahr.
1 p.m.	5½	0·610° Fahr.	63·50° Fahr.
2 p.m.	4½	0·500° Fahr.	63·86° Fahr.
4 p.m.	3	0·216° Fahr.	63·68° Fahr.
6 p.m.	1	0·108° Fahr.	63·50° Fahr.
8 p.m.	½	0·054° Fahr.	62·96° Fahr.
9 p.m.	¼	0·027° Fahr.	62·60° Fahr.

The next table gives some results of experiments on different species of plants.

TABLE II.

Names of Plants.	Hour of Maximum of Vital Heat.	Deviation of the Needle	Maximum of Vital Heat.	Temperature of the Atmosphere.
Rosa canina	10 a.m.	3½	0·380° Fr.	71·60° Fr.
Allium Porrum	11 a.m.	2	0·216° Fr.	74·84° Fr.
Borago officinalis . . .	12 noon.	1½	0·160° Fr.	66·20° Fr.
Euphorbia Lathyris . .	1 p.m.	5½	0·610° Fr.	63·50° Fr.
Papaver somniferum . .	1 p.m.	3½	0·380° Fr.	68·72° Fr.
Cactus flagelliformis . .	1 p.m.	2	0·216° Fr.	67·10° Fr.
Helianthus annuus . .	1 p.m.	3⅔	0·396° Fr.	56·84° Fr.
Impatiens balsamina . .	1 p.m.	1¼	0·108° Fr.	60·80° Fr.
Ailanthus glandulosa . .	1 p.m.	2⅓	0·290° Fr.	71·60° Fr.
Campanula medium . .	2 p.m.	5	0·558° Fr.	61·16° Fr.
Sambucus nigra . . .	2 p.m.	3½	0·380° Fr.	66·74° Fr.
Lilium candidum . . .	2 p.m.	4½	0·504° Fr.	63·10° Fr.
Asparagus officinalis . .	3 p.m.	4	0.450° Fr.	53·6° Fr.
Lactuca sativa	3 p.m.	1½	0.160° Fr.	71·21° Fr.

The hour of maximum varied from 10 a.m. to 3 p.m., and the temperature varied from about one-tenth to rather more than half a degree Fahrenheit. In the case of *Fungi* the following results were obtained:—

TABLE III.

Names of Plants.	Deviation of the Needle.	Heat of Fungus above the Air.	Temperature of the Atmosphere.
Agaricus eburneus . . .	3¼	0·36° Fahr.	68·90° Fahr.
Agaricus colubrinus . .	1½	0·18° Fahr.	68·36° Fahr.
Agaricus annularius . .	1½	0·18° Fahr.	63·50° Fahr.
Boletus æreus	7½	0·81° Fahr.	66·74° Fahr.
Lycoperdon hirtum . .	4¼	0·47° Fahr.	70·06° Fahr.

HEATH. [CALLUNA; ERICACEÆ.]

HEATHER. [ERICA.]

HEBRADENDRON, a genus of Plants belonging to the natural order *Clusiaceæ*. It was established by Professor Graham of Edinburgh, for the Gamboge-Tree of Ceylon. The gamboge of commerce is known by the names of Ceylon and Siam gamboge.

The gamboge of Siam is in cylinders, either solid or hollow, usually called pipes: it is supposed to have this form from being so rolled, or from being poured into the hollow of bamboos, according to Lieutenant White, in his 'Visit to Cochin China.' It is usually of the best quality, but Mr. Pereira has shown that some very impure is occasionally in the form of pipes. As this pipe-gamboge is usually exported from Singapore, it has been doubted whether it was actually the produce of Siam; but we have specimens from Mr. G. Swinton, which were sent to him direct from Siam when he was chief secretary of the Indian government, as the produce of that country, and which are identical with the best pipe-gamboge of commerce. The only information respecting its preparation which we possess is that given to Kœnig by a Catholic priest, who officiated as such to the Catholics of Cochin China, and who stated that the inspissated juice obtained from breaking the leaves and young shrubs, as well as the fragrant lignum aloes, is given as a tribute to the king of Siam by the Christians residing there. The tree must therefore be common, and probably near inhabited places, and therefore very likely to be *Oxycarpus Cochinchinensis* of Loureiro (now referred to the genus *Garcinia*), who names it from its acid fruit, and describes it as cultivated in Cochin China. We have specimens of a plant something similar to this in the form of its leaves from Mr. Malcolmson, collected by him in Rangoon, which he thought might be the gamboge plant, as it contained a yellow purgative juice in the rind of its fruit. Dr. Graham thinks that the Siam plant may be a nearly allied species of the same genus as the Ceylon plant.

The Ceylon gamboge is usually considered inferior; that which forms an article of commerce no doubt is so; and we have been informed by one of the principal merchants of Ceylon that finding the gamboge there very cheap, he had been induced to purchase and send it to England, but had not been able to sell it from its inferior quality. No doubt however some of very excellent quality is produced in Ceylon by the tree which has been called *Hebradendron cambogioides*, and Mrs. Colonel Walker describes it as "brilliant and excellent," and "as good for water-colour drawings as any she ever used." Dr. Graham ascribes its inferiority to want of care in preparing the article for market; though it is yet doubtful whether the Ceylon gamboge of commerce is all yielded by this tree; but Mrs. Walker on one occasion, in passing through a forest of these trees, saw all of them with the bark cut off in various places. Dr. Christison has shown that there is all but an identity of composition with that of Siam; and its medicinal effects are precisely the same, as proved in Ceylon by Dr. Pitcairn, and by Drs. Graham and Christison in Edinburgh.

This plant, though new named, is far from being new. Dr. Graham considers it to be identical with the *Carcapuli* of Herman, the *Cambogia gutta* of Linnæus, the *Garcinia Morella* of late authors, and the *Stalagmitis cambogioides* of Moon's 'Catalogue of Ceylon Plants.' The last name might have been retained, as it was originally intended for it, had it not been discovered by Mr. Brown that the specimens in the 'Banksian Herbarium' collected by Kœnig, and from which Murray's character of the genus and species was established, consist not of one, but of two distinct plants, the flowers of *Xanthochymus ovalifolius* being stuck by sealing-wax upon a branch of what appears to be this Ceylon plant. The genera *Stalagmitis* and *Xanthochymus* are therefore one genus, as was previously inferred by Cambessedes, who has retained for it the former, as the prior name.

The genus *Hebradendron* has diœcious flowers, the male having the calyx membranaceous, 4-sepalled, persistent; corolla 4-petalled; stamens monadelphous; column 4-sided; anthers terminal, opening by the circumcision of a flat and umbilicate terminal lid. The inflorescence of the female tree is similar to that of the male, the flower white and a little larger, with a germen precisely in miniature of the fruit, and surrounded (like it) with several (ten?) abortive stamens. The berry is many (4-) celled; cells 1-seeded, surrounded at the base with some free abortive stamens, crowned by a lobed and muricated sessile stigma; cotyledons fleshy, united; radicle central, filiform; trees with entire leaves.

1, a flowering branch of *Hebradendron cambogioides*; 2, a flower seen from below; 3, a flower seen laterally; 4, anther with its umbilicate lid.

The species called *H. cambogioides* forms a moderate-sized tree, with the leaves obovate, elliptical, abruptly sub-acuminate; the male flowers clustered in the axils of the petioles on short single-flowered peduncles; sepals yellow on the inside, yellowish-white externally; petals yellowish-white, red on the inside near the base; berry about the size of a cherry, round, with a firm reddish-brown external coat and sweet pulp; ripe in July. It is called in Ceylon Kana (eatable) Goraka. *G. cambogia* is called simply Goraka. The gamboge is used by the natives both as a pigment and medicinally. Mrs. Walker describes it as being collected by cutting pieces of the bark about the size of the palm of the hand early in the morning. The gamboge oozes out in a semi-liquid state, but hardens on exposure to the air, and is scraped off by the collectors next morning.

This tree is found in various parts of Ceylon, but not very abundantly near Colombo. In a tour through different parts of the island, Mrs. Walker writes: "We found the Ceylon Gamboge-Tree several times in forests distant from the habitation of man, which proves the tree to be indigenous." Colonel Walker writes to Dr. Wight, that "it is found in great abundance along the western and eastern coast in the neighbourhood of Battocola; but it also grows inland, where it could not have been planted by the Dutch. Its favourite abode seems to be low sandy ground, as about Kanderaane, Negombo, and towards Chilaw; also, 100 miles inland, at so high an elevation as 2000 feet above the sea." *Garcinia elliptica*, a native of Silhet, and *G. pictoria* of the Wynaad district, are thought to be other species of this genus.

Besides the above species there is probably another belonging to the same genus or to the same group of a larger genus, which appears to yield a very good kind of gamboge. It is the *Garcinia pictoria* of Roxburgh, and

H. pictorium of Lindley and other botanists. It is a tall tree, about 60 feet high, of a conical shape, and very full of branches. The bark is pretty thick, scabrous and ramous on the outside, of a dark ferruginous colour, intermixed with many yellow specks, and through its substance, particularly on the inside, considerable masses of gamboge are found. The young shoots are somewhat angular, smooth polished, of a deep green colour. The leaves are opposite, short-petioled, oblong, ventricose, rather acute, entire, smooth on both sides, and of a firm texture, from 3 to 4 inches long, by 1½ or 2 inches broad. The calyx consists of two unequal pairs of concave obtuse leaflets, permanent. Petals 4, oval, longer than the calyx. Anthers from 10 to 15, oblong, 2-lobed, and seemingly fertile. Ovary superior, round, 4-celled, with one ovule in each, attached to the axis a little above its middle. The berry is the size of a large cherry, oval, smooth, very slightly marked with four lobes, crowned with the sessile 4-lobed verrucose permanent stigma. Roxburgh says he received frequent samples of the gamboge of this tree from a correspondent at Tellicherry, and uniformly found it, even in its crude unrefined state, superior in colour while recent, but not so permanent as that from China. The tree grows on the highest parts of Wynaad in India.

(Lindley, *Flora Medica;* Royle, *Materia Medica.*)

HEDENBERGITE. [Augite.]

HEDERA, a genus of Plants belonging to the natural order *Araliaceæ*. The calyx has an elevated or toothed edge. The petals 5 or 10, not calyptrate and cohering; stamens 5 to 10; styles 5 to 10, converging or consolidated; the berry 5- or 10-celled.

H. Helix, Ivy, is a common plant all over Europe, clinging to trees and walls. It has a stem climbing with root-like fibres; leaves coriaceous, smooth, shining, 5-angled, or 5-lobed, the upper or old ones ovate and acute; umbels simple and downy; leaves austere and bitter; berries bitter, aperient, and emetic. It is mentioned as a sudorific, and was once reputed to prevent drunkenness and to dissipate the effects of wine. The berries are black at maturity. The flowers are yellowish, and appear late in the season, and, in consequence, are much resorted to by bees and flies when little other food is to be had.

It is found commonly wild in England, and is dispersed through many distant parts of the Old World, lying between the Canaries and Europe on the west, and the northern parts of China on the east. In the Canaries it acquires its largest size, being what is called in English gardens the Irish or Giant Ivy, which grows so much faster than the European form. In the north of India, and indeed occasionally in Italy, the berries, instead of being black as with us, are bright yellow, and it is supposed that this is more particularly the *Hedera* of the Roman poets. The leaves vary much in form, and there is a kind which never runs or creeps upon other plants, but merely forms a compact bush.

H. umbellifera is a native of Amboyna. It has a shrubby unarmed stem; leaves on long stalks, lanceolate acuminate, distantly serrated; peduncles 16, trifid and umbellate; partial umbels capitate, roundish. It yields a blackish or dull-brown resin with a very powerful aromatic camphorated smell. It is called 'Sarura' in Amboyna. There are 50 species of Ivy enumerated, all of which are of easy culture.

HEDGE-HOG. [Erinaceus.]

HEDGE-MUSTARD. [Sisymbrium.]

HEDGE-SPARROW. [Sylviadæ.]

HEDYPHANE. [Lead.]

HEDY'SARUM (from ἡδύσαρον, the Greek name of the *Coronilla securidaca*), a genus of Plants belonging to the natural order *Leguminosæ*. It has a 5-cleft calyx, with the segments linear-subulate and nearly equal; the corolla with a large vexillum, and obliquely truncate; keel much longer than the wings; the stamens diadelphous; the legume of numerous flat orbicular or lenticular regular 1-seeded joints, which are connected together in the middle, and therefore the sutures are convex on both sides. The species are herbs or under-shrubs, with unequally pinnate leaves, axillary, with simple peduncles, and bearing racemose spikes of large purple, white, or cream-coloured flowers. The old genus *Hedysarum* has been subdivided into many smaller genera. The Saintfoin, *H. onobrychis* of older writers, now forms the genus *Onobrychis*, which differs from *Hedysarum* in the legumes consisting of many joints, not of one joint, as in that genus. [ONOBRYCHIS.]

H. coronarium, French Honeysuckle, has diffuse stems, the leaves with 3-5 pairs of elliptic or roundish leaflets, which are pubescent beneath and on the margins; the spikes or racemes of flowers are ovate, crowded; the wings of the flower twice the length of the calyx; the legumes glabrous, with 25 orbicular prickly joints. It is a native of Spain and Italy. It has deep red or white flowers. In Calabria this plant grows wild in great abundance, and horses and mules are fed with it. It grows well in our gardens, but probably would not make a good field crop.

H. fruticosum has an erect shrubby stem, the leaves with 5-7 pairs of alternate elliptic obtuse leaflets, which are clothed with pubescence on both surfaces; the flowers few, disposed in spikes; the wings hardly longer than the calyx; the vexillum the length of the keel; the joints of the legume wrinkled; the nerves slightly echinate. It is a native of Siberia in sandy places. It has a pale purple flower, and is a very handsome plant. Horses eat it with avidity, and it may be made useful in fixing sand, in which is grows readily.

H. Mackensii has recumbent stems; the leaflets oblong, clothed on both surfaces with canescent pili; the stipules sheathing; the joints of the legume transversely wrinkled and pilose. It is a native of arctic America and about the Saskatchewan, on the Eagle and Red-Deer Hills. The flowers are large and of a red colour. This was described as a liquorice plant by Sir A. Mackenzie, and named after him. The whole plant has a sweet taste.

H. lineare is used in Cochin China as a stomachic, and *H. alpinum* is used in Siberia for the same purpose. The *H. sennoides* of Willdenow, now *Ormocarpum sennoides*, has a root which is used in India as a tonic and stimulant. The *H. Alhagi* of Linnæus is the *Alhagi Maurorum* of recent writers. It is a spiny shrub, and from its branches exudes a sweet substance like manna. *H. tuberosum* of Roxburgh, *Pueraria tuberosa* of De Candolle, grows in the Circar Mountains. The roots are used by the natives as poultices for swellings of the joints.

All the species of the genus *Hedysarum* may be cultivated. They thrive in a light rich soil; the perennial sorts may be increased by dividing the roots; and the seeds of the annual species should be sown in an open border.

(Lindley, *Flora Medica*; Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*.)

HEIMIA, a genus of Plants belonging to the natural order *Lythraceæ*. It has a hemispherical campanulate calyx, bracteolated at the base, with six erect lobes and as many alternating horn-shaped patent angles; petals 6, alternate with the erect lobes; stamens 12, somewhat equal; ovary sessile, nearly globose, 4-celled; capsule included within the calyx; seeds numerous, minute, and wingless. Glabrous herbaceous plants. Peduncles 1-flowered, shorter than the calyx.

H. salicifolia is found in New Spain on the volcano of Jorullo. It has ternate or opposite leaves, the upper often alternate, on very short stalks, lanceolate, acute, narrowed to the base. The petals are obovate. It is a powerful sudorific and diuretic. The Mexicans consider it a valuable medicine, and call it Hanchinol.

HEISTERIA. [PARTRIDGE-WOOD.]

HELAMYS, a genus of Rodents nearly allied to the Jerboas. [PEDETES.]

HELARCTOS. [BEAR.]

HELIA'NTHEMUM, a genus of Plants named from ἥλιος, the sun, and ἄνθος, a flower, because the flowers open with the rising of the sun, and fall with the setting of the sun in the evening. This genus belongs to the natural order *Cistineæ*, or *Cistaceæ*, and the species were at one time included under the genus *Cistus*, but they differ materially in their characters. There are about 150 species enumerated, which are distributed in various parts of the world. They are chiefly found in the south of Europe, the north of Africa, and a few species in America. The calyx consists of 5 sepals, the 2 exterior ones smaller or wanting, 5 deciduous petals, numerous stamens, and 3-valved capsules. The flowers are yellow, red, or white, and are very elegant; none of the species possess any available property in the arts or medicine, but they are extensively cultivated on account of their very beautiful and ornamental appearance.

H. guttatum is an erect herbaceous plant with oblong lanceolate or linear leaves, the racemes without bracts, and the stigma subsessile. The flowers are yellow, with a deep red spot at the base of each petal. It is a native of France, Italy, Spain, Portugal, and Turkey, and is found in Anglesey and Jersey in Great Britain, but is a very rare plant.

H. canum, the Hoary Sun-Rose, is distinguished by its shrubby appearance, without stipules, and having terminal bracteated racemes. The flowers are yellow and small. It is a native of the south of France and Germany, and is rarely found in Great Britain.

H. vulgare, the Common Rock-Rose, is a procumbent shrub, with stipules, bracteated racemes, the style larger than the ovarium, and bent at the base. The flowers are yellow, and bloom from May to September. It is a native of Europe, and is found in Great Britain in dry hilly pastures.

There is a very beautiful variety with double pale yellow flowers, which is much cultivated by florists. The stamens, if touched in the sunshine, spread slowly, and lie down upon the petals.

H. Breweri is a British plant. It has obtuse obovate leaves, without stipules; racemes without bracts.

H. polyfolium is found in Devonshire and Somersetshire. It is a hoary plant, with stellate pubescence; the leaves opposite, ovate-oblong, or oblong-linear; the sepals tomentose, inner ones obtuse.

Almost all the species of *Helianthemum* are elegant plants, of hardy growth, and easily cultivated. They grow best in a light sandy soil, and should be protected during the winter in a frame.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Loudon, *Encyclopædia of Trees and Shrubs*.)

HELIANUS, a genus of Fishes belonging to the *Sciænidæ*, a family of *Acanthopterygii*.

HELICARION. [HELICIDÆ.]

HELI'CIDÆ, a family of Gasteropodous *Mollusca* to which the land Shell-Snails are referred.

Dr. J. E. Gray, in his paper on 'Streptaxis' ('Magazine of Natural History,' vol. i.), observes that zoologists have divided land-shells into several genera; but that the late Baron Férussac united most of them into a single genus, as he wished to establish as a rule that all the genera of *Mollusca* should be alone characterised by some peculiarity in the animal. "The increased knowledge," continues Dr. Gray, "of the animal has shown that some of the species which he (Férussac) referred to the genus *Helix* have very different animals from the typical kinds; and it is probable that eventually several of the genera established before his time (which he attempted to set aside) will be found to be true genera, according to his own theory. The knowledge of the animal, and the history of several species which were unknown at the time he wrote his system, have shown that several of the characters which he considered as of generic importance are common to other species belonging to quite different groups. Thus we now know that some *Helices* (*Carocolla inversicolor*, *Balea Chemnitzii*, and some others) are viviparous, as well as the *Partulæ*; that the degree of development in the lower pair of tentacles is variable in the different species of *Pupa* and *Vertigo*; and that to separate the latter genus from the former, on account of the partial obliteration of these organs, has the effect of dividing very nearly allied species. I am inclined to think that these and numerous similar facts, which must be well known to every practical conchologist, show us that we are warranted in establishing genera from any peculiarity in the structure or form of a series of shells, as well as on a peculiarity in the animal alone; especially when we consider how very few of the animals of the different species which we are called upon to arrange are or ever can be known; and also, as we constantly find by experience, that every peculiarity in the form or structure of the shell is the indication of some peculiarity in the habit or organic structure of the animal which formed it, and warrants its separation from the rest of the species of the family."

The organisation of this group of animals may be illustrated by the structure of the large Roman Snail (*Helix Pomatia*), of which there are several preparations in the museum of the Royal College of Surgeons in London.

Nutrient Organs.—In the Physiological Series—Gallery, No. 301, is a preparation of the *Helix Pomatia*, Linn., showing the form of the mouth and the part which performs the office of teeth. This is a dentated horny substance, of a dark colour and arched form, situated transversely above the aperture of the mouth, and forming, as it were, the margin of the upper lip; the lower lip is divided by a vertical fissure. No. 302 of the same series shews in the head of another Shell-Snail the same structure of mouth. No. 767 shows the soft parts of *Helix Pomatia*, and the alimentary canal has been injected with size and vermilion; so that the salivary glands, from their white colour, may be distinctly perceived upon the parietes of the stomach. These glands are of a flattened, elongated, and irregular form, and of a conglomerate structure; they may be seen diminishing in breadth as they extend upwards towards the pharynx, where their ducts terminate. Here also the semicircular dentated horny jaw, the course and termination of the alimentary canal, and the position and form of the liver, are well displayed. The next preparation (No. 768), which exhibits the mouth, œsophagus, and stomach of the same species, shows the junction of the two salivary glands at their lower extremities, and the termination of their ducts. The œsophagus and stomach being laid open, their internal structure is seen. ('Catalogue'—Gallery, vol. i.)

Circulating System.—In the Shell-Snail (*Helix*) the heart is situated on the right side of the posterior third of the pulmonary sac; and in the Slug (*Limax*) it is situated at nearly the middle of the posterior surface of the pulmonary sac, and protected above by the rudimentary shell, so that this part of the structure in these animals is, as in other points, nearly allied. The preparation in the College Museum, No. 882 (Gallery), is a specimen of *Helix Pomatia* with the shell removed in order to show the heart, which is situated on the left side of the dorsal aspect of the body, near the posterior part of the branchial sac. The pericardium is laid open, and the heart being injected, the auricle, from its thinner parietes, is seen of a red colour; a bristle is passed behind the ventricle, and the aorta may be seen ramifying over the liver. No. 883 is a specimen of *Limax ater*, Linn. (Slug), to show the heart situated in the middle of the back. ('Catalogue'—Gallery, vol. ii.)

Respiratory System.—In the same series the soft parts of *Helix Pomatia* are prepared (No. 1081), to show the pulmonary sac, which receives the air by an anterior orifice on the right side of the neck. The sac is laid open from that orifice to the opposite extremity; and the roof of the cavity, upon which the pulmonary artery or continuation of the veins of the body ramifies, is turned back to exhibit the reticulation of the vascular and respiratory surface. The parts are injected with size and vermilion. No. 1082 is a similar specimen, with the left parietes of the pulmonary sac removed, and the orifice by which the air is admitted and expelled left entire. No. 1083 is the portion of the vascular parietes of the pulmonary sac removed from the preceding preparation, and inverted to show the ramifications of the pulmonary vessels. These are continued from the veins of the body without the interposition of the propelling ventricle. No. 1084 is a similar preparation. No. 1085 shows the roof of the pulmonary sac of another *Helix Pomatia*, with the vessel injected; and in No. 1086 there is, in a similar specimen, a bristle inserted into the rectum, which terminates close to the orifice of the pulmonary sac. ('Catalogue'—Gallery, vol. ii.)

Brain, Nervous System, and Senses.—In the same series of the same collection is a preparation of a Slug (*Limax rufus*, Linn.)—No. 1304—laid open longitudinally along the back to show the nervous system. The viscera are removed. "In this," says Professor Owen, "as in other Encephalous Mollusks, a well-developed ganglion is situated above the œsophagus; it is of a transverse shape, slightly enlarged at its extremities, and supplies the antennæ, or horns, and the eyes. The œsophageal nervous ring is completed by a larger ganglion below the tube, from which numerous nerves radiate to supply the body. The principal nerves are the two inferior ones, which extend on either side the mesial line of the ventral surface straight to the opposite end of the body, giving off nerves to the muscular disc, or foot, from their outer sides. A small unsymmetrical ganglion is formed on the nerve, which supplies the heart and respiratory apparatus." No. 1305 is the same species of slug laid open along the ventral aspect, and the viscera removed, to show more especially the subœsophageal ganglion and its nerves. A bristle occupies the place of the œsophagus. No. 1306 exhibits the nervous system of a Black Slug removed from the body. ('Catalogue'—Gallery, vol. ii.)

Touch.—In the Shell-Snails the sense of touch will be readily supposed, by any one who has observed the motions of a common garden-snail, to reside especially in the ventral disc, or foot, and the lower tentacles. In the museum of the College we find, No. 1391, a specimen of *Helix Pomatia* prepared to show the different character of the surface of the skin in the exposed and protected parts of the body: in the latter it is thin and smooth; in the former, thick, vascular, and rugose. No. 1392 is a snail injected, slit down the back and eviscerated, to show the vascularity of the foot. No. 1393 is a snail injected, with one pair of tentacles, which serve as special instruments of touch, extended. Here too the pulmonary cavity is laid open. ('Catalogue'—Gallery, vol. ii.)

Sight.—In the gallery (Physiological Series) of the same rich museum is a preparation of a *Helix Pomatia* (No. 1756), with the posterior tentacles or horns extended, showing the eye-specks, or ocelli, situated at the side of the extremity of each horn. "In this position, although destitute of appropriate muscles, the eyes have the advantage of all the mobility with which the tentacle itself is endowed; and by the admirable construction of the same part, they are defended from external injury by being retracted and inverted, together with the extremity on which they are supported within the cavity of the tentacle, as in a sheath." (Professor Owen, 'Catalogue,'—Gallery, vol. iii.)

Swammerdam describes the eyes in detail; but some are of opinion that the organs above alluded to are not eyes. Sir Everard Home denied that they were visual organs; and so does M. Gaspard, who allows the snail no senses, save those of taste and touch, the latter of which he admits it to possess in an extreme degree of delicacy. See M. Gaspard's 'Memoir on the Physiology of Helix Pomatia.' (Majendie's 'Journal de Physiol.,' tom. ii. p. 295, et seq.; and an abstract of the paper, with notes, by T. Bell, Esq., 'Zool. Journ.,' vol. i.) See also Mr. Brayley's paper 'On certain Organs of the Helicidæ, usually regarded as their Eyes, &c.' ('Zool. Journ.,' vol. ii.)

Generative Functions.—In the common Shell-Snails (*Helix*), the male and female sexual organs are complete in one individual, but it requires a reciprocal junction of two individuals to produce a fruitful impregnation. The situation of these organs is at the anterior orifice of the neck; and at the time of congress a sharp horny or glass-like excitatory appendage is protruded, apparently for the purpose of stimulus. Some assert that these appendages are absolutely shot out from the body of one snail into the body of another, and engravings even exist where two snails are represented at a distance from each other reciprocally darting these spicula amoris, some of which are seen actually in the intervening space, and others on the ground. There is reason to doubt whether the spiculum amoris is ever thrown: we have had opportunities of examining the common garden shell-snails frequently when engaged in the reproduction of the species, and have never seen the hard excitatory appendage thrown from the body of the snail. Colonel Montagu, it appears, is of the same opinion. He admits the existence of the spicula in the animal of *Helix aspersa*, as well as *H. nemoralis* (or at least some of them); but "that they are missile darts," he continues, "we have much reason to doubt, though it is natural to suppose the animals are furnished with them for the purpose of stimulating each other to love, because it is only at that season they are found to possess them. If such are ever discharged at each other, we have been extremely unfortunate in our observations, for in no one instance could we ever find the dart penetrated, though at the time the animals are close the point may irritate; but it is neither sufficiently strong nor sharp-pointed to penetrate the tough skin with which these animals are furnished; and indeed the extremely viscid secretion with which they are so copiously provided adheres so strongly to the spiculi (spicula), when wholly projected from the body, that they are for a time held by it. Perhaps we may be told hereafter that this tough excretory fluid is used as a cord to regain these darts after they have been discharged; but such we should hold equally fabulous with much of the accounts related by various authors. These celebrated love-darts are sub-pellucid, white, and very brittle, about one-fourth or three-eighths of an inch in length, and somewhat triangular like the blade of a small sword." ('Testacea Britannica.') Dr. Maton often observed these spicula, but never saw them actually projected from one to the other.

Where the reproduction is by means of eggs, as it is in the great majority of *Helicidæ*, these are either enveloped in a skin, and round, as in the common garden-snail, or provided with a hard calcareous shell, generally of a white or of a dirty-white colour, as in *Achatina* and *Bulimus*. [BULIMUS.] These hard-shelled eggs are generally oval; in other instances they are round. Specimens of these eggs, some whole, some showing the young shell included, and others showing it breaking out of the egg-shell, are now in the British Museum (from Mr. Brodcrip's collection). In the museum of the College of Surgeons are several preparations, showing the organs of generation in the shell-snail.

Power of repairing Injuries.—The power which snails, in common with other Testaceous Mollusks, possess of repairing their shells, is known to most observers, and requires no comment; but the extent to which these animals will repair lesions of the soft parts, and even reproduce some of the principal ones after they have been deprived of them, is deserving of notice. The works of Schoeffer, Spallanzani, Bonnet, and others bear testimony to the wonderful vis vitæ in these animals, and its energy in replacing parts, the deprivation of some of which must, it might have been previously thought, have been followed by immediate death. Spallanzani cut off one of a snail's horns: it began to bud again in about 25 days, and continued to grow till it was equal in length to the other. He removed part of the head: in course of time the part was renewed. Not that this was always the case in those instances where the entire head had been taken off; but even in these instances the snail often recovered, and at the end of a few months appeared with a new head in all respects equal to the old one. The snails so treated retired into their shells the moment the operation was over, and there they concealed themselves for weeks and even months, covering the aperture with the parchment-like secretion so well known to those who have seen this temporary sort of operculum. When forced out for examination at the end of 30 or 40 days, some appeared without any marks of renewal; but in others, especially in those cases which had the advantage of warm weather, there was a fleshy globule towards the middle of the trunk, soft, and whitish-ash in colour. At this period no organisation was detected in the globule; but in 8 or 10 days the globule became larger, rudiments of lips were seen, and of the smaller horns, mouth, and tongue. A membranaceous substance was observed fixed in the upper jaw: this proved to be the new tooth. The parts then became further developed and more conspicuous, occupying a greater space, and in two or three months the injury was so completely repaired that the lighter colour only of the new head served to distinguish it from the old one. These experiments were confirmed by others, by Gerardi among the rest.

Hybernation.—M. Gaspard remarks that in our temperate climate, as soon as the first autumnal chills are felt, about the commencement of October, generally, *Helix Pomatia* becomes indolent, loses its appetite, and associates in considerable numbers on hillocks, the banks of ditches, in thickets, hedges, and such places. In a day or two the animals cease feeding, expel the last contents of the intestines, and then hide themselves under moss, grass, dead leaves, or the like rubbish. Here each forms for itself, with the anterior part of its muscular foot, a cavity sufficiently large to contain at least its shell: this cavity it enlarges and excavates by turning itself round on every side, then raising itself against the sides of the cavity, and at last against the roof formed of moss or leaves, or a small quantity of earth brought there by its motions. When it has succeeded in bringing the aperture of the shell to nearly a horizontal position, it stops. The foot is soon contracted within the shell, the snail then expands, so as completely to cover the collar of the mantle, which is at this period very white; and then inspires a quantity of air, after which it closes the respiratory hole. When this is done, a fine transparent membrane is formed with its mucus, and interposed between the mantle and any extraneous substances lying above. The mantle then secretes a quantity of very white fluid over its whole surface, which sets uniformly, like plaster of Paris, and instantly forming a continuous covering about half a line thick. When this is hardened, the animal separates its mantle from it by another and stronger mucous secretion; and after a few hours, expelling a portion of the air it had previously inspired, it is enabled to shrink a little farther into the shell. It now forms another lamina of mucus, expires more air, and thus retires farther into the shell. In this way sometimes a fourth, fifth, and even sixth partition are formed, with intermediate cells filled with air. Such is M. Gaspard's account, but Mr. Bell remarks that it does not completely explain the manner in which the excavation is formed. "It is not by the pressure of the foot," says the last-named zoologist, "and the turning round of the shell, that this is principally effected. A large quantity of very viscid mucus is secreted on the under surface of the foot, to which a layer of earth or dead leaves adheres; this is turned on one side, and a fresh secretion being thrown out, the layer of earth mixed with mucus is left. The animal then takes another layer of earth on the bottom of the foot, turns it also to the part where he intends to form the wall of his habitation, and leaves it in the same manner, repeating the process until the cavity is sufficiently large, and thus making the sides smooth, even, and compact. In forming the dome or arch of the form, a similar method is used, the foot collecting on its under surface a quantity of earth; and the animal turning it upwards, leaves it by throwing out fresh mucus, and this is repeated until a perfect roof is formed. As I have very often watched this curious process, I am certain of the facts. On removing very carefully a portion of the roof soon after its completion, I was enabled to see the formation of the operculum. In about an hour, or even less, after the hybernaculum is covered in, the whole surface of the collar of the mantle instantaneously pours out the calcareous secretion in considerable quantity. This is at first as fluid as thick cream, but very soon acquires exactly the consistence of bird-lime, being excessively adhesive and tenacious; and in about an hour after it is poured out it is perfectly solid."

M. Gaspard states that the labour of each individual continues for about two or three days; but that the whole of the month of October is occupied by the general closing of the shells of the species. He adds that about the beginning of April the hybernation ceases. "The mode by which their escape from confinement is effected is simple and easily comprehended. The air which is contained in the different cells, and which had been expired on the animal withdrawing itself farther and farther into the shell after the formation of the operculum, is again inspired, and each separate membranous partition broken by the pressure of the hinder parts of the foot projected through the mantle. When it arrives at the calcareous operculum, the animal, making a last effort, bursts and detaches its most obtuse angle. Then insinuating by little and little the edge of the foot between the shell and the operculum, it forces the latter off, or breaks it away." ('Abstract of M. Gaspard's Memoir,' by T. Bell, Esq., Pres. L. S., 'Zoological Journal,' vol. i.)

We now proceed to give a sketch of the views of systematists with regard to this numerous tribe of animals.

The genus *Limax* (Slugs) is placed by Linnæus at the head of the *Mollusca* in his last edition of the 'Systema Naturæ,' and is numbered 312. The genus *Helix* is numbered 328, and consequently is widely separated by him from *Limax*. Both land and fresh-water testaceous gastropods were assembled under this genus, which stands between *Turbo* and *Nerita*.

Cuvier's Pulmonés Terrestres, or Terrestrial Pulmoniferous Mollusks, consisted of the Slugs, Limaces (*Limax* of Linnæus, including *Vaginulus*, *Testacella*, and *Parmacella*), the Escargots, (*Helix*), the Nonpareilles (*Clausilia*, Drap.), and the Agatines (*Achatina* Lam.).

Under *Helix* Cuvier arranges *Helix*, *Vitrina* (Helicolimax), *Bulimus*, *Pupa*, *Chondrus*, and *Succinea*.

Then comes the *Clausiliæ* (*Turbo perversus*, *T. bidens*, Linn., &c.).

The *Achatinæ*, including *Liguus* and *Polyphemus* of De Montfort, follow.

Lamarck defines his Colimacés to be Air-Breathing Trachelipods (Trachélipodes Aëricoles), provided with or deprived of an operculum, and having cylindraceous tentacles. Their shell he characterises as spirivalve, having no projecting parts on its exterior except the striæ and riblets (costules) of growth, and whose aperture is often recurved or reflected outwards. He divides this, the first family of his Phytiphagous (Plant-Eating) Trachelipods, into the following sections and genera:—

(*a*) Four Tentacles.

Helix, *Carocolla*, *Anostoma*, *Helicina*, *Pupa*, *Clausilia*, *Bulimus*, *Achatina*, *Succinea*.

(*b*) Two Tentacles.

Auricula and *Cyclostoma*.

M. de Férussac makes the fourth and fifth orders of Gastropods consist of the Pulmoniferous Gastropods without an operculum (Pulmonés sans Opercule), and the Pulmoniferous Gastropods with an operculum (Pulmonés Operculés).

The fourth order consists of the following sub-orders and genera:—

1st Sub-order. *Geophila*.

The 1st Family of this order consists of the different genera of Slugs, and of *Parmacella*, *Testacella*, &c.

The 2nd Family embraces the following genera of Snails:—*Helicarion*, *Helicolimax*, *Helix*, *Vertigo*, *Partula*.

2nd Sub-order. *Gehydrophila*.

3rd Family (Les Auricules), *Carychium*, *Scarabus*, *Auricula*, *Pyramidella*, *Tornatella*, *Pedipes*.

3rd Sub-order. *Hygrophila*.

This sub-order consists of the Limneans, or Water-Snails, such as *Limnæa*, *Planorbis*, &c.

The fifth order contains two families:—

1st. The Heliciniians (*Helicina*).
2nd. The Turbicinians (*Cyclostoma*).

The *Pulmobranchiata* form the first order of M. De Blainville's *Paracephalophora Monoica*, the second sub-class of the second class (*Parcephalophora*) of his *Malacozoa*.

M. De Blainville gives the following description of the *Pulmobranchiata*:—

Organs of respiration retiform or aërian, lining the roof and floor (plafond) of the cavity situated obliquely from left to right on the origin of the back of the animal, and communicating with the ambient fluid by a small rounded orifice, pierced on the right side of the swollen (renflé) border of the mantle. All these animals are more or less framed for breathing air; the greater part are terrestrial; some live on the banks of fresh waters, and others on the sea-banks (rivage des mers). None bury themselves in the mud, with the exception of the Limnaceans, during the rigorous season; all are phytiphagous. Some of them are known in all lands.

M. De Blainville divides the *Pulmobranchiata* into the following families and genera:—

1st Family, the Limnaceans. (*Limnæa*, *Physa*, *Planorbis*).
2nd Family, the Auriculaceans. (*Pedipes*, *Auricula*, *Pyramidella*.)
3rd Family, the Limacinians. (*Succinea*, *Bulimus*, *Achatina*, *Clausilia*, *Pupa*, *Tomogeres*, *Helix*, *Helicolimax*:—*Testacella*, *Parmacella*, *Limacella*, *Limax*, *Onchidium*.)

M. Latreille divides the Pulmonés, his fourth order of his first section of Gastropods (the Hermaphrodites), into the following families and genera:—

1st Family, Nudilimaces. (The Slugs, and *Parmacella*, *Testacella*, &c.)
2nd Family, Géocochlides. (*Helicarion*, *Vitrine* (Helicolimax), *Succinea*, *Helix*, *Carocolla*, *Anostoma*, *Pupa*, *Chondrus* (Grenaille), *Clausilia*, *Bulimus*, *Achatina*, *Vertigo*, *Partula*.)
3rd Family, Limuocochlides. (*Carychium*, *Scarabus*, *Auricula*, *Conovula*, *Cassidula*, *Limnæa*, *Physa*, *Planorbis*, *Ancylus*.)

The second section, the Diœcious Gastropods, consists of his fifth order (*Pneupomes*), and contains two families:—1st, the Helicinides (*Helicina*); 2nd, the Turbicines (*Cyclostoma*.)

M. Rang, in his 'Tableau Méthodique,' makes the Limaçons of Férussac (Trachélipodes Colimacés of Lamarck; Limaciués of De Blainville; Géocochlides of Latreille) the second family of the Pulmonés Inoperculés of Férussac (Pulmobranches of De Blainville).

M. Rang, following De Férussac, thus, with some slight alterations, defines and arranges the family:—Animal elongated, having the body distinct from the foot, and forming a twisted spiral, rarely furnished with a cuirass, but always showing a fleshy collar which closes the shell. Tentacula to the number of four, rarely two, the upper ocellated. Pulmonary cavity placed forward, and opening in the thickness of the collar. Organs of generation united in front; vent near the respiratory orifice. Shell always spiral, very variable in form, receiving the animal more or less completely. Terrestrial.

TETRACEROUS.

A. A cuirass and a collar.

Genera, *Vitrina*, Draparnaud. (*Helicolimax* and *Helicarion* of Férussac.)

B. A collar without a cuirass.

Genera, *Helix*, Müller (*Helix*, *Succinea*, *Amphibulimus*, *Acavus*, *Polydontes*, *Tomogeres*, *Anostoma*, *Carocolla*, *Bulimus*, *Achatina*, *Polyphemus*, *Pupa*, *Clausilia*, &c., &c., Fér.)

(†) *Redundantes.*

‡ *Volutatæ*:—*Helicoides.*

I. Sub-genus. *Helicophanta*, Férussac.
Peristome simple.
1st Group. *Vitrinoides*, Fér. (*Helix brevipes*, &c.).
Peristome thickened and subreflected.
2nd Group. *Vesiculæ*, Fér. (*H. Cafra*, &c.).
‡‡ *Evolutatæ:—Cochloides.*

II. Sub-genus. *Cochlohydra*, Fér. (*Succinea*, Drap.; *Amphibulima*, Lam.; *Amphibulimus*, Montf.).
(††) *Inclusæ.*
‡ *Volutatæ:—Helicoides.*

III. Sub-genus. *Helicogena*, Fér. (*Helix*, Linn.).
Columella solid and twisted.
1st Group. *Columellatæ.*
a. Peristome simple. (*Helix naticoides*, &c.)
β. Peristome reflected or thickened. (*Helix Jamaicensis*, &c.)
Shell perforated.
2nd Group. *Perforatæ*, Fér. (*Helix ligata*, &c.).
Shell umbilicated; umbilicus entirely covered.
a. Shell globulose or subtrochoid.
3rd Group. *Acavi* (*Helix aspersa*, &c.).
Shell imperforate.
β. Shell somewhat depressed (surbaissée).
4th Group. *Imperforatæ*, Fér.
1. Mouth rounded; peristome open. (*Helix guttata*, &c.)
2. Mouth sinuous; peristome strongly reflected. (*Helix, squamosa*, &c.)
3. Mouth turning over (versante); columellar border sinuous, flattened, and subdentated. (*Helix cognata*, &c.)

IV. Sub-genus. *Helicodonta*, Fér. (*Tomogeres*, Montf.; *Anostoma*, Lam.).
1st Group. The Grimaces, *Personatæ*, Fér. (*Helix dentiens*, &c.).
Aperture defended by one or more elongated and internal laminæ.
2nd Group. *Lamellatæ*, Fér.
* Many laminæ. (*Helix carabinata*, &c.)
** A single lamina. (*Helix labyrinthica.*)
Peristome furnished with large teeth, one of which at the base of the columella forms a gutter.
3rd Group. *Maxillatæ*, *Polydontes*, Montf. (*Helix imperator*, &c.).
Mouth reversed, furnished with elevated folds, the impressions of which are visible outwards.
4th Group. Anostomes, Fér.; *Anostoma* (*Helix ringens*, &c.), *Streptaxis*, Gray.
Interior border of the aperture furnished near the peristome with elevated longitudinal folds, the impressions of which are visible outwards.
5th Group. *Impressæ* (*Helix cepa*, &c.).

V. Sub-genus. *Helicigona*, Fér.
Umbilicus covered.
1st Group. *Carocolla*, Montf. (*Helix angistoma*, &c.).
Umbilicus masked or visible.
2nd Group. *Vortices*, Ok. (*Helix marginata*, &c.).

VI. Sub-genus. *Helicella*, Fér.
Peristome reflected.
1st Group. Lomastomes, *Lomastoma*, Fér. (*Helix carascalensis*, &c.).
Peristome simple.
2nd Group. Aplostomes, *Aplostoma*, Fér.
* *Verticilli.* (*Helix lineata*, &c.)
** *Hyalinæ.* (*Helix olivetorum*, &c.)
*** *Fasciatæ.* (*Helix candida*, &c.)
Peristome bordered.
a. Shell horn colour or brown, nearly unicoloured, rarely fasciated, often hairy; peristome rather spread; epidermis caducous.
3rd Group. *Hygromanes*, Fér. (*Helix cinctella*, &c.)
β. Shell white or reddish, very much ornamented with bands or small vivid-coloured lines; epidermis insensible, never hairy; sometimes carinated; peristome bordered but not spread.
4th Group. *Heliomanes*, Fér.
* Shell somewhat depressed or globulose. (*Helix groyana*, &c.)
** Shell trochoid and a little carinated. (*Helix pyramidata*, &c.)

VII. Sub-genus. *Helicostyla*, Fér.
Columella straight; peristome simple; shell subdepressed.
1st Group. Aplostomes, *Aplostoma*, Fér. (*Helix misella*, &c.).
Columella twisted, truncated as it were at its base, or furnished with an internal spiral rib, forming a gutter, and appearing under the form of a tooth or callosity.
2nd Group. *Canaliculata*, Fér. (*Helix delicatula*, &c.).
Columella flattened, without either tooth or lamina, forming a sort of gutter at its intersection with the penultimate whorl; peristome reflected.
3rd Group. *Marginatæ*, Fér. (*Helix studeriana*, &c.).

‡‡ *Evolutatæ.—Cochloides.*
* Mouth generally toothless.
Columella solid.
a. En filet, not truncated at its base.

VIII. Sub-genus. *Cochlostyla*, Fér.
Peristome reflected.
1st Group. Lomastomes, Fér. (*Helix metaformis*, &c.).
Peristome simple.
2nd Group. Aplostomes, Fér. (*Helix Dufresnii*, &c.).
β. Columella solid, flattened, and truncated at its base.
† Shell conic, or very ventricose; aperture enlarged.

IX. Sub-genus. *Cochlitoma*, Fér.
Shell conical; mouth short; anterior border advanced.
1st Group. The Rubans, Fér. (*Helix exarata*, &c.).
Shell ventricose; mouth very large; external border in a vertical direction.
2nd Group. *Achatinæ.*
†† Shell ovoid or turriculated; mouth elongated and narrow.

X. Sub-genus. *Cochlicopa*, Fér.
Shell ovoid; mouth long; exterior border in a vertical direction.
1st Group. The Polyphemes, Montf. (*Helix Priamus*, &c.).
Shell turriculated; mouth short; external border a little advanced.
2nd Group. Styloides, Fér. (*Helix fulminea*, &c.).
Shell perforated or umbilicated; umbilicus masked or uncovered; peristome simple.
a. Whorls of the spire equalised; the last whorl shorter than the others united.

XI. Sub-genus. *Cochlicella*, Fér.
Only group, *Turritæ*, Fér. (*Helix conoidea*, &c.).
β. Last whorl of the spire generally larger and longer than the others united.

XII. Sub-genus. *Cochlogena*, Fér.
† Peristome simple or thickened, but with sharp edges.
a. Shell umbilicated; columella straight.
1st Group. *Umbilicatæ*, Fér. (*Helix flammata*, &c.).
β. Shell perforated; columella twisted.
2nd Group. *Perforatæ*, Fér.
* Shell oblong. (*Helix fasciolata*, &c.)
** Shell ovoid. (*Helix costulata*, &c.)
†† Peristome reflected or dentated.
Mouth crescent-shaped, without either teeth or folds; peristome reflected and regular; columella twisted, perforated; last whorl of the spire sometimes shorter than the others united.
3rd Group. Lomastomes, Fér.
* Last whorl of the spire larger and longer than the others united, shell ornamented with vivid colours. (*Helix Favannii*, &c.)
** Last whorl shorter and less than the others united; shell unicoloured. (*Helix Beticata*, &c.)
Mouth short, crescent-shaped; peristome simple or thickened and regular; columella twisted, more or less projecting and bent, or furnished with a plait which turns upon it and makes it appear subtruncated; umbilicus masked or exactly closed; last whorl of the spire sometimes shorter than the others united.
4th Group. Helicteres, Fér. (*Achatinella*, Sw.).
* Shell coniform. (*Helix vulpina*, &c.)
** Shell turriculated. (*Helix turritella*, &c.)
*** Shell ovoid. (*Helix tristis*, &c.)
Mouth angular at its extremities, or overlaid superiorly, often narrowed by the sinuosities of the external border; columella large, more or less spiral, and forming a plait more or less projecting in the aperture. Peristome thick and reflected; last whorl of the spire longer and more convex than the others united.
5th Group. Stomotoides, Fér. (*Helix Auris Leporis*, &c.).
Mouth crescent-shaped, rather angular at its extremities, most frequently furnished with short teeth at the peristome, which is bordered or a little opened out or reflected; never any laminæ; columella twisted, hollow, flattened at its base, or forming a protuberance; generally perforated.
6th Group. Dontostomes, Fér.
(*) Last whorl of the spire larger and longer than the others united. (*Helix Auris Bovis*, &c.)

(**) Whorls of the spire equalised, often pressed and narrow. (*Helix turgnus*, &c.)

(***). Mouth generally furnished with teeth or laminæ.

1. Without gutters; peristome generally not continuous.

XIII. Sub-genus. *Cochlodonta*, Fér.

Shell cylindrical.

1st Group. *Pupa*, Fér. (*Helix*, *Uva*, &c.).

Shell fusiform.

2nd Group. Cereales, Fér. (*Helix Moricandi*, &c.).

2. One or two gutters; peristome generally continuous.

XIV. Sub-genus. *Cochlodina*, Fér.

* Shell right-handed.

† Mouth without teeth or laminæ.

Peristome not continuous.

1st Group. Pupoides, Fér. (*Helix Carinula*, &c.).

Peristome continuous.

2nd Group. Tracheloides, Fér. (*Helix Sloanii*, &c.).

†† Mouth armed with great plaits or elongated teeth. (*Helix Gargantua*.)

** Shell left-handed.

Mouth without any lamina. (*Balea*, Gray.)

3rd Group. Anomales, Fér. (*Helix perversa*, &c.).

Mouth armed (with laminæ, one of which performs the part of an elastic operculum).

4th Group. *Clausilia*, Draparnand (*Helix torticollis*, &c.).

DICEROUS.

Genera. *Vertigo* (Muller).—Animal elongated, demi-cylindrical, with a rather large spiral body and a collar closing the shell; only two tentacles, long, obconical, retractile, rounded at their extremity; orifice of the pulmonary cavity upon the collar and to the right, approximated by that of the vent; organs of generation united and showing their orifice near the right tentacle. Oviparous.

Shell cylindrical, very spiral; aperture straight, in the direction of the axis, short, often dentated; peristome often sinuous and reflected; right or left handed (dextral or sinistral).

Partula (Fér).—Animal elongated, demi-cylindrical, with a rather large spiral body; a collar closing the shell and carrying the orifice of the pulmonary cavity on the right and at the external angle of the aperture; two tentacles only, cylindrical and retractile, ocellated on their summit; organs of generation united (?), showing their orifice near the right tentacle. Ovoviviparous.

Shell oval, pointed; spire conical, last whorl convex and longer than the others united, whorls of the spire 4 to 6; aperture straight in the direction of the axis, short, sometimes dentated, or furnished with elevated laminæ; peristome commonly very much reflected, with the edge in the same vertical plane; columellar side or lip callous at its base; dextral or sinistral.

M. Rang's third family of Inoperculate Pulmoniferous Mollusks consists of the Auricules of Férussac (*Auriculacea* of De Blainville; *Auriculidæ* of Gray; Limnocochlides (à collier) of Latreille). These are either terrestrial or marine, and one has been announced as fluviatile. They comprehend the genera *Carychium*, *Auricula* (*Auricula* and *Conovula*, Lam.; *Melampus*, Montf.), *Pedipes*, and *Scarabus*. To these may be added *Chilina*, Gray; *Acmea*, Hartmann; and *Marinula*, King. None of these can be considered to belong to the *Helicidæ*, properly so called.

The fourth family, the Limneans of Lamarck (*Limnacea* of De Blainville; Limnocochlides (without a collar) of Latreille), is entirely fluviatile, consisting of the genera *Planorbis*, *Limnæa*, or, as Lamarck writes it, *Lymnæa*, and *Physa*, *Aplexus*, Flem., and *Amphipeplea*, Nils. This family cannot be considered as belonging to the *Helicidæ*, properly so called.

The order Pulmonés Operculés of Férussac (Trachélipodes Colimacés of Lamarck; Pectinibranches of Cuvier; Chismobranches Cricostomes of De Blainville; Pneupomes of Latreille), is thus defined by M. Rang:—

Animal furnished with a foot fitted for creeping, no branchiæ, but a pulmonary cavity receiving the ambient fluid by a large opening placed above the head; tentacles two in number; organs of generation on different individuals.

Shell external, complete, spiral, globulose, or conical. Operculum calcareous or horny. All terrestrial.

M. Rang observes that this order was established by M. De Férussac at the expense of the *Pectinibranchiata* of M. Cuvier, and for the genus *Cyclostoma* only; but afterwards M. De Férussac added to it the genus *Helicina*, which was at one time confounded with the Colimacés of Lamarck. At present, continues M. Rang, the Operculated Pulmonians establish very well the passage from the Pulmonians to the Pectinibranchians, because they are related to the first with reference to the organs of respiration, and to the second with reference to the separation of the sexes.

1st Family.

Helicines of Férussac (Helicinides of Latreille).

Animal furnished with a collar, and two filiform tentacles carrying the eyes at their external base upon tubercles.

Shell more or less globulose, with a demi-oval aperture, and the columella transversal and delicate. Operculum horny, sometimes calcareous externally.

M. Rang observes that M. De Férussac established the two families of Helicinians and Tubicinians for two genera nearly approximated, and that it would be perhaps more convenient to unite them, the difference between them being really not very remarkable, except in their testaceous envelope; but Mr. Gray has pointed out that one has an annular and the other a spiral operculum. See also the Rev. M. G. Berkeley's 'Memoir' hereinafter alluded to.

Genera. *Helicina*, Lam. (*Oligyra*, Say; *Ampullina*, De Blainville).—Animal very spiral, furnished with a proboscidiform head and a bilabiated muzzle; tentacles filiform, carrying the eyes at their extended base on tubercles; foot short, rounded, with a transverse anterior furrow; pulmonary cavity opening in front of the mantle by means of a large transversal slit.

Shell sub-globulose or conoid, a little depressed, not umbilicated, with a low spire, an aperture demi-oval, or nearly oval, the peristome reflected into a border (bourrelet), the left lip enlarged upon the umbilicus, which it entirely covers; columella transversal and planulate. Operculum horny, sometimes slightly calcareous externally; lines of growth concentric.

Helicina was established by Lamarck, and placed by him among his Colimacés. M. Rang is of opinion that the genera *Ampullina* of De Blainville and *Oligyra* of Say ought to be referred to *Helicina*, an opinion which seems to be in unison with that of M. De Blainville himself, who has arranged both these genera under *Helicina* in his 'Manual.' Dr. Gray has published a valuable monograph of the genus in the first volume of the 'Zoological Journal,' and the late Rev. Lansdown Guilding has recorded some other species, with plates of the animal, in the same work, vol. iii.

The definition of M. De Férussac's second family, the Turbicinians, is—Animal without a collar, provided with two tentacles, ocellated at their external base.

Shell conoid, more or less elevated, with a roundish aperture and continuous borders. Operculum calcareous.

Cyclostoma (Lamarck).—Animal very spiral, furnished with a proboscidiform head, which bears two cylindraceous tentacles, convex, or swollen at their summit, contractile, and ocellated at their external base; foot elongated and oblong; pulmonary cavity communicating with the exterior by means of a large slit at the superior and anterior part of the mantle; position of the male organ indicated by a tentaculiform appendage situated at the right side.

Shell conoid, discoid, or turriculated, more or less elevated, with a sharp or mammillated summit, having all the whorls rounded; aperture round, with continuous and reflected borders. Operculum calcareous, with concentric lines, summit subcentral. (Rang.)

The species of *Cyclostoma* are very numerous, and many of them are very beautiful. Mr. G. B. Sowerby has added considerably to the catalogue. They are principally the inhabitants of temperate or warm climates; there is one English species, *C. elegans*. The reader will find an excellent paper on the anatomy of this species, by the Rev. M. G. Berkeley, in the 4th vol. of the 'Zoological Journal.'

M. Rang adds to these Pulmoniferous Operculated Mollusks, the fossil genus—

Ferussina, Grateloup (*Strophostoma*, Deshayes).—Animal unknown. Shell oval, subglobulose; aperture round, bordered, oblique, simple, toothless, turned over from the side of the spire; umbilicus more or less large. Operculum? (Rang.)

M. Rang remarks that M. Grateloup established this genus for a fossil shell from Dax, which seems at the first view very near to *Anostoma*, but which M. Grateloup, from the examination of its aperture, considers as more approximate to *Cyclostoma*. M. Rang states that he participates in this opinion, which the knowledge of the operculum can alone confirm; and he goes on to observe that M. Deshayes, doubtless not having seen the publication of this genus in the first number of the 'Bulletin of the Linnean Society of Bordeaux,' had subsequently published it under the name of *Strophostoma*. Three or four species are known.

Some may have doubts as to the propriety of placing these operculated pulmoniferous terrestrial mollusks under the family *Helicidæ*. But we believe, notwithstanding the difference of the operculum, that their general organisation will warrant their being so placed; and that the terrestrial shell-snails may without violence be placed in one great family, which may be subdivided into the *Helicidæ* without opercula, and the *Helicidæ* with opercula.

Before we conclude this part of the subject, we must draw the reader's attention to the following arrangement proposed by Dr. J. E. Gray:—

Terrestrial.

Tentacles retractile. Eyes pedicillate.

Gasteropodous. *Limacidæ*.

Trachelipodous. *Helicidæ*.

Aquatic.

Tentacles contractile. Eyes sessile.

Trachelipodous (mantle thick-edged). *Auriculidæ.*
Trachelipodous (mantle thin-edged). *Limnæadæ.*
Gasteropodous (mantle shield-like). *Onchidiadæ.*

With regard to the arrangement, Dr. Gray has since corrected that of the first division, because the distinction between the first two families, though it is that used by Lamarck, Cuvier, and others, is, in his opinion, artificial, and of little importance; and the knowledge which he has since acquired of the animals of several genera which were before unknown, have shown him that the character which De Férussac pointed out as the distinction between *Arion* and *Limax* (but which many succeeding naturalists have considered of little importance) is even of more importance than was accorded to it by De Férussac, affording a good character for dividing the Land Pulmonobranchous *Mollusca* into two families. Thus, he observes, the *Arionidæ* are characterised by having a gland on the end of the tail (which, in the gasteropodous genera, is produced beyond the mantle), and they have the orifices of the organs of generation on the right side immediately under the respiratory hole; whilst in *Helicidæ* there is no gland on the end of the tail, and the orifice above referred to is just behind the base of the upper right tentacle. There is also, he states, an important difference in the nervous system between the two families: in the first, the under part of the infra-gular ganglion is 6-lobed, whilst it is only 4-lobed in the *Limacidæ*. Dr. Gray is further of opinion that at present only a few genera, as *Arion* and *Helicarion*, Fér., *Nanina*, Gray, and *Stenopus*, Guilding, can be referred with certainty to the *Arionidæ;* but he thinks it very probable that, when the animals of other shells are known, many of them may be found to belong to that family.

Geographical Distribution and Habits.—The *Helicidæ* are most widely diffused over the surface of the earth; scarcely any countries but those where the climate is surpassingly rigorous are without some species of the family. Many of the shells are strikingly beautiful in form and colour, and these are mostly the inhabitants of intertropical countries. Some of the genera (*Achatina*, for instance) attain a very large size, and lay eggs in proportion. *Helix aspersa*, the common Garden Snail, is distributed over a large portion of the globe. It is found, for instance, at the foot of Chimboraço, in the forests of Guyana and Brazil, and on all the coasts of the Mediterranean in Europe, Asia, and Africa. *Helix Pomatia* has been naturalised with us, and is still found in some countries. The first importation is attributed by some to Sir Kenelm Digby. Merrett mentions it as a British inhabitant before his time. A moist and rather warm state of the atmosphere seems most congenial to this family. To avoid great dry heat they get under stones, under old trunks of trees, leaves, &c., and some of the species will burrow into the earth for protection against it. A shower will bring them forth in such numbers sometimes, the smaller species especially, as to induce the belief in some cases that it has been raining snails. Most of the species hybernate.

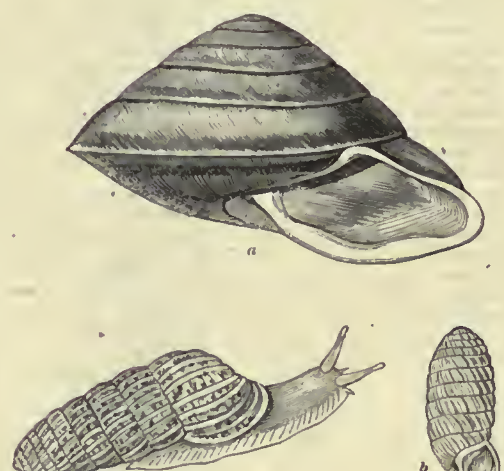
Utility to Man.—The *Helicidæ*, from their voracity, are very injurious to the agriculturist and horticulturist; but there can be no doubt that the larger species are good food. We know that they were a favourite dish with the Romans, who had their 'Cochlearia,' where they were regularly fattened with new wine boiled down and meal (sapa et farre, &c.) (Pliny, 'Hist.,' lib. ix. c. 56.) *Helix Pomatia* is used as food in many parts of Europe during Lent, and the snails are kept in an escargotoire (snaillery), which is generally a large place boarded in, having the floor covered half a foot deep with herbs, where the animals fatten. Many are familiar with the passage in Pliny (loc. cit.), who, on the authority of Varro, relates the incredible size to which the art of fattening had brought the snails. There must, one should think, be some mistake in the text, which says—"Cujus artis gloria in eam magnitudinem perducta sit, ut octoginta quadrantes caperent singularum calices." Pennant, referring to this and to Varro ('De Re Rusticâ'), says, "If we should credit Varro, they grew so large that the shells of some would hold ten quarts! People need not admire the temperance of the supper of the younger Pliny ('Epist.,' lib. i.; Epist., xv.), which consisted of only a lettuce a-piece, three snails, two eggs, a barley cake, sweet wine and snow, in case his snails bore any proportion to those of Hirpinus."

The following cuts, and those given under Bulimulus and Bulimus, will afford the reader an idea of some of the forms of the *Helicidæ:* —*Partula, Anostoma, Carocolla, Clausilia, Streptaxis, Balea, Vertigo, Cyclostoma.*

Partula Australis.

Anostoma depressum.

Carocolla Lamarckii.



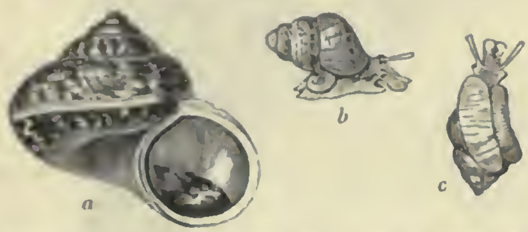
a, Carocolla albilabris; b, Pupa Uva; c, Pupa Chrysalis, with the animal.

a, Clausilia Macascarensis; b, the same, broken, to show the clausium, *c.*

Streptaxis contusa.

Balea fragilis, magnified.

a, *Vertigo pusilla*, *b*, another species of *Vertigo*, with the animal; both magnified.



a, *Cyclostoma involvulus*; *b*, *Cyclostoma elegans*, with the animal; *c*, *Cyclostoma elegans*; showing the alternate contraction of the two sides of the animal's foot.

The following is a list of the genera and species of British *Helicidæ* given in Forbes and Hanley's 'British Mollusca:'—

Vitrina pellucida.
Zonites cellarius.
Z. alliarius.
Z. nitidulus.
Z. purus.
Z. radiatulus.
Z. nitidus.
Z. excavatus.
Z. crystallinus.
Helix aperta.
H. Pomatia.
H. Arbustorum.
H. Cantiana.
H. Carthusiana.
H. nemoralis.
H. Pisana.
H. virgata.
H. caperata.
H. ericetorum.
H. obvoluta.
H. lapicida.
H. rufescens.
H. hispida.
H. revelata.
H. sericea.
H. lamellata.
H. aculeata.
H. fulva.
H. fusca.
H. pulchella.
H. rotundata.
H. umbilicata.
H. pygmæa.
Bulimus acutus.
B. Lackhamensis.
B. obscurus.
Pupa umbilicata.
P. Muscorum.
P. Anglica.
P. secale.
P. edentula.
P. minutissima.
P. pygmæa.
P. substriata.
P. antivertigo.
P. pusilla.
P. Venetzii.
Balea fragilis.
Clausilia laminata.
C. biplicata.
C. plicatula.
C. nigricans.
Zua lubrica.
Azeca tridens.
Succinea putris.
S. oblonga.

Fossil Helicidæ.—Fossil species of *Helicidæ* are by no means rare. Thus M. Deshayes enumerates thirty-five species of *Helix*, two of *Anostoma*, one of *Helicina*, three of *Pupa*, two of *Clausilia*, three of *Bulimus*, three of *Achatina*, seven of *Pedipes*, and six of *Cyclostoma*, &c., as fossil (tertiary), mostly in the Pliocene period of Lyell, and many of them as both living and fossil. Other species have also been found fossil.

HELICINA. [HELICIDÆ.]

HELICOLIMAX. [HELICIDÆ.]

HELICOSTEGA. [FORAMINIFERA.]

HELICTIS (Gray), a genus of *Mammalia* belonging to the order *Carnivora*. The species inhabit eastern Asia, and have the general appearance and colouring of *Mydaus*, combined with a dentition resembling that of *Gulo* or *Mustela*, but differing from both the latter genera in the large internal central lobe of the upper carnivorous tooth. The genus is thus characterised by Dr. Gray:—

Incisors (primores) $\frac{6}{6}$; canines (laniarii) $\frac{1-1}{1-1}$; molars $\frac{5-6}{5-6}$.

Head elongated. Feet short; soles of the feet nearly naked to the heel; toes 5—5; claws strong, the anterior ones long and compressed. Tail cylindrical and moderate.

There are two species, *H. moschata* from China, and *H. Nepalensis* from Nepaul. [MUSTELIDÆ.]

HELIOPORA, a genus of stony *Polypiaria*, established by De Blainville, from observations of Messrs. Quoy and Gaimard on a recent species called by Lamarck *Pocillopora cærulea.*

It is characterised as follows:—Animal short and cylindrical, provided with a simple circle of thick tentacula, 15 or 16 in number, contained in vertical or diverging cylindrical cells; cells immersed, internally crenulated by imperfect radiating lamellæ, united into a calcareous mass, which is regularly porous in the intervals of the cells. The coral is found attached to various bodies.

Three recent species are mentioned by De Blainville, all from warm seas. One of the fossil species (*Heliopora porosa*, De Bl.; *H. interstincta*, Bronn) abounds in strata of the Silurian system; others occur in the chalk and in tertiary deposits. ('Manuel d'Actinologie.')

HELIORNIS, Bonaterre's name for a genus of Water-Birds (Grébifoulques of Buffon), which have lobated feet like the Coots and Grebes, but with a greater development of tail, and they have sharper claws. [PODOA.]

HELIOTROPE. [BLOOD-STONE.]

HELIOTROPIUM (from ἥλιος, the sun, and τροπή, a turning), a genus of Plants belonging to the natural order *Ehretiaceæ*. It has a salver-shaped corolla, with the throat usually naked, but in some species bearded; the segments of the limb furnished with a single fold or a tooth between each; the stigma sub-conical; the carpels 4, 1-celled, combined, closed at the base, without any manifest receptacle. The species are annual or shrubby plants, with alternate leaves, and circinate spikes of small blue or white flowers.

H. Peruvianum, Peruvian Heliotrope, or Turnsole, has a shrubby stem, petiolate oblong-lanceolate wrinkled leaves, terminal branched spikes; the tube of the corolla hardly the length of the calyx. The mouth of the corolla is intersected with five plicatures of a purple-lilac colour, with a greenish throat. It is a shrub, growing one or two feet high, and is much cultivated on account of the scent of its flowers, which resembles very much the smell of the vanilla or cherry pie. It is a native of Peru.

H. Europæum, the European Turnsole or Heliotrope, has an herbaceous erect stem, with ovate flat-lined finely tomentose leaves, the lateral spikes solitary, the terminal ones conjugate, the calyx spreading in the fruit-bearing state. It is a native of the south of Europe and the regions of the Caucasus. The flowers are sweet-scented. The leaves were formerly used medicinally.

H. villosum has an herbaceous erect very villous stem, with ovate, flat, villous leaves; the spikes lateral, terminal, solitary, and conjugate; the corollas large; the calyx spreading in the fruit-bearing state. It is a native of Greece and of the islands of the Archipelago. It has large white corollas with a yellow throat. This appears to be the Ἡλιοτρόπιον μέγα of Dioscorides (iv. 190) and the *H. supinum*, the Ἡλιοτρόπιον μικρόν.

Upwards of 80 species of this genus have been enumerated. They are natives of the warmer parts of Europe, Asia, Africa, and America, and are found in Australia. They do not possess any active properties.

Many other species besides those here described have sweet-scented flowers, and are cultivated on that account. Some of them are consumed in large quantities by perfumers for the sake of their volatile oil. They are astringent and also mucilaginous, and poultices made of the leaves have been applied to cancerous and scrofulous sores. It is supposed that the plant used for the cure of warts, and called *Verrucaria*, belonged to this genus. In their cultivation the shrubby and perennial kinds will be found to thrive in any kind of rich light soil, and cuttings will root readily in sand under a hand-glass. The European annual species may be propagated from seed sown in an open border, whilst the tropical annual species must be sown upon a hot-bed before being planted out.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*; Fraas, *Synopsis Plant. Floræ Classicæ.*)

HELIX (Linnæus), a genus of Pulmoniferous *Mollusca*, embracing the various forms of animals called Snails. The following are the characters of this genus:—Shell spiral, opaque, or translucent, solid or thin, more or less globose, in some discoid, smooth or sculptured; surface variously coloured, but seldom covered with a polished epidermis; mouth lunated, thickened within, simple or toothed; peristome frequently reflexed. Animal moderately large in proportion to shell; head with four developed tentacles; mantle not reflected on shell; tail lanceolate and never truncate; foot often ample; tongue with the edge teeth serrate. (Forbes and Hanley.)

The species of this genus, at the approach of winter, or in very dry weather in summer, recede into their shell, and secrete a quantity of mucus, which forms a covering over the aperture. This thickened matter, which the animal has the power of throwing off by producing fresh mucus within, is called an 'epiphragm.' The power of forming this kind of epiphragm was supposed to be confined to the Land *Mollusca*, but it is now known that the Pond-Snails (*Limneus* and *Planorbis*), when left dry by the evaporation of the water in which they live, have the same power of thickening the edge of the lip, and forming a distinct epiphragm. [HELICIDÆ.] We shall now subjoin the descriptions of some of the most common British species.

H. aspersa, the Common Snail. The shell is obliquely subglobose, beneath the epidermis pale fawn-coloured, with four (usually interrupted) chocolate-brown bands. This is the commonest and one of the handsomest of British snails. It is found wherever there is vegetation, but is more especially addicted to gardens. This snail is collected and sold in Covent-Garden and other markets as a cure for diseases of the chest. It is prepared by being boiled in milk. Large quantities are collected, and sent every year from this country to the United States of America, where they are said to be regarded as delicacies. They are packed in casks, in which way they travel very well, as they fix themselves on one another around the circumference of the cask, leaving a vacant space in the centre. At Newcastle-upon-Tyne the glassmen hold a snail feast once a year, when large quantities of this species of snail are consumed.

H. Pomatia, the Edible Roman Snail, or Large-Shelled Snail. The shell is solid globose, coarsely wrinkled lengthways, most minutely striated in a spiral direction; pale-tawny, with rufous bands. The animal is of a general brownish-gray, speckled with whitish and brown granulations.

This species in Great Britain is nearly confined to the chalk districts of the south of England. It has been found as far north as Wiltshire. There is a notion prevalent that it is not an original inhabitant of England, but that it was introduced by the Romans, who were famous for its culture. [HELICIDÆ.] There is no evidence to prove this, and it is found in Sweden, where the climate is much more rigorous than our own. Its great necessity is chalk, and where this substance prevails it is found. This snail is eaten in this country. Lister says, "They are boiled in spring-water, and, when seasoned with oil, salt, and pepper, make a dainty dish." Dr. Turton says, "After the animal has been extracted there remains at the bottom of the shell a glairy transparent matter, which affords one of the best and most durable cements in nature, resisting every degree of heat and moisture."

H. Arbustorum, Shrub-Snail. Shell brown, closely marbled, with small linear paler markings, usually one-banded; outer lip white and reflected. This snail is very generally distributed in woods and in damp gardens throughout the British Isles. It is remarkable for being found higher up the sides of mountains than any other British species. In the Alps it nearly approaches the snow-line.

H. Cantiana, the Kentish Snail. Shell depressed, globular, semi-transparent, bald, open; adult, pallid above, rufous below, and towards the lip, periphery not angulated; outer lip edged within; umbilicus moderately large. It is chiefly found in England in localities south of the Thames, where it occurs amongst brambles and by hedges throughout the whole district. It has been taken in the west of England.

H. Carthusiana, Gibbs's Snail. Shell rather small, depressed, whitish, bald; mouth margined within by a milk-white rib; umbilicus minute. This shell is only found on the chalk downs of Kent and Surrey. It was discovered by Mr. Gibbs in 1814.

H. nemoralis, the Garden, Girdled, or Brown Snail. The shell is depressed globose, imperforated when adult, with or without coloured bands, not marbled; outer lip reflected; pillar lip callous, retiring.

The species thus characterised embraces the *H. hortensis* and *H. hybrida* of other naturalists. Messrs. Forbes and Hanley, in the 'British Mollusca,' say, "We have followed Pfeiffer, Deshayes, &c., in reuniting *hortensis* and *hybrida* to the typical *nemoralis*, not being able to detect any peculiarity in individuals of the dark-mouthed form which is not likewise represented in the white-mouthed variety, between which extremes the *hybrida* is the connecting link.

H. virgata, Zoned Snail. Shell depressed turbinate, smooth, banded; bands not linear; upper whorls for the most part with only a single zone above the suture; mouth usually livid red; outer lip edged internally.

This species is found in prodigious numbers in many chalk and limestone districts. It is also found in larger numbers near the sea. On the chalk off the coast of Kent it occurs frequently in great profusion. It is widely diffused and is found in the same localities throughout central and southern Europe.

H. ericetorum, Heath-Snail. Shell depressed, semi-transparent, not regularly striated, banded with brownish-yellow; mouth small, outer lip acute, not edged with colouring matter; umbilical region capacious.

This snail prefers calcareous soils, and is often abundant on sandy soils near the sea. It is very widely diffused through the British Isles, ranging to the north of Scotland.

H. hispida, Bristly-Snail. Shell reddish horn-coloured, more or less depressed; outer lip edged below, with white internally; umbilicus moderately large.

The species *H. depilata* and *H. concinna* may be regarded as varieties of this species. It is an abundant species, on waste places, by hedges, and under stones in all parts of the British Isles.

H. sericea, Silky Snail. Shell depressed, globular, pallid, transparent, closely downy; spire more or less raised; umbilicus decidedly small. It is widely distributed, and appears to be most abundant in the neighbourhood of wet mossy rocks. "It is more frequent in the west and south than elsewhere." (Forbes and Hanley.)

H. fusca, Brown Snail. Shell depressed, subglobular, almost imperforated, not minute, transparent, umber-coloured, wrinkled; outer lip acute.

It appears that this delicate and well-marked species is peculiar to the British Islands. It is found in bushy places in many parts of England and Ireland.

H. pulchella, White Snail. Shell depressed, minute, white; mouth nearly circular, its edge flatly reflected. The animal is milky white. It is very generally found in Great Britain. It lives under stones, in walls, and on the ground often in dampish places. A ribbed variety has been described under the name of *H. costata*.

H. umbilicata, Open Snail. Shell small, dark brown, unpolished, merely wrinkled; whorls five, of slow increase; umbilicus large; mouth small; outer lip acute. The animal is dusky, nearly black. It is the *Zonites umbilicata* of Gray. It is abundant in many localities on the faces of rocks and walls, or under stones in dry places.

H. pygmæa, Pigmy Snail, resembles the last, but smaller, paler, more transparent, more compressed, composed of four turns at most; the mouth less circular. It is found in wet places, among dead leaves in ditches, and by springs. It is often overlooked on account of its minuteness.

For a list of species of *Helix* found in Great Britain see HELICIDÆ.

(Forbes and Hanley, *A History of the British Mollusca;* Dr. Turton, *A Manual of the Land and Fresh-Water Shells*, edited by Dr. J. E. Gray.)

HELLEBORE, BLACK. [HELLEBORUS.]

HELLEBORE, WHITE. [VERATRUM.]

HELLEBORUS, a genus of Plants belonging to the natural order *Ranunculaceæ*. It has 5 permanent sepals, rounded, blunt, large, often herbaceous; petals 8 or 10, very short, tubular, nectariferous, narrowed to the base; stamens 30 to 60; stigmas terminal, orbicular; capsules leathery; seeds arranged in two rows, elliptical, umbilicated.

H. niger, Christmas Rose, is found in the shady woods of the lower mountains of many parts of Europe. The plant is herbaceous, with a perennial blackish-coloured rhizoma, tuberculated and scaly, from which descend numerous thickish radicles. The leaves are all radical, with long cylindrical and spotted foot-stalks, pedately divided, with the lobes from 7 to 9, oblong-lanceolate, sometimes cuneate-obovate, largely serrated towards their apices, and arranged apparently along the forked terminations of the petiole; they are stiff, almost leathery, of a dirty green colour, smooth above, paler and reticulate beneath. The scape is shorter than the petiole, furnished with two or three oval bracts, often simple and single-flowered, sometimes forked and 2-flowered. The flower is large, terminal, white, with a tinge of pink, the most conspicuous part being the petaloid calyx. Of this the sepals are 5, ovate and permanent; the petals, 8 to 10, are small, greenish-coloured, tubular, tapering towards the base, with the limb tubular, bilabiate, and their outer margins terminated in a tongue-shaped lip; stamens numerous, longer than the petals; ovaries 6 to 8; stigmas terminal, orbiculate; capsules follicular, leathery; seeds many, elliptical, umbilicated, arranged in two rows. It is a narcotic acrid poison, and was long supposed to be the genuine Black Hellebore of the ancients. The fibres of the rhizoma are the parts used officinally.

H. orientalis is found in mountainous broken ground in Greece and the Levant. It has a black thick rhizoma, with cylindrical fibres; the radical leaves are stalked pedate, downy beneath, their segments almost sessile, oblong, acutely serrulate; stem taller than the leaves, corymbose, 3-5-flowered; floral leaves subsessile, palmated, the lobes 3 to 5, oblong-acute, serrulate; calyx purple, with oval very blunt sepals; capsules 5. The root was formerly much celebrated in mania, epilepsy, and dropsy. It is still used in the Levant, and is called 'Zoptâne' by the Turks. It is acrid and violently cathartic.

H. viridis is found in the woods and thickets of Europe on a chalky soil. It has a black fleshy rhizoma, with numerous long stout fibres; the leaves are a bright deep green, quite smooth, pedate, the cauline ones subsessile and palmate; the segments oblong, undivided, entire at the base, somewhat serrated at the apex; stems often forked, one foot and a half high; the flowers are few, terminal, and axillary, stalked, mostly solitary, drooping, green in every part; the sepals are roundish-ovate; capsules 3 to 4, short and wrinkled. This is said by Stevenson and Churchill to be the best substitute for *H. orientalis*, though less active.

H. fœtidus is found in thickets and waste ground, chiefly in a chalky soil, in the more western parts of Europe. It has a leafy many-flowered stem; the leaves are stalked pedate, of a livid green colour, quite smooth, with linear oblong or lanceolate serrated segments, the upper ones gradually losing their blade, and changing into pale lanceolate entire bracts; the flowers are numerous, panicled, and drooping; petals nearly erect, stained with dull purple about the edges. It is similar in its effects to *H. niger*. The leaves are emetic and purgative. They have been strongly recommended as a vermifuge against the large round worm (*Ascaris lumbricoides*). The fresh root of Hellebore applied to the skin induces inflammation and vesication, given internally, it acts as an irritant to the intestinal canal, producing vomiting and purging.

(Royle, *Materia Medica*; Lindley, *Flora Medica*.)

HELMINTHIA, a genus of Plants belonging to the natural order *Compositæ*, to the sub-order *Cichoraceæ*, and the section *Scorzonereæ*. It has the phyllaries in one row, equal, with equal subulate adpressed ones at the base, and surrounded by 3-5 leaf-like loose bracts; the receptacle dotted; the fruit compressed, transversely rugose, rounded at the end, and with a slender beak longer than itself; pappus in several rows, feathery. There is but one species inhabiting Great Britain, *H. echioides*, the Ox-Tongue. It is a plant from 2 to 3 feet in height; the branches, stem, leaves, and involucre are covered with strong prickles springing from white tubercles, and with 3 minute hooks at the apex. It is found on dry banks; and blossoms in July, August, and September. (Babington, *Manual of British Botany*.)

HELMINTHOCORTON. [ALGÆ.]

HELODUS. [FISH.]

HELONIAS, a genus of Plants belonging to the natural order *Melanthaceæ*. It has a 6-parted perianth; segments narrow, rather unequal, obtuse, not striated or herbaceous, nor imbricating; stamens 6, inserted into the base of the segments, unequal; filaments subulate; anthers reniform, with confluent cells; capsule separating into 3 many-celled follicles; seeds compressed, winged at the apex, or wingless.

The species of this genus contain veratria. The *H. officinalis* of Don, it is well known, has been employed for obtaining this substance. This plant differs from *Helonias*, and Dr. Lindley has described it under the name of *Asagræa officinalis*. [CEBADILLA.] The other species of *Helonias* used medicinally are as follows:—

H. frigida (*Veratrum frigidum*, Schlectendal). It is found in the alpine region of Mount Orizaba in Mexico. It is a poisonous plant, and called Savoeja by the Mexicans.

H. erythrosperma is a native of the United States in moist situations, on river banks, and high mountains. It is used in the southern states of America for destroying flies.

H. dioica, Unicorn's-Horn and Devil's-Bit of the Americans. It is found in wet meadows and bogs, and in hilly and mountainous regions in the United States. It is bitter, and is used as an anthelmintic and tonic.

(Lindley, *Flora Medica*.)

HELOTIDÆ (Leach), a family of Coleopterous Insects of the section *Heteromera* and sub-section *Stenelytra*. Distinguishing characters:—Head short, obtusely terminated anteriorly; mandibles notched at the apex; antennæ placed near the eyes, generally filiform, or nearly so, or slightly thickened at the apex, where the joints are short; the basal joint of the antennæ hidden above by a projected margin of the head; the third joint long; terminal joint of the maxillary palpi large and securiform; eyes emarginated anteriorly; legs moderate; the penultimate joint of the tarsi generally simple or but slightly emarginated; claws simple; body usually convex, and of an oval form.

The larvæ of these insects live in rotten wood, upon which they feed; they are of a cylindrical form, hard to the touch, and have six small legs, attached, two to each of the thoracic segments. The perfect insects are, like the larva, also found in rotten wood, or under the bark of trees; they are rather slow in their movements, and generally adorned with metallic colours.

In the genus *Helops*, as it is now restricted, the joints of the antennæ are somewhat compressed; the two basal joints are short, the third is long; the two or three terminal joints are short and obconic, the last joint is the shortest; the intermediate joints are moderately long and nearly cylindrical. The thorax approaches to a square form, or is slightly attenuated behind, and is closely applied to the elytra: the body is of an oblong oval form.

H. caraboides, an insect very abundant in various parts of England, will afford an example of this genus. It is rather less than half an inch in length, of an oval form and deep brown colour, having a bronze gloss in certain lights; the upper surface of the body is finely punctured, and so are the striæ of the elytra. This insect is usually found under the bark of trees, near the root.

H. cæruleus is another species of this genus, which is common in many parts of England. This insect is nearly three-quarters of an inch in length, and of a violet-blue colour. It is generally found in old pollard willow-trees. The larva is cylindrical in form, of a yellowish-white colour, and has two recurved hooks on the terminal segment of the body.

Upwards of sixty species of the genus *Helops* are enumerated in catalogues, and these are chiefly confined to Europe and North America.

HELOPS. [HELOPIDÆ.]

HELOSCIA'DIUM, a genus of Plants belonging to the natural order *Umbelliferæ* and to the tribe *Ammineæ*. It has a calyx of 5 teeth or obsolete; the petals ovate, entire, with a straight or incurved apiculus; the fruit ovate or oblong; the carpels with 5 filiform prominent equal ridges; the interstices with single vittæ, the carpophore entire. There are 3 British species of this genus:—

H. nodiflorum, with the leaflets obtusely serrate; *H. repens*, with the leaflets roundish ovate, unequally and acutely inciso-serrate; and *H. inundatum*, with the leaflets of the lower leaves divided into capillary segments. The first is a native of brooks and ditches, and is frequently mistaken for the water-cress. [SIUM.] The second is a rare plant in Great Britain. The last species is found in ponds.

(Babington, *Manual of British Botany*.)

HELVELLACEÆ (Lindley), a natural order of Plants belonging to the *Fungales*, and equivalent to Berkeley's order *Ascomycetes*. The genera included in it are embraced in Fries' cohort *Hymenomycetes*. [FUNGI; HYMENOMYCETES.]

HELVIN, a crystallised Mineral of which the primary form is a cube. Cleavage parallel to the planes of the regular octohedron, indistinct. Fracture uneven. Hardness 6·0 to 6·5; scratches glass. Colour, pale-wax and greenish-yellow. Streak white. Lustre resinous, vitreo-resinous; translucent; transparent on the edges. Specific gravity, 3·166. It is found at Schwarzenburg in Saxony.

Before the blow-pipe or charcoal it melts with effervescence into a globule of the same colour as the mineral; in the oxidising flame the colour becomes deeper and the fusion is more difficult; with borax it yields a transparent glass often coloured by manganese. Analysis by Gmelin:—

Silica	35·272
Glucina	8·026
Alumina and Glucina	1·445
Protoxide of Manganese	29·344
Protoxide of Iron	7·990
Sulphuret of Manganese	14·000
Loss by calcination	1·155
	97·232

HELWINGIACEÆ, *Helwingiads*, an order of Diclinous Exogenous Plants, represented by one species *Helwingia Rusciflora*. This plant is a native of Japan, where its young leaves are eaten. It is a shrub with alternate stipulate leaves, and fascicled flowers. Decaisne, who first constituted the order, regarded it as allied to *Hamamelidaceæ*. But its minute embryo and unisexual flowers remove it far from this order, whilst its inferior fruit and seed bring it near to *Garryaceæ*. It has an indirect affinity also with *Santalaceæ*. (Lindley, *Vegetable Kingdom*.)

HEMATITE. [HÆMATITE.]

HEMERIPUS. [ELATERIDÆ.]

HEMERO'BIUS, a genus of Insects of the order *Neuroptera* and section *Planipennes*. The genus, as established by Linnæus, has been dismembered by subsequent entomologists, and is now equivalent to a family distinguished by the filiform antennæ and by the number (four) of the palpi of the insects included in it. They have soft slender bodies, much exceeded in length by the large reticulated wings, which, when the animal is at rest, are deflexed. Their eyes are globular and vividly metallic. The larvæ are ferocious in habit, and prey upon plant-lice, seizing them with their powerful jaws and sucking their prey to death. When full grown, they spin and envelop themselves in a silken cocoon. The eggs of *Hemerobii* are deposited on plants, and are penduncilated, so as to resemble fungi, for which they have sometimes been mistaken. These insects range from Europe to Australia, and there are many species natives of the British Isles.

HEMEROCALLIS, a genus of Plants belonging to the natural order *Liliaceæ*. It has a campanulate corolla, seated on a cylindrical tube; the stamens are bent down; the capsule is 3-edged; the root is composed of thick fibres; the leaves are scattered, linear; the flowers are large, yellow or yellow-brown. The species are called Day-Lilies. *H. flava* is a native of Germany, and *H. fulva* of Italy. Several species are cultivated in our gardens, as *H. disticha* from China, *H. Sieboldii* from Japan, *H. speciosa*, and *H. graminea*.

HEMICARDIUM. [CONCHACEA.]

HEMICI'DARIS, a genus of Fossil *Echinodermata*, from the Oolite.

HEMICYCLO'STOMA, M. De Blainville's name for the fourth family of his order *Asiphonobranchiata*, the latter being the second order of the first sub-class (*Paracephalophora dioica*) of the class *Paracephalophora*, the second class of his *Malacozoa*. [NERITIDÆ.]

HEMIDACTYLUS. [GECKOTIDÆ.]

HEMIONUS. [EQUIDÆ.]

HEMIPNE'USTES, a genus of Fossil *Echinodermata*, from the Chalk-Marl.

HEMIPODIUS. [TETRAONIDÆ.]

HEMI'PTERA (from ἡμί, half, and πτερόν, a wing), one of the orders of the class *Insecta*.

The order *Hemiptera*, according to the twelfth edition of the 'Systema Naturæ' of Linnæus, contains insects which agree in having incomplete metamorphoses (that is, the larva and pupa both possess the power of locomotion, and bear a great resemblance to the perfect insect), and also in having the superior wings generally coriaceous, and the inferior membranous. Thus Linnæus included in this order the Cockroaches, Locusts, Grasshoppers, Bugs, *Cicadæ*, &c. The last-mentioned insects, the Bugs and *Cicadæ*, however differ very materially from the former, inasmuch as they possess a suctorial instead of a masticatory mouth; and as these latter characters have been considered of great importance by all the more modern entomologists, the term *Hemiptera* has been restricted to such insects as have imperfect metamorphosis and a suctorial mouth.

This definition will include the Linnæan genera *Fulgoria*, *Cicada*, *Notonecta*, *Nepa*, *Cimex*, *Aphis*, *Chermes*, *Coccus*, and *Thrips*, and these, with the addition of the genus *Pulex*, constitute the order to which Fabricius applies the name of *Ryngota*. Without the last-mentioned genus they constitute the order *Hemiptera* according to Latreille, Burmeister, and most of the foreign entomologists; and the orders *Hemiptera* and *Homoptera* according to Leach, Stephens, M'Leay, and several other British authors.

The *Hemiptera* are divided by Latreille into two sections; to the first he applies the name of *Heteroptera*, and to the second that of *Homoptera*. [HOMOPTERA.] The *Heteroptera* are characterised by having the rostrum attached to the fore part of the head; the elytra coriaceous with the extremity membranous, folding one over the other when at rest, and the first segment of the trunk (or the prothorax) the largest, and forming the most conspicuous part of the thorax. The second section, *Homoptera* (which by many of the English entomologists is regarded as an order), is distinguished by the proboscis being attached to the lower portion of the head, near the chest; the elytra almost always of a uniform coriaceous texture, with their inner margin straight and contiguous: the three segments of the thorax are united in a mass, and the first is frequently shorter than the second. All the insects of this section feed exclusively on vegetable juices. [HOMOPTERA.] We shall at present confine our remarks to the first section, or to the true Hemipterous insects.

In the greater number of the Heteropterous *Hemiptera* the head is small, situated on the same plain as the thorax, or nearly so; the fore part is somewhat produced; the eyes are of moderate size, very convex, and hence project rather suddenly from the sides of the head: between the eyes there are in many species two ocelli, or simple eyes; the antennæ are of moderate size, composed of long joints, few in number, and situated in front of the eyes: the part usually termed the thorax in descriptions, but which is in fact the prothorax, is of moderate size, often broader than long, and very frequently produced on each side, so as to form an angular projection; the scutellum is large, generally triangular; but in some (the *Scutelleræ*, for instance), it assumes the form of the body, and is so large that it completely covers that part; the body itself is often flat or concave above; convex and more or less distinctly keeled beneath: when the wings are closed the upper part of these insects generally presents a flat or slightly convex surface, and is seldom very convex. The legs are of moderate size, or not unfrequently long. In certain groups (the *Coreidæ*) the posterior thighs of the males of many of the species are remarkably large, and many have the tibiæ also large, often broad and compressed.

The proboscis springs from the fore part of the head, and when not in use is suddenly curved downwards and backwards, and lies close to the under surface of the thorax and between the fore pair of legs. It consists of a jointed process (*a*), which is grooved upon the upper side, and in this groove there are four setæ (*b*), or bristle-like organs, which are covered above, at their base, by another appendage (*c*), which is supposed to be analogous to the upper lip or labrum of mandibulate insects; whilst the four setæ probably represent the mandibles and maxillæ, and the jointed process the labrum. In the figure, the setæ (*b*) are represented as disengaged from their sheath (*a*), and the labrum is lifted up. When in the ordinary position these organs form together a tube, by means of which the juices of plants or animals are extracted and conveyed to the œsophagus.

The *Heteroptera* are divided by Latreille into two families; the first, or the *Geocorisæ*, are characterised as having the antennæ free, longer than the head, and inserted between the eyes and near their anterior margin. The tarsi are 3-jointed, but the first joint is sometimes very short. The second family, to which the name of *Hydrocorisæ* is applied, have the antennæ inclosed and hidden in a groove beneath the eye; the tarsi have but two distinct joints, and the eyes are generally very large.

The species of the family *Geocorisæ* are for the most part found on the leaves of trees or small plants; some there are which do not quit the ground, and there are others which live upon the surface of the water. The genera *Hydrometra*, *Gerris*, and *Velia* afford examples of this mode of life. [HYDROMETRIDÆ.]

The insects belonging to the second family (*Hydrocorisæ*) live, as their name implies, in the water, and they prey upon other insects.

The two families which have just been characterised are by most entomologists regarded as sections or subsections rather than families; the latter is in fact an aberrant group, the former containing by far the greater portion of the species. Regarding them therefore as sections, they may be divided into the following families:—

Geocorisæ.

Family 1. *Scutelleridæ*. Family 5. *Cimicidæ*.
2. *Pentatomidæ*. 6. *Reduviidæ*.
3. *Coreidæ*. 7. *Hydrometridæ*.
4. *Acanthiidæ*.

Hydrocorisæ.

Family 1. *Nepidæ*. Family 2. *Notonectidæ*.

HEMIRAMPHUS. [ESOX.]

HEMITRAGUS. [CAPREÆ.]

HEMI'TRYPA, a genus of Fossil *Polypiaria*, in the Limestone of Devonshire, allied to *Fenestella*. (Phillips.)

HEMLOCK. [CONIUM.]

HEMLOCK, WATER. [CICUTA.]

HEMP. [CANNABIS.]

HEMP-AGRIMONY. [EUPATORIUM.]

HEMP-NETTLE. [GALEOPSIS.]

HENBANE. [HYOSCYAMUS.]

HENBIT. [LAMIUM.]

HENIOCHUS. [CHÆTODON.]

HENNA. [LAWSONIA.]

HENSLOVIA'CEÆ, a very small natural order of Exogens. Of this order there is but one genus, *Henslovia*, and three or four species. They are all natives of the hot and damp parts of the East Indies. They are all trees, with opposite entire exstipulate leaves, and minute racemose apetalous flowers, with as many anthers sessile in the sinus of the calyx as there are lobes of that organ; a 2-celled many-seeded ovary, and a single style.

Henslovia pubescens.
1, a flower magnified; 2, a vertical section of the ovary.

In his 'Vegetable Kingdom' Dr. Lindley says of this order:— "After vain attempts at settling the true place of the genus *Henslovia* in the natural system, some specimens with ripe fruit, for which I am indebted to Mr. Griffith, place the question nearly at rest. The habit of the plant was evidently that of *Viburnum*; but its superior ovary and indefinite ovules forbade any reference to Caprifoils. But Hydrangeads differ from that order mainly in their indefinite seeds, small quantity of albumen, and constant tendency to produce a superior ovary. *Henslovia* agrees with them still further; the flowers are polygamous, the seeds are winged, which is also the case in *Hydrangea cordifolia* and others, and the albumen is wholly deficient. The chief distinction consists in the complete adhesion of the styles into one undivided cylinder; but in Hydrangeads we have the same pecularity in *Schismphragma* and *Brousssisia*. On that account however *Hensloria* may be regarded as a relation of *Brexia*, but its decidedly opposite leaves are unfavourable to the union of the two in the same order."

HEPATICÆ, that portion of the old family of *Musci*, or Mosses, known commonly as Liver-Worts, have received this name. In his alliance, *Muscales*, Dr. Lindley refers the orders *Ricciaceæ*, *Equisetaceæ*, *Jungermanniaceæ*, and *Marchantiaceæ* to the division *Hepaticæ*. [ACROGENS; RICCIACEÆ; JUNGERMANNIACEÆ; MARCHANTIACEÆ; MUSCI.]

HEPATITE. [BARYTES.]

HEPATUS, Latreille's name for a genus of Brachyurous Crustaceans, placed by M. Milne-Edwards under the tribe of Calappians, and, in the opinion of the latter, establishing the passage between the Cancerians, which they approach in their general form; the *Calappæ*, which they resemble in the disposition of their chelæ (manus); and the Leucosians, from which they differ but little with reference to the method of the organisation of the mouth. The carapace is large, convex, regularly arched anteriorly, strongly narrowed posteriorly; the hepatic regions are very large, and the branchial regions very small. The front is narrow, straight, rather projecting, and placed a good deal above the level of the lateral border of the carapace, which prolongs itself under the orbits to reach the sides of the buccal frame. The orbits are small, circular, and placed on the same level with the front. The internal antennæ are somewhat apart, and are bent back very obliquely under the front. The external antennæ occupy the internal angle of the orbits, which they separate from the antennary pits; their basilary joint is narrow, but rather long; the second is, on the contrary, small, and their terminal stem is nearly rudimentary. The buccal frame, which is very narrow forwards, and nearly regularly triangular, prolongs itself beyond the level of the lower border of the orbits, and is entirely occupied by the external jaw-feet, the third joint of which is triangular and terminated internally by a straight edge, under which are concealed the remaining joints. The sternal plastron is oval, and presents nothing remarkable. The anterior feet are strong without being large, and are capable of a close and exact application against the lower surface of the body, where they are entirely concealed: the hand is surmounted by a crest, and the claws are rather inclined downwards and inwards. The remaining feet are of moderate length, and the abdomen is divided into seven joints in both sexes.

The only species known, *Hepatus fasciatus* (*Calappa angustata* of Fabricius; *Cancer princeps* of Herbst; and *Calappa angustata* of Bosc), and *H. Chiliensis*, are inhabitants of the coasts of America: the first having been found in the north and at the Antilles; the second on the coast of Valparaiso. (Milne-Edwards.)

Hepatus fasciatus.

HEPIALIDÆ, a family of Lepidopterous Insects of the section *Lepidoptera Nocturna* of Latreille. The Moths belonging to this family are distinguished by the want of tongue, the wings being deflexed, long and narrow, and the thorax devoid of crest. Their larvæ live in the interior of vegetables, on which they feed, or in some instances they live in the ground, and feed upon the roots of plants; they are fleshy, naked, and have six thoracic, eight abdominal, and two anal feet. The pupæ have the segments of the body denticulated.

The principal genera contained in this family are *Hepialus*, *Cossus*, *Stygia*, and *Zeuzera*.

In the genus *Hepialus* (Fabricius) the antennæ are much shorter than the thorax, the wings are long and narrow, the posterior pair nearly equal to the anterior. The larvæ live in the ground and upon the roots of plants.

Hepialus Humuli, an insect commonly known by the name of Ghost-Moth, will afford an example of this genus. This moth measures from 1½ to 2 inches in width when the wings are expanded, and a large female is sometimes 3 inches in width. The male is of an immaculate silvery-white colour above, and brown beneath. When on the wing, which is usually in the evening about twilight, it is seen with tolerable distinctness if below the eye, on account of its white colour; but upon a slight change in its position, when the darker colour of the underside of the wings is opposed to the eye, it suddenly disappears; hence probably arises the name which has been applied to it.

Mr. Stephens, in his 'British Entomology,' however accounts for the name in another manner; he says it is "very common in grassy places in the middle of June, and not unfrequently met with in churchyards, whence its name of Ghost-Moth." The female Ghost-Moth is very dissimilar in colour to the male; indeed such is the case in all this species of *Hepialus*. The anterior wings are of a buff yellow colour above, with spots of a deeper hue; the under wings are palish-brown, having a faint pink-tint.

Five or six other species of this genus inhabit this country.

(Stephens, *Illustrations of British Entomology*.)

HERACLE'UM, a genus of Plants belonging to the natural order *Umbelliferæ* and the tribe *Peucedaneæ*. The calyx consists of 5 minute teeth, the petals abcordate with an inflexed point, the outer ones radiant. There are thirty-four species noticed, but only one of these is found in Great Britain, and few are applied to any useful purpose.

H. Sphondylium, Cow-Parsnip, or Hog-Weed, has ternate pinnate leaves, the leaflets lobed or pinnatifid, cut, and serrated. The stem is about 4 feet high, the lower leaves very large, and the flowers white or reddish. It is a native of Europe, and probably of Siberia, and is found plentifully in the meadows and hedges of Great Britain. The whole plant affords wholesome and nourishing food for cattle, and is collected in Sussex for fattening hogs; hence it is sometimes called Hog-Weed. Cows and rabbits are also fond of it, and horses will sometimes eat it, but it does not appear to be so agreeable to them. The Kamtschatkadales and Russians are in the habit of using the shoots and leaf-stalks as food, after the rind, which is bitter, has been taken off. They collect large bundles of the plants, and during the process of drying the stalks become covered with a saccharine efflorescence, which is esteemed a great delicacy. The Russians distil an ardent spirit from the stalks thus prepared, by first fermenting them in water with bilberries. The seeds of the plant are diuretic and stomachic, and exhale a powerful odour.

H. pubescens has ternate leaves, somewhat pubescent beneath; the leaflets toothed and pinnatifid; the umbels of many rays; involucre from 1 to 2 leaves; the fruit elliptic having the disc rather villous. It is a native of Taurida in shady places, and of the Caucasus in alpine places. The young shoots are filled with a sweet aromatic juice, which is eaten by the natives of the Caucasus in a crude state.

H. Pyrenaicum has large leaves, tomentose beneath; the leaflets lanceolate, toothed, or ternate; the involucre of few leaves; the young fruit covered with long hairs; the matured ones glabrous and nearly orbicular. It is a native of the Eastern and Central Pyrenees, and of Italy. D. Don thinks that this plant is identical with the *H. gummiferum* of Willdenow, which was supposed to yield the Gum Ammoniacum of commerce. Don has however identified the plant which yields this gum, and has placed it in a new genus. [DOREMA.]

All the species of *Heracleum* grow well in any soil, and are easily propagated by seeds or by dividing the root.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*; Babington, *Manual of British Botany*.)

HERBARIUM, the name given to specimens of Plants when they have been collected and dried. The possession of an herbarium is almost essential to the study of systematic Botany, as it is impossible to cultivate at once the larger proportion of the species of plants which inhabit the earth's surface. The use also of an herbarium will be found constantly to supply the place of recent plants. Hence all persons who study botany possess themselves of an herbarium more or less extensive according to the range and nature of their studies. The following hints for forming an herbarium are chiefly derived from Professor Balfour's valuable 'Class-Book of Botany:'—

The specimens to be dried and kept in the herbarium should, if possible, be gathered in fine weather, and free from external moisture. In selecting them care should be taken to have the plants in a perfect state of growth, with all the parts from which the characters of the order, genus, or species are taken. The entire plant, where practicable, should be preserved. Of course this is impossible with trees, but the completer the specimens the better for study. In trees, portions of the branches, with the leaves, flowers, and fruit should be taken, and, where possible, sections or small portions of the stem, roots, &c. In the case of tall and slender grasses and sedges, they may be folded once or twice backwards and forwards, to make room for them on a single sheet. Thick branches, roots, stems, &c. may be split to allow of pressure. In plants with diœcious flowers, both the staminiferous and pistilliferous flowers should be obtained. Some plants, as species of the genus *Rubus* and *Salix*, demand that both flowering and leafing shoots should be gathered. In glueing the plants on to the paper, care must be taken to expose both sides, so that all parts of the structure may be seen. Careful dissections of plants may be dried and fastened on to paper, and these will facilitate subsequent examiuation very much. All bad, doubtfnl, injured, or imperfect specimeus should be rejected.

In collecting plants a trowel will be found useful, and when gathered they should be placed in a tin box or vasculum till they are transferred to paper. Some plants require drying or pressure immediately. Under these circumstances, Dr. Balfour recommends a field-book, consistiug of some bibulous paper strapped between two pieces of board, iuto which the plants needing drying may be thrust at once.

The paper employed may he ordinary blotting-paper, but the paper-makers have made a paper for botanical use which may be more advantageously employed. Iu London, Bentall's drying-paper is used; there is also another paper used iu Scotland, called the 'Edinburgh botanical drying-paper.' It is made in sheets 18 inches long and 11 inches broad. This paper is included between boards. These should be exactly the size of the drying-paper. Several sets of boards of varying thicknesses should be employed, and pressure may be applied by means of a weight or straps. The letter is the most easy process whilst travelling. Iu order that the plants may dry freely, various suggestions have been made for makiug holes iu the boards or forming them of a kind of framework, by which the air would pass through.

In putting down the plants the following plan should be pursued:—"A parcel of not less than four sheets of paper is put on one of the outside boards, then one or more specimens are laid on this sheet according to their size. The specimens should be spread out carefully, their natural habit being preserved as far as possible. When plants require to be folded, the slips of paper already mentioned are passed over the bent portions so as to retain them in their position. Having placed one specimen or set of specimens on the sheet, another parcel of not less than four sheets is laid over them; and in doiug this the leaves and other parts are arranged with the haud or the forceps. The same process is repeated until a dozen or more such parcels have heen arranged one over the other. Then a thin hoard is iuserted, and other parcels of paper and specimens are arranged above it, until they are exhausted, or until the hundle is of sufficieut size. Another such board is then laid on the top, and the whole is subjected to pressure. The paper is changed after twelve hours' pressure, the plants being lifted by means of the forceps and placed in dry parcels of paper, while that which is moist is hung up to dry. The intervals between the changing of the paper may be increased or diminished according to circumstances." Very succulent and wet plants require frequent changing and much drying. Most specimens will dry in eight or ten days. Succulent plants need to bo killed first by immersion in boiling water. Aquatic plants and wet plants should be placed in a napkin and pressed before they are put into the paper. The moist paper will dry in ten or twelve hours. Along with the plant a lahel should he inserted, with all particulars known about the specimen, as where gathered, what elevation, &c.

When the specimens are thoroughly dry a selection is made for the herharium. These should be fastened by means of thin fine glue on thick wide paper, 17 inches long and 10½ inches hroad. The name of the plant, its locality, or any other particulars, may be then written on the paper. In order to preserve the specimens from the attacks of insects, &c., they should he touched with a strong solution of corrosive sublimate in camphorated spirit, or in a solution of naphtha (half a drachm to the ounce). The sheets may then be arranged in a case, according to their genera or natural orders.

Fruits, specimens of wood and bark, large roots, lichens and algæ on rocks and stones, may be arranged iu drawers, glazed cases, or glass jars. Succulent fruits and roots are hest preserved in a strong solution of salt and water, or in pyroligneous acid, diluted with 3-5 parts of water, or iu alcohol. In some instances a solution of 4 ounces of bay salt, 2 ounces of burnt alum, and 5 grains of corrosive sublimate, in 2 quarts of boiling water, has been used with advantage. These jars are best covered with a stout piece of caoutchouc tied round the neck.

For the preparation of specimens for the microscope, see MICROSCOPE in ARTS AND SC. DIV.]

HERB-PARIS. [PARIS.]

HERCINITE. [SPINEL.]

HERDERITE, a Mineral, which occurs in crystals embedded in fluor at Ehrenfriedersdorf in Saxony. Primary form a right rhombic prism. Cleavage parallel to the lateral planes, and in the long diagonal of the prism. Fracture small, conchoidal. Hardness 5. Colour grayish and yellowish-white. Streak white. Lustre vitreo-resinous; nearly transparent. Specific gravity, 2·985.

HERI'ADES, a genus of Hymenopterous Insects of tho section *Mellifera* (Latreille) and family *Apidæ*. Distinguishiug characters:—Body elongated, slender, almost cylindrical, that of the males with a small cavity beneath near the apex; mandibles triangular; maxillary palpi 2-jointed.

The little bees belonging to this genus, we are informed by Latreille, make their nests in holes in old trees; we presume that, as in the genus *Chelostoma*, the holes are made by the bees themselves.

H. campanularum, a species very common in various parts of England, is about a quarter of an inch in length, of a black colour, and sparingly covered with grayish hairs. This little bee is by far the smallest British species known of the family to which it belongs; it is common during the summer and autumnal months in the flowers of the various species of *Campanulæ*, and apparently is uever found in the flowers of any other genus of plants. "The males are often taken asleep in these flowers; their abdomen is then doubled, so that the tubercle with which its base is armed fits iuto the cavity near the anus."

(Kirby, *Monographia Apum Angliæ;* Latreille, *Genera Crustaceorum et Insectorum.*)

HERMÆA. [NUDIBRANCHIATA.]

HERMAPHRODITE. [MONSTER.]

HERMASIA, a genus of Plants belonging to the natural order *Paronychiaceæ*. It has 5 sepals; 5 filiform petals iuserted with the 5 stamens on a perigynous ring; 2 stigmas nearly sessile; fruit 1-seeded, indehisceut, membranaceous; leaves opposite. The species are insignificant plants. Three have beeu recorded as natives of Great Britain. One, *H. hirsuta*, is a doubtful native; the other two are very rare.

H. glabra has a prostrate herbaceous stem, with clusters of sessile flowers coalescing on the lateral hranches into a slightly leafy spike. It has been found in Suffolk and Liucolnshire iu Englaud, and iu West Kerry, Ireland.

H. ciliata. The sepals are tipped with a large bristle; the clusters of flowers are distinct, sessile, and axillary. It has been found at Lizard Point, Cornwall.

HERMINIUM, a genus of Plants helonging to the natural order *Orchidaceæ* and the tribe *Ophrydineæ*. The periauth is bell-shaped, segments all erect; lip 3-lobed, tumid beneath at the hase, without a spur; glands of the stalks of the polleu-masses exserted, naked. *H. monorchis*, the Musk-Orchis, is a British species. The stem is about six inches high, and the spike of flowers is dense and slender; the sepals are ovate and greenish. (Babington, *Manual.*)

HERMIT-CRAB, the common English name for the well-known crustaceans that occupy the empty turbinated shells of testaceous mollusks. [PAGURUS.]

HERNANDIA. [HERNANDIACEÆ.]

HERNANDIA'CEÆ, a natural order of iucomplete Exogeuous Plants. It has monœcious or hermaphrodite flowers, with an involucellum in the pistilliferous and hermaphrodite flowers; a petaloid calyx, tubular, 4-8-parted, deciduous; definite stamens inserted into the calyx iu two rows, of which the outer is often sterile, with the anthers bursting longitudinally; the ovary superior, 6-celled, with a pendulous ovule and peltate stigma; a drupaceous fruit with one seed, which is pendulous; the embryo is iuverted, without albumeu; the cotyledons somewhat lobed, shrivelled, and oily. Tho species are trees with alternate entire leaves, and flowers arranged iu axillary or terminal spikes or corymbs.

This order has heen constituted hy Blume. It contains ouly two genera, *Hernandia* and *Inocarpus*. These were sometimes referred to *Myristicaceæ*, from which they differ in the absence of albumen from their seeds. Their longitudinal authers distinguish them from the *Lauraceæ*, in which order they have also been placed. Their affinity is undoubtedly with *Thymeleaceæ*, from which they differ only in their drupaceous fruit, lohed cotyledons, and the iuvolucel to some of the flowers.

Hernandia, the typical genus of this order, was named after Hernandez, a naturalist sent out to Mexico by Philip II. of Spain; and it is said to havo been given to these plants, which have large leaves and little flowers, in allusion to the great opportunities afforded to this naturalist and the little use he made of them. The characters of this genus are the same as the order.

H. sonora is a tall erect tree, with cordate peltate leaves, yellowish panicled flowers, a large iuflated succulent calyx, with a small roundish entire mouth. It is a native of tho various parts of the East aud West Indies, and has obtained its naue 'sonora' from the noise made by tho wind in whistling through its persisteut iuvolucels. The bark, the seed, and the young leaves of this treo are slightly cathartic. Rumphius says that the fibrous roots chewed and applied to wounds infected with the Macassar poisou, act as an effectual cure. The juice of the leaves is employed as a depilatory. It destroys the hair wherever it is applied, and this without producing paiu. The wood of this species is very light, and Aublet says that the wood of *H. Guianensis* takes fire readily from a flint and steel, and may he used as tinder. Several species of *Hernandia* are mildly purgative.

(Lindley, *Natural System;* Lindley, *Flora Medica;* Burnett, *Outlines of Botany.*)

HERNSHAW, or HERONSHAW, a name for the Common Heron. [ARDEA.]

HERON. [ARDEA.]

HERON'S-BILL. [ERODIUM.]

HERPESTES (Illiger), a genus of Digitigrade Carnivorous *Mammalia* allied to the Civets. It is the *Ichneumon* of Lacépède, Geoffroy, and others; the *Mangusta* of Olivier and others; and the Mangouste of the French.

It has the following characters:—Feet short, with 5 demi-palmated toes, armed with claws which are slightly retractile; tongue furnished with horny papillæ; ears small; a voluminous simple pouch, which does not contain odoriferous matter, and at the bottom of which the vent is pierced. Body very much elongated; tail long, strong at its base. Hairs of the fur annulated. Dental formula:—

$$\text{Incisors, } \frac{6}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{6-6}{6-6} = 40.$$

The following cut (F. Cuvier) exhibits the dentition generally of the Civets, Ichneumons, Gennets, and *Paradoxuri*; for, though there are particular differences, they are not sufficient in the opinion of F. Cuvier to demand separate illustrations of the dental system of those groups. [VIVERRIDÆ.]

Teeth of Ichneumon (*Herpestes*).

Mr. Bennett has noticed some peculiarities in the dentary system of these animals. In *H. fasciatus* and *H. Gambianus* he found the following arrangement:—

$$\text{Incisors, } \frac{6}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{5-5}{5-5} = 36.$$

The incisors were small, simple, and regular; the canines of moderate size; the first two false molars of the normal form; the third carnassier of rather small size, compared with its analogue in genera more decidedly carnivorous; and the last two, in both jaws, tuberculous. The rudimentary false molar mentioned by F. Cuvier was, Mr. Bennett observes, wanting in both these species; nor could its absence be owing to the age of the specimens examined as he remarks, for he tells us that some were evidently young animals, though arrived at adult age. Its entire absence was further confirmed by the situation of the teeth respectively in the reciprocal position of the jaws, the first inferior false molar filling up the entire vacant space between the corresponding superior tooth and the canine of the same jaw. "This system," writes Mr. Bennett, "differs considerably from that ascribed to *Herpestes* by F. Cuvier ('Dents des Mammifères,' i. 99), but agrees in all respects with the description of M. Desmarest. The following however is equally foreign to the accounts of both these authors, and, were not all the other characters so perfectly accordant with those of *Herpestes*, would decidedly indicate a new genus. Indeed it so stands in my notes under the name of *Mungos*, but with a note of interrogation, as I have only been able to examine a single specimen.

"*Mungos* (?) *vitticollis* (*H. vitticollis*, Bennett). Dental formula:—

$$\text{"Incisors, } \frac{6}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{6-6}{7-7} = 42$$

"The incisors and canines have nothing remarkable either in form or number. The first false molar in either jaw is tuberculous; the second and third consist of one large conical fang in the centre, and a smaller tubercle on each side of it; then follows the carnassier, and after it two tuberculous teeth in the upper and three in the lower jaw. The first of these in the upper jaw is large and triangular; the second short and broad, its latitudinal dimensions more than doubling its longitudinal; the three of the lower jaw are small, simple, rather distant from each other, and of cylindrical form. This is a system of dentition which as far as I am aware is altogether peculiar, and if confirmed by the examination of other specimens will undoubtedly form the type of a new genus. Perhaps further and more rigid examination may even detect different species from the different localities, as specimens have arrived for the Society from Travancore and Bombay, and one from Madras, at the British Museum."

The species of the genus *Herpestes* are found in Asia and Africa.

Arrangement and Natural History.—Linnæus, in his last edition of the 'Systema Naturæ,' gives one species of Ichneumon under the name of *Viverra Ichneumon*, his genus *Viverra* being placed between the Cats (*Felis*), and Weasels (*Mustela*). It stands as the first species of the genus, and three varieties are noticed, one of them with a query whether it may not be a distinct species. The first of these varieties is evidently the celebrated Egyptian Ichneumon (*Ichneumon Pharaonis* of Geoffroy, *Herpestes Pharaonis* of Desmarest and others).

Gmelin gives three species, namely—*Viverra Ichneumon* (the Egyptian), *V. Mungo*, and, apparently, *V. cafra*.

Pennant places it among the 'Weesels.'

Cuvier gives the form (Les Mangoustes) a position between *Paradoxurus* and *Ryzæna* (the Suricates).

Dr. Gray arranges the Ichneumons (*Herpestes*, Illiger) under the *Felidæ*, in his fourth sub-family *Viverrina*, between *Genetta* (Cuvier) and *Crossarchus* (F. Cuvier).

Dr. Fischer places the form, under the name of *Mangusta*, between *Mephitis* and *Crossarchus*: he enumerates nine species.

M. Lesson, in his 'Manuel,' arranges it, under the name of *Ichneumon*, between *Genetta* and *Crossarchus*.

Mr. Swainson's '*Viverinæ*,' Musk-Weasels (*Viverrinæ*), form the first sub-family of his family *Mustelidæ*. *Herpestes*, which is placed between *Cynictis* and *Viverra* (Linnæus), is the second genus of that sub-family.

H. Ichneumon, the Ichneumon (*Ichneumon Pharaonis*, *Viverra Ichneumon*, *a*, of Linnæus). The fur a mixture of chestnut-brown and yellow, each hair being annulated with those two colours; the feet and muzzle black or deep chestnut; the tail terminated by a tuft of long hairs.

This appears to have been one of the sacred animals of the ancient Egyptians; and we read in Herodotus (ii. 67) that the *Ichneutæ* (ἰχνευταί), which the best critics consider to be synonymous with Ichneumons, were, as well as dogs, buried "in holy repositories." There is no good reason to doubt that it is the Ichneumon (Ἰχνεύμων) of Aristotle ('Hist. Anim.,' ix. 6; vi. 20, 35), Diodorus Siculus, Strabo, Ælian, and others; and as little that it is the *Ichneumon* of Pliny. Aristotle (ix. 6) relates, that when the Ichneumon sees the serpent called the Asp or Aspic (Ἀσπίς), he does not attack it till he has called to his assistance other ichneumons, and in order to defend themselves from the venomous bites of the snake, they cover themselves with mud by rolling on the earth after having dipped themselves in the water.

Pliny ('Hist. Nat.,' viii. 24), gives a somewhat similar account. Diodorus and Strabo relate a much more marvellous feat; nor is Pliny slow to lend his aid in spreading the wonderful tale, how, when the crocodile is lulled asleep with open jaws, the Ichneumon darts like a weapon down his throat and gnaws his entrails ("erodit alvum"). ('Hist. Nat.,' viii. 25.) It may be thought hardly worth while to refute such a fable; but it was long entertained as credible, and it may not be amiss to turn to Sonnini's observations on this point, more especially as they contain some interesting remarks on the habits of the animal. "Much," says Sonnini, who speaks of the Ichneumon as one of those animals which the Egyptians have domesticated, "has been written concerning it, and much of this writing has been fabulous. It was one of the animals held sacred in ancient Egypt. Honours were rendered to it on its death; it was maintained with the greatest solicitude during life; funds were set apart for its support; they served up to it, as to cats, bread steeped in milk, or fish of the Nile cut down into morsels; and it was generally forbidden to kill any of the race. Object of the worship of a celebrated people, the pretended protector of the most singular country in the world against a scourge the most grievous to an agricultural nation, a stranger and unknown in our climates—what a field for the production of the marvellous! Accordingly it has not been spared. The greater part of travellers have seen the Mangouste without examining it; and with their minds prejudiced by the stories which the ancients and the moderns have spread respecting it, they have successively copied their relations." Sonnini then, after a compliment to Buffon, and a statement that he had had it in his power to observe the Mangouste in its native country and in its state of liberty, proceeds as follows:—"With very great dispositions to familiarity, the Mangoustes are not altogether domestic in Egypt. Not only do they now rear none in their habitations, but the inhabitants have not even the recollection that their ancestors reared any. Most probably then those which Belon and Prosper Alpin assert that they had seen domesticated were merely a few individuals preserved rather as objects of curiosity than for any useful purpose; for if they hunt away rats and mice, they likewise seize upon the poultry; and this appetite would more than overbalance the good which they could do in purging the houses of noxious animals, which cats would destroy more certainly and with less inconvenience. Having some resemblance in their habits to weasels and polecats, they feed upon rats, birds, and reptiles. They ramble about the habitations of men; they even steal into them, in order to surprise the poultry and devour their eggs. It is this natural fondness for eggs which prompts them frequently to scratch up the sand with the intention of discovering those which the crocodiles deposit there, and it is in this manner that they prevent, in reality, the excessive propagation of these detestable animals. But it is absolutely impossible to abstain from laughing, and not without reason, when we read of their leaping into the extended mouths of the crocodiles, of their sliding down into their belly, and not returning till they have eaten through their entrails.* If some Mangoustes have been seen springing with fury on little crocodiles presented to them,† it was the effect of their appetite for every species of reptiles, and not at all that of a particular hatred, or of a law of nature, in virtue of which they would have been specially commissioned to check the multiplication of those amphibious animals, as many people have imagined.‡ It had been equally reasonable to say that nature placed Mangoustes on earth merely to prevent the too great propagation of chickens, to which they are far more hostile in reality than to crocodiles. And what proves more clearly that men have been mistaken in ascribing such intentions to nature respecting Mangoustes is this—in more than half of the northern part of Egypt, that is to say, in that part comprised between the Mediterranean Sea and the city of Siout, they are very common, although there are no crocodiles there; whilst they are more rare in Upper Egypt, where the crocodiles are, in their turn, more numerous. The Mangoustes are nowhere more multiplied than in Lower Egypt, which, better cultivated, more inhabited, more humid, and more shaded, presents also more abundantly the means of supplying them with prey and with food, and, I again repeat it, crocodiles never appear there."

Egyptian Ichneumon (*Ichneumon Pharaonis*).

That Belon saw this Ichneumon in Egypt there can be no doubt. That accurate observer, in the 'Portraits,' gives a figure of it superscribed "Portrait de l'Ichneumon, que les Egyptiens nomment Rat de Pharaon." Beneath is the following 'quatrain:'—

> "Voy le portrait du Rat de Pharaon,
> Qui chasse aux Rats, comme fait la Belette:
> Au demeurant fort cauteleuse beste,
> Qui autrement est nommée Ichneumon."

Hasselquist mentions the *Viverra Ichneumon*, the Ichneumon of the Nile, as met with in Upper and Lower Egypt, living, during the inundation of the Nile, in gardens and near the villages, but, in the dry season, as dwelling in the fields and near the banks of the river. He says that it creeps slowly along, as if ready to seize its prey, and that it feeds on plants, eggs, and fowls, killing the latter in the night, when it frequents the villages. He states that in Upper Egypt it searches for the eggs of the crocodile, which lie hid in the sand on the shore, and eats them, preventing by that means the increase of that dangerous animal. "The Ichneumon," he continues, "may easily be tamed, and frequently goes about the houses like a cat. Mr. Barton, who has been the English consul nineteen years in Egypt, has kept a tame one for several years. It makes a growling noise, and barks when it is very angry. The Arabians call it Nems. The French in Egypt, who give everything they don't know names of their own making, have called this Rat de Pharaon, which Alpin and Belon have followed, and called it *Mus Pharaonis* (the Mouse of Pharaoh). The resemblance it has to a mouse (*Mus terrestris*) in regard to the colour and hair might have induced ignorant people who know nothing of natural history, to call it a mouse; but I cannot conceive why they should call it 'Pharaoh's Mouse.' The Egyptians were too intelligent in the time of Pharaoh to call it a mouse, having knowledge enough to give true descriptions and significant names to all natural bodies; nor is it at this day called Phar by the Arabs, which is the name for mouse, but they call it Nems. What is related concerning its entering the jaws of the crocodile is fabulous." Hasselquist travelled during the years 1749-50-51-52: Sonnini's travels commenced in 1777, and terminated in 1780. In the Arabic used in the neighbourhood of Tangier, whence two specimens were sent by Mr. Drummond Hay to the Zoological Society of London, *Herpestes Pharaonis* is called Serro.

* Sonnini's notes. See almost all the ancient authors, and, among the moderns, Maillet, Jauna, and others.

† Maillet, 'Descr. de l'Egypte.'

‡ Maillet, &c.

Mr. Bennett, in his account of a specimen of *Herpestes griseus* kept in the Tower, says that on one occasion it killed no fewer than a dozen full-grown rats, which were let loose to it in a room sixteen feet square, in less than a minute and a half.

The story of the *Ichneumon Mungo*, or *Mungos* (*Viverra Mungo* of Gmelin), having recourse to the plant Hampsddu Tanah, or Mungo-root, as an antidote when bitten by serpents in its encounters with them, will be found in the 'Amœnitates Exoticæ' of Kæmpfer, who says (p. 574) that he had one of these animals which slept with him, and followed him about like a dog through the city and fields.

H. badius, the Ratlamuchi, is a native of South Africa. Dr. A. Smith, in the work above quoted, says that *H. badius* appeared restricted to sandy districts abounding in brushwood, and in these was occasionally seen running from one copse to another. He states that it is extremely shy, and flies with great rapidity on the approach of man to its hiding-places. Nothing except the remains of insects were found in the stomachs of those which were procured by the expedition; but Dr. Smith adds, that, if the natives are to be believed, *H. badius* feeds with avidity also upon lizards, snakes, mice, &c. Lucan and Rumphius both notice the skill of the Ichneumon in seizing serpents by the throat so as to avoid injury. Lucan, who names it *Pharias*, describes its attack on the Egyptian asp elegantly and at length (iv. 724).

Dr. J. E. Gray states that there are two very distinct varieties of this species. The one described by Dr. Smith is of a red bay, the hairs being of a uniform colour except a few just over the shoulder-nape, which have a black subapical ring. The other has most of the hairs of the back and sides with long white tips edged below with a black band, giving the back a grizzled appearance.

The following species are given in the 'British Museum Catalogue:'—

H. Widdringtonii, the Andalusian Ichneumon. South of Europe; Sierra Morena.

H. Caffer, Cape Ichneumon. South of Africa.

H. Mutgigella, the Mutgigella. Abyssinia.

H. Smithii, Dr. Smith's Ichneumon. Cape of Good Hope.

H. apiculatus, Brown-Tipped Ichneumon. Cape of Good Hope.

H. Javanicus, the Garangan. Java.

H. griseus, the Moongus. India; Nepaul.

H. Nyula, the Nyula. India; Nepaul.

H. paludosus, Brown Ichneumon. Cape of Good Hope.

H. brachyurus, Malacca Ichneumon. Malacca.

H. punctulatus, Spotted Ichneumon. South Africa; Natal.

This last species has been recently described by Dr. J. E. Gray, who says it most nearly approaches *H. Mutgigella.*

HERPETOLOGY (from Ἑρπετὸν and λογὸς), the branch of science which treats of the structure, habits, and classification of Reptiles. [REPTILE; ALLIGATOR; CROCODILUS; AMPHIBIA; OPHIDIA; CHELONIA; ICHTHYOSAURUS; PLESIOSAURUS; PTERODACTYL; SAURIA; BOIDÆ.]

HERRERITE, a Mineral occuring in reniform masses. Cleavage in three directions, affording rhomboidal fragments with curved faces. Colour pistachio- emerald- and grass-green; streak yellowish-gray. Hardness 4·0 to 4·5; brittle. Lustre vitreous to pearly, and shining on fresh surfaces; translucent. Specific gravity 4·3. It is found at Albarradon in Mexico. The following is an analysis by Herrera:—

Carbonic Acid	31·86	
Peroxide of Nickel	12·32	
Tellurium	55·58	
		99·76

This mineral is probably a mixture rather than a definite compound.

HERRING. [CLUPEIDÆ.]

HERSCHELLITE, a Mineral which occurs in attached hexagonal crystals, associated with *Phillipsite*, in the cavities of trap, and also in granular *Olivine*. Primary form a rhomboid; cleavage not ascertained. Fracture conchoidal. Hardness 4 to 4·5. Specific gravity 2·11. Translucent or opaque; colour white. Found at Aci Reale in Sicily. [CHABAZITE.]

HE'SIONE, the name of a genus of Dorsibranchiate *Annelida*, with a short but rather stout body, composed of a few ill-defined rings. A very long cirrhus, which probably executes the function of branchiæ, occupies the upper part of each foot, which has also another lower one and a packet of fine bristles. The proboscis of *Hesione* is large, and without either jaws or tentacles.

HESPERIDIUM, one of those fruits which, in common botanical language, is confounded with the word *Bacca* [BACCA], but which indicates a different structure. It has a tough separable rind, the seeds hardly lose their attachment when ripe, and the cells readily separate through the dissepiments. Of this nature is the fruit of the orange, which is the type of the *Hesperidium.* [FRUIT.]

HESPERI'IDÆ (Stephens), a family of Lepidopterous Insects of the section *Lepidoptera diurna* of Latreille. They have the following characters:—Antennæ terminated by a distinct club, generally with a minute hook at its extremity; tibiæ with two pairs of spurs, one at the apex, and the other near the middle; claws very small, bifid; body thick; wings small, the posterior pair with a groove to receive the abdomen. The larvæ are pubescent, or naked, and have a large head; pupa smooth, inclosed in a web.

These little butterflies have a large head, and a thicker body and smaller wings than the more typical species; they are moreover at once distinguished from them by their possessing two pairs of spurs, or spines, to the legs; their flight is short and in frequent jerks; hence they have received the name of Skippers.

H. sylvanus is about one inch and a quarter in width; the wings are of a rich brownish-yellow above, with the outer margins deep-brown; the anterior wings are spotted towards the apex with yellow, and have an oblong black dash near the base; the posterior wings have some indistinct spots.

This butterfly, which is very common in various parts of England, and is chiefly found on the borders of woods, will afford an example of the tribe of which we are treating.

There are several other species of the family *Hesperiidæ* found in this country, of which the *Thymele alveolus* may be noticed. This is a little black butterfly with numerous silver-like spots, and is known by the English entomologists by the name of the Grizzled Skipper.

HESPERIS (from 'Hesperus,' the evening), a genus of Plants belonging to the natural order *Cruciferæ*, and the tribe *Sisymbreæ*. The flowers emit a sweet fragrance during the night, and hence the genus derives its name. The pods are quadrangular, or sub-compressed, the valves keeled and somewhat swerved, the seeds in a single row. There are only three species enumerated, and none of these are made use of by man but as ornamental and sweet-scented plants.

H. matronalis, Dame's Violet, is the only British species; it has an erect branched stem, ovate lanceolate leaves, and large handsome lilac fragrant flowers. The ladies of Germany have pots of this plant placed in their apartments; hence it has been called Dame's Violet. Parkinson calls it Queen's Gilliflower; and Gerard, Damask Violet.

All the species thrive best in a light rich soil, and require the same treatment as most other tardy garden-plants.

(Don, *Dichlamydeous Plants*; Babington, *Manual*.)

HETEROBRANCHIA'TA, M. De Blainville's name for the fourth order of his *Acephalophora*.

The 1st Family (Ascidians) is divided into two tribes: 1, Simple Ascidians, of which *Bipapillaria* and *Fodia* are examples. [BIPAPILLARIA; FODIA.] 2, Aggregated Ascidians, an example of which is *Botryllus*. [TUNICATA; BOTRYLLIDÆ.]

The 2nd Family consists of the Salpaceans, and is also divided into two tribes: 1, the Simple (*Biphora*, &c.); 2, the Aggregate (*Pyrosoma*). [SALPA.]

HETERO'CERCAL, the term chosen by M. Agassiz to express a peculiar form of the tails of fishes, which affords a very obvious, and, as far as yet appears, a very correct indication of the geological age of formations. Among existing fishes the tail is either simple, as in the eel, bifurcate, as in the salmon, expanded to a round figure, as in the wrasse, or unequally bilobate, as in the shark. It is to this latter irregular form of tail that the term Heterocercal is applied: the others, by way of distinction, are called Homocercal.

Eel.

Salmon.

Wrasse.

Shark.

The peculiarity of the Heterocercal Fishes is that the vertebral column runs along the upper caudal lobe: in the other forms of tail it is symmetrically placed with respect to the posterior finny expansion. M. Agassiz has found this peculiarity of the tail, which is least common among living fishes, and confined to particular groups, to belong to every species of fishes, of whatever group, and however differing in other respects, which occur in strata older than the Oolitic system, while in and above that system Homocercal forms appear. It is therefore a characteristic of geological time; and among the conjectures as to the relations of this form to physical conditions of the surface, or laws of the animal economy, we prefer the opinion that it is one among several marks of the sauroid character of the fishes which lived in early geological periods. Some of the fishes of the Oolitic Rocks exhibit a slight inequality of the lobes of the tail, and some difference in the arrangement of the scales thereon, but without (we believe) the characteristic continuation of the vertebral column into the upper lobe. These may be thought to mark the gradual transition from the Heterocercal to the ordinary types of structure. *Lepidosteus*, with sharks, and other cartilaginous fishes of the existing creation, which were ranked by Linnæus, as 'Amphibia Nantes,' thus appear the few surviving representatives of organic forms which, in earlier periods of the history of the globe, were exclusively predominant.

(Agassiz, *Recherches sur les Poissons Fossiles*.)

HETERO'CERUS, a genus of Pentamerous Coleopterous Insects established by Bosc. Latreille places it in his second section of his family *Clavicornes*, and forms of it a tribe under the name of *Acanthopoda*, on account of the flattened broad limbs armed with spines. These beetles have small oval depressed bodies, and eleven-jointed antennæ, the last six articulations forming a cylindrical club. They live in sand or mud, by streams or among marshes, burrowing in the ground by means of their spinous tibiæ. When disturbed or alarmed they come out of their holes. The larvæ live in the same situations with the perfect insects. Several species are found in Britain.

HETEROCLIN. [MANGANESE.]

HE'TERODON, M. De Blainville's name for a genus of Dolphins. The term *Heterodon* had been applied by M. De Beauvois to a genus of serpents placed by Cuvier under his great genus *Coluber*. [CETACEÆ.]

HETEROGANGLIA'TA. The *Heterogangliata* of Professor Owen comprise all the *Mollusca* of Cuvier, with the exception of the *Cirripedia*.

HETEROGYNA. [HYMENOPTERA.]

HETERO'MERA, the second section of Coleopterous Insects in the arrangement of Latreille, including such as have five articulations in the first four tarsi, and four in the two posterior. They are all vegetable feeders. Latreille divided the *Heteromera* into four groups:

1st, the *Melasoma*, dusky or black insects, for the most part apterous and having hard elytra, which are often anchylosed. Their jaws are furnished with a hook, their claws are simple, and their eyes are oblong and depressed, a character which indicates nocturnal habits. They live in sand, or under stones, and often in cellars and vaults. They are very tenacious of life, living many months after being transfixed by a pin and placed in the cabinet. Doubtless this is owing to the quantity of fat in their bodies, which much exceeds that found in allied insects, and enables them to subsist for a long period without food. They are found in all parts of the world. The genera *Pimelia*, *Blaps*, and *Tenebrio* are types of as many tribes among the *Melasoma*. The Darkling Beetle, *Blaps mortisaga* [BLAPS], and the Meal-Worm, *Tenebrio molitor*, are familiar British examples.

2nd, the *Taxicornes*, insects without hooked jaws, with more or less square bodies, hard elytra, wings, short antennæ, and feet adapted for running, furnished with simple claws. They live under the bark of trees, or in the fungi parisitical on their trunks. A few live on the ground under stones. The genera *Diaperis* and *Coryphus* are types of tribes in this division.

3rd, the *Stenelytra*, which differ from the preceding in the structure of the antennæ, those organs being perfoliate or clavate in the *Taxicornes*, but simple among the insects of the present section. In other respects they are similar. The genera *Hylops*, *Cistella*, *Dircæa*, *Œdemera*, and *Myctera*, are types of tribes. They mostly inhabit wood. The *Œdemeræ* are found on flowers: they fly well.

4th, the *Trachelides*, beetles having triangular or heart-shaped heads, remarkable for being pedunculated. The neck is not retractile. Their bodies are soft, and furnished with wings, protected by flexible elytra. The jaws are not furnished with hooks, and the claws are bifid. *Lagria*, *Pyrochora*, *Mordella*, *Anthecus*, *Horia*, and *Meloe* are types of tribes in this division. In the tribe of *Cantharidea*, of which *Meloe* is the type, are found the Blistering Beetles, which were probably the insects known to the ancients under the name of *Buprestis*, and regarded as poison to cattle and even to man. [CANTHARIDÆ.]

HETEROMYS, a genus of Animals belonging to the order *Rodentia*. The genus is described as having the cheek-pouches of the Hamsters, the general form of the body and tail of the Rats properly so called, and the dorsal flattened spines of *Echimys*, Geoff. (*Loncheres*, Illiger). The dental system is unknown; feet with six callosities below, and five toes, the internal toe very small. (Lesson.) *H. Thompsonii*, Lesson (*Cricetus anomalus*, Desm.; *Mus anomalus*, Thompson; *Dasynotus anomalus*), the Spiny-Pouched Rat. It has the habits and is of the size of a rat. It is a native of the island of Trinidad. (See *Linn. Trans.*, vol. xi. p. 161, t. 10.)

HETEROPODA (Lamarck), the fifth order of the Gasteropodous *Mollusca* according to Cuvier's arrangement. They are distinguished from all other *Mollusca* by their foot, which, instead of forming a horizontal disc, is compressed into a vertical muscular lamina, which they use as a fin; and on the edge of which, in several species, is a sucker in the form of a hollow cone that represents the disc of the other orders. It embraces the genera *Carinaria*, *Atlanta*, and *Firola*. [ATLANTA; CARINARIA.]

HETERO'PORA, a genus of *Polypiaria*, proposed by De Blainville to include species of the genus *Ceriopora* of Goldfuss, which have unequal cellules. From the Chalk of Maestricht. (*Manuel d'Actinologie*.)

HETEROPTERA. [HEMIPTERA.]

HETEROPUS. [MACROPODIDÆ.]

HETEROSITE. [MANGANESE.]

HEUCHE'RA, a genus of Plants named in honour of John Henry de Heucher, professor of botany at Wittemberg, and the author of the 'Hortus Wittenbergensis.' This genus belongs to the natural order *Saxifragaceæ*, and consists of about sixteen species. It has a permanent 5-cleft calyx with an imbricated æstivation; undivided somewhat unequal petals; 5 stamens; 2 styles, very long, distinct, the length of the stamens, eventually diverging; the capsule crowned by the withered flower, at the lower part united to the calyx, 1-celled, dehiscing between the styles. The species are herbs with leafless stems, radical leaves, and racemose or panicled flowers.

H. Americana, Alum-Root, has rough scapes and leaves, and the whole plant pubescent; the leaves on long petioles, somewhat 5-7-lobed, toothed; the inflorescence elongated, panicled; the lobes of the calyx short, obtuse; the petals lanceolate, the length of the calyx; the stamens much exserted. This plant is a native of North America, where it has obtained, on account of its astringent properties, the name of Alum-Root. It contains tannin, and it is to this principle that its astringent character is to be ascribed. The other species contain tannin, but are not used for any purpose in the arts or medicine.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

HEULANDITE, a Mineral occurring crystallised and massive. Primary form an oblique rhombic prism. Cleavage parallel to the oblique diagonal of the prism, very distinct. Fracture uneven, slightly conchoidal. Hardness 3·5 to 4. Brittle. Colour white, brown, gray, yellow, and red. Translucent, transparent. Lustre vitreous, pearly on the cleavage planes. Streak white. Specific gravity 2·2. The massive varieties are granular. It is found in Scotland, Ireland, Iceland, and the Faroe Islands, usually lining cavities in trap rocks.

Before the blow-pipe it fuses with ebullition and phosphorescence into a white opaque globule. It does not gelatinise in acids.

The following are analyses by Thomson and Rammelsberg:—

	Thomson.	Rammelsberg.
Silica	59·145	58·2
Alumina	17·920	17·6
Lime	7·652	7·2
Water	15·400	16·0
	100·117	99·0

Lincolnite is a form of this mineral.

HIANS, Lacépède's name for the Grallatorial Bird called the Open-Beak or Open-Bill, *Anastomus* of Illiger.

HIATELLA. [PYLORIDIA.]

HIBBERTIA. [DILLENIACEÆ.]

HIBISCUS, so named from one of the Greek names (ἱβίσκος) of the Mallow, a genus of Plants belonging to the natural order *Malvaceæ*.

The species, upwards of 100 in number, of this genus, are chiefly herbaceous, though of a large size, but a few are perennial and arboreous. They abound in the hot parts of Asia and America, and also in Africa and the tropical islands; a few extend into Europe, North America, and to the Cape of Good Hope. *H. Trionum*, which occurs in Europe, is also found in Cashmere.

The genus is characterised by having an exterior many-leaved calyx; carpels united into a five-celled capsule; valves with the partitions in their middle; cells many-seeded, or very rarely containing only a single seed. The species are remarkable, like the family to which they belong, for abounding in mucilage, and for the tenacity of the fibre of their bark, whence several are employed for many economical purposes in the different countries where they are indigenous. The abundance of mucilage in some of the species renders them useful as articles of diet, as the unripe fruit of *H. esculentus*, the Okro or Gombo of the West Indies, which is employed both for thickening soup and as a vegetable; so in India *H. longifolius*, there called Ram Turai, is similarly employed, and much approved of by many Europeans, but objected to by others on account of its clamminess. The calyxes of *H. Sabdariffa* as they ripen become of a red colour and are pleasantly acid, whence in the West Indies the plant is called Red Sorrel. The calyxes are employed there, as well as in India, for making tarts; and a decoction of them, sweetened and fermented, is described in Browne's 'Jamaica' as a cool and refreshing drink, much used in many of the sugar islands. *H. Syriacus* and *H. Rosa Sinensis* are known as ornamental plants; the flowers of the latter are employed for blackening the eyebrows, as well as leather, both in India and China.

The species of *Hibiscus* are chiefly useful for the tenacity of their fibre, and hence several are employed in rope-making. Thus *H. cannabinus* is cultivated everywhere in India in the rainy season for this purpose, and its fibre is often imported into Europe as a substitute for hemp. It is known by the name Sun in Northern India, Ambaree in Western India, and Mesta Pat in Bengal. In the island of Otaheite rope and string are manufactured from the bark of *H. tiliaceus*, which is also made into matting of a white colour, and of different degrees of fineness. Forster states that the bark is also sucked as an article of diet, when the bread-fruit fails there: it is also so employed in New Caledonia. Indeed the mucilage which all these plants contain will no doubt afford some nourishment. In the West Indies, the whips with which the slaves were lashed were made from the fibres of *H. arboreus* (Mohoe or Mohaul). The bark of so many species of this genus being used for its tenacity, it is impossible to enumerate all. Dr. Roxburg particularly recommends the cultivation in India of *H. strictus*, in consequence of its long, fine, and strong fibres, of a beautiful glossy white appearance, and as likely to be an advantageous substitute for such as are already cultivated for this purpose.

Hibiscus Abelmoschus, so called from Hab-al-Mooshk, the Arabic name of its musk-scented seeds, is now often named *Abelmoschus moschatus*, and formed into a new genus. Its seeds are said to be added to coffee in Arabia, and are in India employed as a cordial medicine. The plant abounds in mucilage, and is employed in the process of clarifying.

HIBO'LITHUS, one of De Montfort's subdivisions of *Belemnites*.

HIBOU. [STRIGIDÆ.]

HICKORY. [CARYA.]

HIERA'CIUM, a genus of Plants belonging to the natural order *Compositæ*. The heads are many-flowered, the involucre imbricated with many oblong scales. Fruit terete, angular, and furrowed, with a very short crenulated margin. There are nineteen British species of this genus, but none of them are valuable on account of the properties they possess.

H. Pilosella has a leafless single-headed stem; elliptic-lanceolate or lanceolate leaves, hairy above, glabrous beneath. The flowers are of a pale lemon colour with a red stripe on the back. It is found on dry banks and elevated places.

H. alpinum has lanceolate leaves narrowed into a foot-stalk, entire or toothed; the involucre is covered with long silky hairs, and the florets externally hairy and of a bright yellow colour. It is found on rocks in Great Britain.

(Babington, *Manual of British Botany.*)

HIERAX. [FALCONIDÆ.]

HIERO'CHLOE, a genus of Grasses belonging to the *Phalarideæ*. It has two glumes, nearly equal, membranous, 3-nerved, about as long as the flowers; 3 flowers, the lower with 3 stamens, the upper palea with 2 keels, the upper flowers with both stamens and pistils; the stamens 2, the upper palea with 1 keel. One species of this genus, the *H. borealis*, has been found in Great Britain: it has an erect panicle, glabrous pedicels, and flowers without awns. The stem is about a foot high. It has only been found in Scotland. (Babington, *Manual of British Botany.*)

HIERO-FALCO, Cuvier's generic name for the Gyrfalcons. [FALCONIDÆ.]

HIGHTEA, a genus of Fossil Plants from the Isle of Sheppey. (Bowerbank.)

HIMANTHALIA. [FUCACEÆ.]

HIMA'NTOPUS, the generic name for the Long-Legged Plover, Longshanks, or Stilt. [SCOLOPACIDÆ.] The term is also applied by Müller to a genus of *Microzoaria*.

HINNITES. M. Defrance gave this name to a few fossil species of *Conchifera Monomyaria*, which occur in supracretaceous strata; one (*H. Dubuissonii*, of Sowerby) is found in the English Crag.

HIPPA. [HIPPIDES.]

HIPPA'LIMUS, a genus of *Zoophyta* proposed by Lamouroux. Goldfuss supposes that it may be included in his genus *Scyphia*. It is fungiform and pediculated, with pores on the upper surface only, and a deep central pit. From the blue marls of the department of Calvados.

HIPPELAPHUS. [CERVIDÆ.]

HIPPIDES (Latreille), *Hippa Tribe*, Hippians of Milne-Edwards, a family of *Crustacea*. Milne-Edwards thus describes these Crustaceans belonging to his family of *Pterygura*. The tribe is composed of a small number of anomurous crustaceans which appear to be especially framed for burrowing in the sand, and which present extraordinary forms. The carapace is longer than it is wide, and very convex transversely, presenting always on each side a great lamellar prolongation, which more or less covers the base of the feet; it is truncated posteriorly, and appears to be continuous with the anterior portion of the abdomen, which is very wide and lamellar laterally. One of the pair of antennæ is always very long. The external jaw-feet do not present a conformation like that which is observable in the greater part of the crustaceans treated of in the prior part of Milne-Edward's system; they have neither flagrum (fouet) nor palp, and their last three joints are very well developed. The sternum is linear, and the feet are imperfectly extensile; those of the first pair are monodactylous, or subcheliform, and those of the two or three succeeding pairs are terminated by a lamellar joint proper for burrowing. The posterior feet are filiform, semimembranous, recurved forwards, and hidden between the lateral parts of the carapace and the base of the preceding feet. The penultimate ring of the abdomen is always furnished with a pair of false feet, terminated by two more or less oval ciliated blades or laminæ; but these appendages have a forward curvature, and are not applied against the seventh segment so as to form with it a fan-shaped caudal-fin, as in the *Macrura*. The vulvæ are on the first joint of the third pair of feet. The branchiæ are disposed on a single line and inserted by a peduncle which rises near the lower third of their internal surface.

This tribe is divided into three genera, which Milne-Edwards distributes as follows:—

			Genera.
Tribe of Hippians.	External antennæ large, short, and terminated by a multi-articulate rudimentary filament.	Anterior feet subcheliform.	*Remipes.*
		Anterior feet cylindrical, monodactylous, and not at all subcheliform.	*Albunea.*
	External antennæ very large, and terminated by a stout and very long filament.		*Hippa.*

Albunea (Fabricius).—Most analogous of any of the tribe to the *Ranina*, as well by their general form as by the disposition of their feet. Their carapace, which is straight from before backwards, and convex transversely, is only a little prolonged above the base of the feet; it is terminated anteriorly by a nearly straight border, which occupies its whole width; it is of an oval shape, posteriorly and strongly notched for the insertion of the abdomen. A small mesial point represents the rostrum. The ocular peduncles are large and lamellar, whilst the eyes, situated on their external border, are extremely small. The internal antennæ are very large, and they are terminated by a single multi-articulate filament longer than the body, slightly flattened and ciliated on its edges. The external antennæ, inserted nearly on the same line as the internal, are large, short, and terminated by a small stem composed only of from seven to eight small joints. The external jaw-feet are more or less pediform; their second and third joints are almost cylindrical, and the terminal portion formed by the three last joints is sometimes as long, and almost as large, as the basilary portion. The feet are short; the first pair are terminated by a large hand rather subcheliform than cheliform, the moveable finger applying itself to its anterior border, the lower angle of which scarcely projects, and consequently does not really constitute an immoveable finger. The three following pairs are nearly of the same form, and terminate in a falciform joint. The posterior feet are almost filiform. The fist ring of the abdomen is small, and received in a notch of the carapace; the second is, on the contrary, very large, and presents on each side a considerable lamellar prolongation, which rides a little on the carapace. The third and fourth abdominal segments diminish progressively, but are nearly of the same form as the second; while the fifth, sixth, and seventh are very narrow, and present no lateral prolongation; the sixth supports a pair of false natatory feet, terminated by two oval laminæ; and the seventh has the form of a nearly circular lamina. (Milne-Edwards.)

Albunea Symnista may be taken as an example. The length of the carapace is 10 lines. It inhabits the seas of Asia.

Albunea Symnista.

Remipes (Latreille).—Carapace nearly regularly oval, convex, and less than once and a quarter as long as it is wide; front rather large and truncated; orbits semicircular, and their external angle much more projecting than the front. The ophthalmic ring is covered above by the front, but is not surrounded by the carapace; the ocular peduncles are composed of two moveable portions, one basilary, which is stout and short, the other terminal, cylindrical, slender, carrying at its extremity a very small imperfectly retractile cornea; the eyes, in fact, can scarcely be turned backwards, as in the greater part of the Decapods, but advance and recede a little by the motion of the basilary portion of their peduncle. The internal antennæ are inserted below the base of the ocular peduncles, and are very large; their basilary portion is composed of three joints nearly of the same size, and their terminal portion consists of two long filaments which are multi-articulate, stout, and directed forwards. The external antennæ are inserted within the internal, nearly on the same line, and under the latero-anterior edge of the carapace; they are short but very large; their first joint is much wider than it is long; the second and the third are nearly of the same dimensions, and the succeeding joints diminish rapidly in volume. The buccal frame is not closed anteriorly. The external jaw-feet are wide and short; their first joint is nearly globular, and carries neither palps nor flagrum; the second joint, which is so large in the *Brachyura*, is rudimentary here; and it is the third, which, becoming very large and nearly oval, constitutes solely the species of operculum formed ordinarily by the second and third joints united; the three last joints form a sort of large claw, which applies itself against the anterior border of the third joint. The jaw-feet of the second pair are equally destitute of the flagrum, but have a flabelliform palp; it is the same with the anterior jaw-feet; their palp is lamellar, dilated anteriorly and disposed nearly as in the *Oxystomes*. The jaws of the second pair present nothing remarkable; those of the first pair are very small. The mandible, which is strongly dentilated, is furnished with a palp composed of two small lamellar joints, separated from the body of the mandible by a large membranous furrow; the sternum is linear. The anterior feet are long; their second and third joints are enlarged; but the last three are cylindrical; and the last, which is nearly as long as the preceding one, is slightly flattened, pointed, and incapable of being bent back upon it. The two following pairs are large, and terminated by a large hastiform lamina; the fourth pair are held by a small nearly conical joint. The fifth pair are slender, long, and membranous, and are bent back upon the lateral prolongation of the carapace. The last thoracic ring, which supports these appendages, is complete above, moveable, and not covered by the carapace, so that it might be easily taken for the first abdominal segment. The abdomen is very large, and presents on each side a lamellar oval prolongation which rides upon the carapace; its anterior border is notched for the lodgement of the second abdominal ring, which is oval; the third and fourth segments diminish progressively in volume; the fifth and sixth are equally small, but are soldered together; and the seventh has the form of a great triangular lamina, the length of which exceeds that of all the rest of the abdomen. The first three rings in the female are furnished with simple oviferous filaments; the fourth and fifth rings are without appendages, while the sixth ring carries a very large pair of false natatory feet, terminated by two raised oval plates which are ordinarily bent forwards. (Milne-Edwards.)

Remipes testudinarius may be given as an example. The length of the carapace is about 15 lines. It inhabits the coasts of Australia.

Remipes testudinarius.

Hippa (Fabricius).—When Fabricius established the genus it was much more extensive in its limits, and at present it only contains those Hippians whose external antennæ are terminated by a long and stout multi-articulate filament. Body oval, or rather ellipsoid, being rather less wide forward than backward. Carapace truncated posteriorly, very convex transversally, and presenting towards the middle a transversal curved furrow, which indicates the posterior tenuity of the stomachal region; its latero-anterior border is concave, but its latero-posterior border is very convex. The rostrum is small and triangular, and on each side of its base is a notch which exposes the insertion of the ocular peduncles and the internal antennæ, and which is bounded externally by a projecting tooth which advances above the internal edge of the great antennæ. The ophthalmic ring, which is covered in its mesial part by the rostrum, is of a horse-shoe shape, and its two extremities are exposed; the ocular peduncles, inserted at its extremity, are composed of three pieces, and of these the two basilar, which are very short, are bent under the carapace in the form of V, and the last, which is slender, cylindrical, and very long, advances between the internal and external antennæ, and terminates by a small pyriform enlargement which carries the cornea. The internal antennæ are of moderate size, and their basilary joint, which is cylindrical and a little curved downwards, is hardly larger than the succeeding one, which is furnished on the external side with a strong tooth directed forwards; the third joint is short, and gives insertion to two multi-articulate stemlets (tigelles). The external antennæ are very large, but easily escape observation, for they are ordinarily bent backwards and hidden almost entirely between the mouth and the external jaw-feet. The first joint of their peduncle is small and but little apparent; the second is large and armed anteriorly with two spiniform teeth, the external of which is much the strongest; the two succeeding joints are small, and form by their union a globular mass, whence springs a last peduncular joint, which is cylindrical, and supports in its turn the multi-articulate terminal filament, which last is very large, nearly of the length of the carapace, and fringed externally with a double row of long hairs. The external jaw-feet are of considerable size and operculiform, but their first two joints are very small, and it is the third only which presents that disposition; the last three joints form a long, delicate, and lamellar appendage, which is inserted in a notch of the external angle of the preceding joint, and is bent back under its internal edge, but does not constitute a claw as in *Remipes*. The palp of the two pairs of succeeding jaw-feet is terminated by a lamellar enlargement. The feet are short, and hidden under the carapace; the first pair are stout and applied against the mouth, terminating with a ciliated nearly oval lamina. The tarsus of the two succeeding pairs of feet is lamellar and hastiform, and that of the fourth pair is stout, conical, and very short. The posterior feet, which are long, membranous, and very slender, are bent back between the lateral part of the carapace and the base of the preceding feet. The last thoracic ring is not free and exposed as in *Remipes;* but the first joint of the abdomen is nearly of the same form, and the succeeding rings present also the disposition already noticed in these crustaceans. (Milne-Edwards.)

Hippa Emerita is the best example. The length of this species is from 1 inch to 15 lines. It inhabits the coasts of Brazil.

Hippa Emerita.

HIPPOBOSCA. [HIPPOBOSCIDÆ.]

HIPPOBOSCIDÆ, a family of Dipterous Insects belonging to the section *Pupipara* or order *Homaloptera*, containing the Forest-Flies, which exhibit such remarkable variations in their typical structure that they have been regarded by some authors as forming a distinct order. The head is received into a cavity in front of the thorax; it is divided transversely into two parts, the anterior or smaller of which supports the mouth and two small tubercles, almost imbedded at the lateral angles, being rudimental antennæ. The mouth is composed of two curved setæ, inclosed in a tubular canal, covered by two narrow elongated coriaceous plates, regarded by Latreille as palpi. The ocelli are wanting. The body is short, flat, and very coriaceous; the wings are either large or entirely wanting; the nervures of the anterior margin are very strong, but they are effaced behind. In the winged species a pair of balancers are also present. The legs are very strong, and terminated by robust curved claws, which are toothed beneath. The abdomen is composed of a continuous leathery-like membrane, capable of very great distension, which peculiarity is owing to the remarkable circumstance that the young of these insects are singly nourished within the body of the parent, where they not only acquire their full size, but actually assume the pupa state, under which form, like very large eggs, they are deposited by the female. This egg-like cocoon is at first soft and white, nearly as large as the abdomen of the parent fly; but by degrees it hardens, becomes brown, of a rounded form, and often notched at one end, which is covered by a shining kind of cap, which is detached on the insect's assuming the perfect state. This cocoon is moreover entirely destitute of annular incisions, in which respect it differs from those of other Dipterous Insects. It is composed of the uncast skin of the larva, beneath which the insect becomes a real inactive pupa, with the limbs of the perfect insect laid along the breast, as in other species which undergo the strict coarctate species of transformation. M. Réaumur was the first to discover these curious particulars; and he was so anxious to observe the development of the insect from these singular eggs, that he carried them in his pocket by day and took them to bed with him at night, in order that they might have a uniform degree of warmth; great was his surprise therefore when, instead of grubs as he expected, perfect flies were produced.

These insects are interesting in their habits. They live exclusively upon quadrupeds and birds; the horse is especially subject to the attacks of one of these species, hence called *Hippobosca equina*. This species is the type of the genus *Hippobosca*, in which the eyes are large and distinct, being placed at the sides of the head; the antennæ are in the shape of turbercles with three dorsal setæ; the wings are large. Mr. Curtis observes that these flies move swiftly, and like a crab, sideways or backwards; they are very tenacious of life, and live principally on horses, attaching themselves to the belly between the hind thighs and under the tail, where they are less protected by hair. It is remarked by Latreille that the ass fears them most, and that horses suffer very little from them. In the New Forest they abound in a most astonishing degree. Mr. Samouelle says, "From the flanks of one horse I have obtained six handsful, which consisted of upwards of a hundred specimens. They abound most on white and light-coloured horses."

The other genera are:— *Ornithomyia*, *Craterina*, *Oxypterum*, *Hæmobora*, *Melophagus*, *Feronia*, *Lipotepna*, and probably *Braula*. Of these the first three are British, and are found upon various birds, the *Craterina hirundinis* depositing its egg like a cocoon in the nest of the swallow, where it receives all the necessary warmth; for which it repays the poor swallow by sucking its blood. The wings in this genus are very long and narrow. The genus *Melophagus* comprises a single species, *M. ovinus*, which is destitute of wings, and attacks the sheep. It is of a dark reddish colour, with the abdomen whitish. It is commonly called the Sheep-Louse, and is so tenacious of life that Ray states that it will exist in a fleece twelve months after it is shorn, its excrements even giving a tinge to the wool, which is very difficult to be discharged.

HIPPOBRO'MA (from ἵππος, a horse, and βρῶμα, food), a genus of Plants belonging to the natural order *Lobeliaceæ*. It has the limb of the calyx 5-parted with linear segments; the tube of the corolla long, straight, entire, with the limb 5-parted, nearly equal; the stamen-tube projecting, completely monadelphous and syngenesious; the stigma sloped, the capsule 2-celled, 2-valved, many-seeded.

H. longiflora is the only species. It is an herbaceous plant, with short axillary pedicels, mucronate or coarsely toothed leaves, with long slender white flowers. It is a native of Jamaica, St. Domingo, Cuba, and Martinique, in damp places and by the side of streams. This is one of the most poisonous of plants. If the juice only accidentally touches the lips or eyes it produces a burning inflammation. Horses are violently purged after eating it.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

HIPPOCAMPUS. [SYNGNATHIDÆ.]

HIPPOCEPHALOI'DES. By this name Plott and other writers understood the inner casts of certain equivalved *Conchifera*, especially *Trigonia*.

HIPPOCRA'TEA, a genus of Plants belonging to the natural order *Hippocrateaceæ*, so named after Hippocrates, and which might therefore be expected to contain many useful or medicinal plants. But it is not so. The species consist of moderate-sized trees, which are found in the hot parts of the world, as in the tropical parts of America, in Sierra Leone, the warmer parts of India, and the Island of Timor. The genus is characterised by having the calyx 5-leaved, but very small; petals 5, usually hooded at the apex; stamens 3, anthers 1-celled, opening transversely at the apex; carpels 3, samaroid, bivalved, valves keeled and compressed; seeds winged from the funiculus being widely expanded. The fruit of some of the plants of the family is eatable; but the seeds of one species only of *Hippocratea* are mentioned as being of any use; those of *H. comosa*, being oily and sweet.

HIPPOCRATEA'CEÆ, a small natural order of Exogenous Plants remarkable for the presence of three monadelphous stamens in a pentapetalous flower. The fruit consists of from one to three cells, and is frequently extended at the back in a membranous manner, so as to resemble the samara, or key of the ash-tree. The species are woody, and often climbers; they inhabit Africa, the Mauritius, and the tropical parts of America; in general they are of no importance for economical or medical purposes. The fruit of *Tonsella pyriformis* is eaten in Sierra Leone. The nuts of *Hippocratea comosa* are oily and sweet. They are called in the French West India Islands Amandier du Bois. In Brazil other species have eatable fruits. The order has 6 genera and 86 species. They are related to *Chailletiaceæ*, *Celastraceæ*, *Malpighiaceæ*, and *Aceraceæ*.

HIPPOCRE'PIS (from ἵππος, a horse, and κρηπίς, a shoe, on account of the curved shape of its pods), a genus of Plants belonging to the natural order *Leguminosæ*, the tribe *Hedysareæ*. It has diadelphous stamens, an acute style; the legume curved, with numerous 1-seeded joints; the seeds cylindrical or compressed, oblong, curved, fixed to the middle part of the joint, and therefore the umbilicus is in the middle of the curve. The species are herbs, or under-shrubs, with unequally pinnate leaves and yellow flowers, which are sometimes solitary and axillary, sometimes sessile, but usually disposed in umbels on the tops of the axillary peduncles.

Hippocratea.
1, a flower expanded; 2, a section of the same, showing the ovary.

H. Balearica, Minorca Horse-Shoe Vetch, is a shrubby erect plant, with the peduncles longer than the leaves, bearing an umbel of flowers at the apex, the legumes glabrous, a little arched. It is a native of the Island of Minorca. It is a pretty plant, worthy of cultivation, but requires the greenhouse in winter. It grows well in a soil composed of loam and peat; and cuttings strike readily under a hand-glass.

H. comosa, Common Horse-Shoe Vetch, has the pods umbellate, their joints rough, curved, neither dilated nor bordered, glabrous; the peduncles longer than the leaves. It is a native of Europe, and is found on dry chalky banks in Great Britain. It is also found in the north of Africa.

There are seven or eight more species of Horse-Shoe Vetch. They are all worth cultivation on account of their beauty. The perennial species are adapted for rockwork and banks, and may be propagated by dividing the roots. The annual species should be grown from seeds, which may be sown early in spring.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

HIPPOGLOSSUS, a genus of Fishes belonging to the family *Pleuronectidæ*. The two eyes are on the right side. The jaws and pharynx are armed with sharp and strong teeth; the body elongated. The species are known by their being stouter and longer than those of the genus *Platessa* and other *Pleuronectidæ*.

H. vulgaris, the Holibut, Halibut, or Fletan, is the only British species. It is a very frequent fish in the northern fisheries, and is common on the coasts of Norway, Iceland, and Greenland. They are obtained in large quantities by the inhabitants of the Orkneys. In the Northern seas they are sometimes caught weighing 500 lbs. They are found around the coasts of Ireland, and are often seen in the London markets. The form of the body is elongated, the surface smooth, covered with small oval-shaped soft scales; the lateral line arched over the pectoral fin; the colour composed of different shades varying from light brown to dusky brown; the surface of the under side perfectly smooth and white.

(Yarrell, *British Fishes*.)

HIPPO'LYTE, the name of a genus of *Crustacea* belonging to the tribe of Palemonians. [PALEMONIDÆ.]

HIPPOMANE, a genus of Plants belonging to the natural order *Euphorbiaceæ*, and tribe *Hippomaneæ*. The tribe *Hippomaneæ* is characterised by solitary ovules, apetalous flowers in spikes, and bracts one- to many-flowered. The genus *Hippomane* embraces the famous Manchineel-Tree.

H. Mancanilla, the Manchineel-Tree, is a plant which has as bad an American reputation as that of the Upas-Tree in the Indian Archipelago. It is a tree of very considerable size, and of a handsome aspect, belonging to the natural order *Euphorbiaceæ*, and among the most poisonous of all known vegetable productions. The leaves are alternate, ovate-acute, serrated, and shining, with a roundish depressed gland between the blade and the petiole. The flowers are small, unisexual, and arranged on slender axillary spikes, the lowermost only being female, all the others male. The male flowers grow in clusters, and have each a small calyx of two sepals, containing a tetrandrous column of stamens. The females have a calyx of three sepals, a round ovary crowned by six or seven reflexed stigmas, and containing as many cells. When the fruit is ripe it is a fleshy yellowish-green round body, very like an European crab-apple. The tree is common in the West India Islands, although pains have been taken to extirpate it. In some places it forms thick woods, as upon Sandy Island, near Tortola, to the exclusion of all other vegetation, for not a blade of grass will grow beneath its branches. The whole plant abounds in a milky juice of the most venomous description: dropped on the skin it produces a sensation of severe burning, followed by a blister; and the fruit, when bitten, causes dangerous inflammation of the mouth. This is denied by some of the West Indian settlers, but is undoubtedly true, according to the elder Jacquin, and to the more recent testimony of Sir Robert Schomburgk, who suffered severely from having tried the experiment of eating the fruit. Jacquin however asserts that to sleep beneath the shade of the Manchineel-Tree is not dangerous, as is commonly reported. But Sir Robert Schomburgk says that if rain passes through the branches and drops upon the skin of a person below them, it produces severe inflammation, and that the dew which falls at night causes the same effects, as he saw in certain cases which came beneath his own observation; but he adds that it acts differently upon different persons, he himself not suffering any inconvenience from rubbing the juice on the skin. But while the dangerous qualities of this tree are thus undoubted, it is very uncertain whether the poisonous quality which, it is believed in the West Indies, the land-crabs acquire from the Manchineel-Tree is really owing to that cause. Jacquin denies it, and Sir Robert Schomburgk could obtain no proof that it is so; all that is certain is, that land-crabs are frequently found under the shade of manchineel woods, and that those animals are often poisonous. The wood of this tree is represented to be of fine quality, handsome, and well suited for cabinet-makers' purposes.

Manchineel-Tree (*Hippomane Mancanilla*).
1, a ripe fruit; 2, a transverse section of the same; 3, a male flower; 4, a female flower; 5, an ovary.

HIPPO'NÖE, a genus of Dorsibranchiate *Annelida*, considered by Messrs. Audouin and Milne-Edwards to approach the genus *Amphinome*. *Hipponöe* is deprived of a caruncle and has only a single packet of bristles to each foot, and a single cirrhus.

HIPPO'PHAË, a genus of Plants belonging to the natural order *Elæagnaceæ*. It has diœcious flowers with ovate scaly bracts. The stameniferous flowers have a perianth of two leaves adhering by their points; the stamens have four very short filaments; the pistilliferous flowers have the perigone tubular and cloven at the summit; the style is short, the stigma elongated; the nut 1-seeded, clothed with the large coloured berry-like perigone.

The only species of this genus is the *H. rhamnoides*, Sea-Buckthorn, which is a small shrub found on the east and south-east coasts of Great Britain, and other parts of Europe. The acid berries yielded by this plant are often eaten as a salad both in this country and in France. This plant also yields a colouring matter, which is used for dyeing yellow. Although in this country the berries are innocuous, they seem to exert a deleterious influence, or are supposed to do so, in some of the countries of the south of Europe. They are said to be a favourite food with the Tartars, and the fishermen of the Gulf of Bothnia eat them with their fish.

(Babington, *Manual of British Botany;* Burnett, *Outlines of Botany.*)

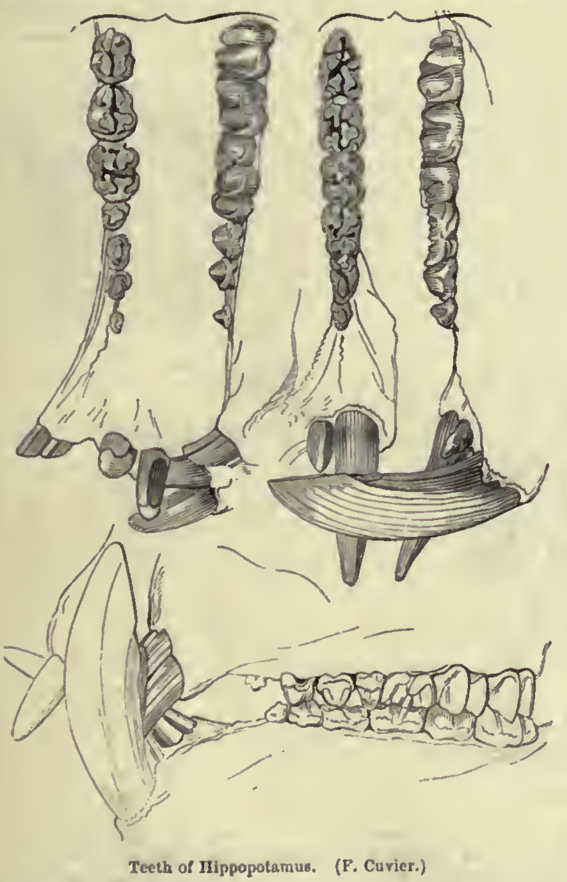
HIPPO'PODA, a genus established by Messrs. Quoy and Gaimard for a marine floating Mollusk which M. De Blainville considers identical with *Protomedea* of Lesueur's manuscripts, and places under his (M. De B.'s) *Physograda*. [ACALEPHÆ.]

HIPPOPO'DIUM, a fossil genus of *Conchifera Dimyaria* proposed by Mr. J. Sowerby in the 'Mineral Conchology of Great Britain.' It includes only one British species, *H. ponderosum*, which is found in the Lias.

HIPPOPOTAMUS (Ἵππος and ποτάμιος), the Roman name for the River-Horse, and retained by modern zoologists as the generic appellation of the animals of that Pachydermatous form.

Dental Formula:—Incisors, $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{7-7}{6-6} = 38$.

Cuvier remarks that there is no animal that requires to be more studied at different ages than the Hippopotamus, in order to acquire a perfect knowledge of the molar teeth, which change their form, their number, and their position; and, in his 'Ossemens Fossiles,' he goes into minute details of those changes.



Teeth of Hippopotamus. (F. Cuvier.)

In the upper jaw the first incisor is conical, straight, and a little worn on its internal side; the second is equally conical, but curved inwards. The canine tooth is short, and cut, as it were, obliquely, in consequence of its abrasion against its opposite. The four molars which succeed the canine are strictly false molars. The first is very small, is shed as the animal advances in age, and is not reproduced; it is separated by an interval from the rest of the molar teeth. These, nearly of the same size, are also shed during the youth of the animal, are replaced by others, and the first teeth are more complicated than the second. When these, the true and permanent molars, are worn by use, they exhibit the form of a trefoil on their crowns. The three last resemble each other generally: they are composed of four large tubercles approximated in pairs, and conical before the points are worn by attrition consequent on mastication. After the first effects of abrasion they each present, by the contour of the enamel, the figure of a trefoil, or, in other words, three lobes disposed more or less regularly in the form of a triangle; but as the abrasion proceeds and the tooth is farther worn down, they exhibit the form of a cross with a disc in the middle.

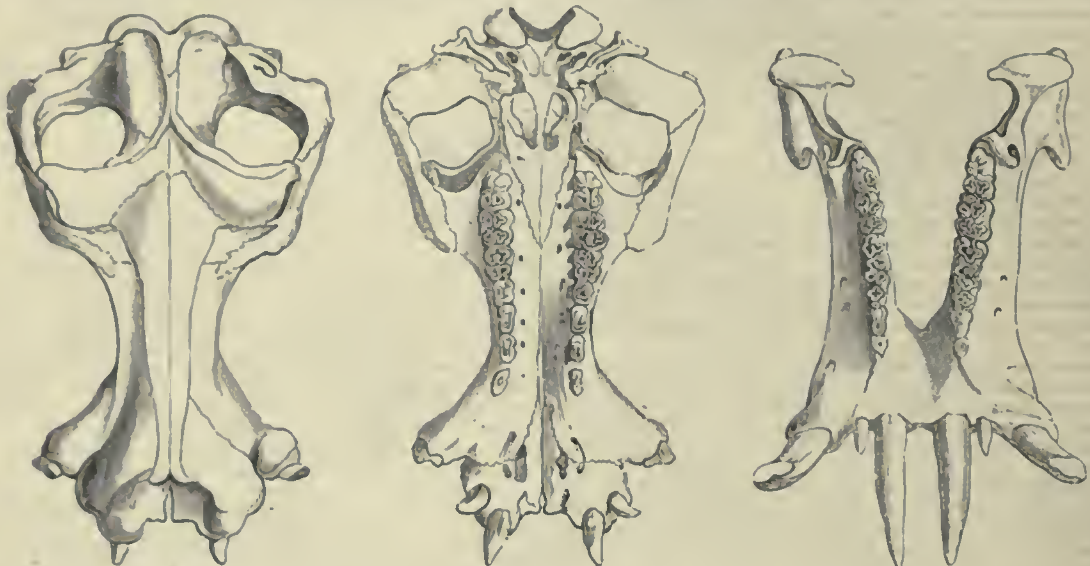
In the lower jaw the first incisor is long, subcylindrical, terminated in a point, and a little worn on its external side. The second is of the same form as the first, but much smaller. The canines are enormous tusks sharpened into a somewhat chisel-like edge, the polished and abraded internal surface of which presents a shape inclined to elliptical. The molars form a continuous series; the first and the second are false molars, the first being the smallest, and dropping as the animal advances in age, never to be replaced. The four succeeding teeth exhibit the same general forms as those of the upper jaw. The first, which is smaller than the others, has an anterior isolated tubercle: the succeeding teeth are nearly of the same size, and have also an isolated tubercle, but it is posterior.

Cuvier makes the first section of his second family of Pachydermatous Mammifers (Ordinary Pachyderms) consist of those which have four, three, or two toes; and these he separates into two great genera, the *Hippopotami* and the Hogs [SUIDÆ]. The *Hippopotamidæ* are further characterised generically as having on all their feet four toes, which are nearly equal and terminated by small hoofs (sabots), an immensely massive body destitute of hair, very short legs, a belly trailing against the ground, an enormous head, terminated by a large tumid muzzle which incloses their great anterior teeth, a short tail, and small eyes and ears. Their stomach is divided into many compartments. They live in rivers, on roots and other vegetable substances, and are ferocious and stupid. The genus is placed by Linnæus among his *Belluæ*, between *Equus* and *Sus*. Dr. J. E. Gray brings it under *Elephantidæ*, his third family of the fifth order, *Ungulata*, as a genus of his sub-family *Hippopotamina*, and has suggested that the form is allied to the *Halicoridæ*.

The anatomy of these creatures is in accordance with their bulk and unwieldiness.

The skeleton of the *Hippopotamidæ* approaches that of the Ox and of the Hog; but it presents differences which distinguish it from that of any other animal. The skull, whilst in the connection of the bones and the arrangement of the sutures, it bears great similitude to that of the *Suidæ*, has its own peculiarities, which render its form extraordinary.

The number of vertebræ are 7 cervical, 15 dorsal, 4 lumbar, 7 sacral, and 14 coccygial = 47. The atlas and the axis, besides the ordinary articular facets, have each two others also towards their dorsal aspect; but taken as a whole, the cervical vertebræ approach nearest to those of the Hog. There is nothing very remarkable about the rest of the vertebræ, except that their bodies are rather flat. There are 7 true and 8 false ribs of a side = 30, nearly as much arched as those of the Rhinoceros, but distinguishable from them, as well as from those of the Elephant, in as much as they are much wider and flatter at the part nearest to the vertebræ than at the opposite end. The anterior part of the sternum is compressed into a ploughshare-like shape and very much prolonged into an obtuse point below the first rib. The rest is depressed, and the number of pieces is seven. The scapula may be easily distinguished from those of the Rhinoceros and Elephant, being larger than that of the first and less than that of the second, and also differing in form. In its general aspect this bone reminds the observer a little of the scapula of the Hog, but approaches nearer to that of the Ox in the more essential characters of the spine and articulating surface. The humerus bears a singular resemblance to that of the Ox; while there is some similitude to that of the Hog, which is however less in proportion towards the bottom. The radius and ulna are anchylosed at an early age, leaving on the outside only a rather deep furrow which occupies only three-fourths of the length of the radius, and on the inside a simple aperture towards the upper fourth part. These bones of the fore-arm resemble those of the Ox very much, but those of the latter are more elongated, and the articular facets of the lower head of the bone are, in the last-named animal, less oblique. There are in the carpus points of resemblance to the Hog; but its characters distinguish it both from that quadruped and the Ox. In the metacarpus all comparison with that of the Hog ceases. The pelvis is easily distinguishable from those of the Elephant and Rhinoceros, from the smaller width of the ilia in the Hippopotamus, and other differences. The Ox perhaps approaches it more closely in these parts; but, besides other discrepancies, the lower part of the pelvis and especially the oval holes are much more elongated in the Hippopotamus. The sacrum is very large, but the bones of the pubis project but very little. The femur, which possesses a ligamentum teres, is well-shaped and straight, the shaft nearly equal throughout, regularly cylindrical anteriorly. The great trochanter, which is compressed laterally, does not exceed the height of the head of the bone; the small trochanter is moderate: there is no third, as in the Rhinoceros, the Tapir, and the Horse. But its principal resemblance is to the femora of the great ruminants; though the upper head of the bone is much more detached and more spherical, and the lower head is much wider, especially behind. These differences will assist in distinguishing it from the femur of the Ox; that of the Giraffe, which, being of the same size, might more readily be mistaken for it, may be known by its more approximated upper head, its relatively larger condyles, and the more elevated and pro-

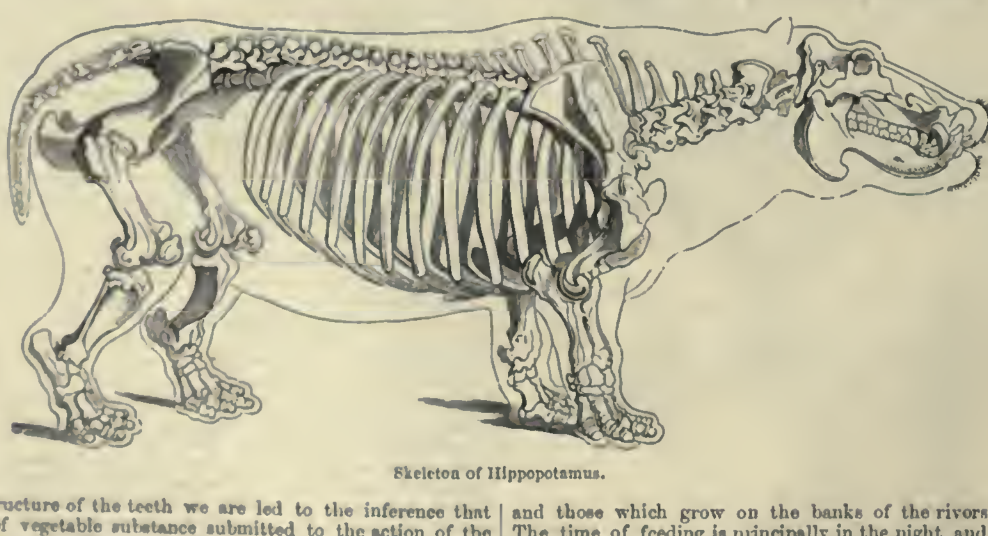


a b c

Skull of Hippopotamus.

a, seen from above; *b*, seen from below; *c*, lower jaw seen from above.

jecting internal edge of the lower articulating surface. The femur of the Hog more resembles that of the Hippopotamus in the upper part, but much less below; and its dimensions prevent the possibility of a mistake. The tabia is short and stout, almost beyond that of any other quadruped, especially at the extremities. It approaches nearest to that of the Ox, but the latter is more elongated, and differs in other respects. The tibia of the Hog is also more elongated in comparison, and offers other discrepancies. The fibula is very slender, and is throughout very distant from the tibia, except at the two extremities. The malleolar bone is anchylosed to the lower extremity. The tarsus is framed principally on the plan of that of the *Suidæ*.



Skeleton of Hippopotamus.

From the structure of the teeth we are led to the inference that the quantity of vegetable substance submitted to the action of the digestive organs of the *Hippopotamidæ* must be very great in proportion to the nourishment extracted from the mass. The principle on which the jaws and teeth are constructed seems to be a principle for rudely tearing and dividing, but not comminuting, the hard and tough vegetables which form the staple food of the animal. The jaws are so constructed that the process executed by them is more a bruising than a grinding process. The food therefore when transmitted to the stomach has undergone but little alteration, and that organ is employed in extracting from the coarse and ill-prepared load the greatest amount of nutritive matter. The stomach of a full-grown Hippopotamus is said to be capable of containing five or six bushels, and the large intestine is of a size commensurate with such a capacity, for it is stated to be eight inches in diameter. The Hippopotamus mentioned by Mr. Burchell ('Travels in South Africa') was considered to be only half grown, but three bushels, at least, of half-chewed vegetables were taken from its stomach and intestines.

The time of gestation of the Hippopotamus is stated to be nine months; but this does not seem to be accurately ascertained. The birth takes place on the land; and on the slightest alarm both parent and young take to the water. Thunberg, during his visit to Caffraria (1773) was assured by an eye-witness that he, having watched, when on a hunting party, one of these animals which had gone up from a neighbouring river to calve, lay still with his company till the calf was produced, when one of the party fired and shot the mother dead. The Hottentots immediately rushed from their hiding-place to take the calf alive, but its instinct saved it, for it made for the river, and escaped. The male specimen now (1854) in the Gardens of the Zoological Society, Regent's Park, was with difficulty caught, though only two days old. The food of the Hippopotamus consists of water-plants and those which grow on the banks of the rivers which it haunts. The time of feeding is principally in the night, and these enormous animals, when in the neighbourhood of cultivated lands, do incalculable damage, not only from the quantity that they actually consume, but the still greater quantity that they spoil and lay waste by their crushing bulk. As they are able to remain beneath the surface of the water for some time, there must be some muscular arrangement for closing the nostril, such as we see in the Seals. Hasselquist, on the authority of 'a credible person' who lived twelve years in Egypt, states: "1, that the hide of a full-grown Hippopotamus is a load for a camel. 2, that the River-Horse is an inveterate enemy to the Crocodile, and kills it whenever he meets it. 3, that the River-Horse never appears below the cataracts in Egypt,* wherefore the inhabitants of Upper Egypt only can give any account of it. The Egyptians, he adds, very seldom bring the hide of it to Cairo; and, he continues, it is impossible to bring thither the living animal. 4, the River-Horse does much damage to the Egyptians in those places he frequents. He goes on shore, and in a short space of time destroys an entire field of corn or clover, not leaving the least verdure as he passes; for he is voracious, and requires much to fill his great belly. They have a curious manner of freeing themselves, in some measure, from this destructive animal: they remark the places he frequents most, and there lay a large quantity of peas; when the beast comes on shore, hungry and voracious, he falls to eating what is nearest him, and filling his belly with the peas, they occasion an insupportable thirst; he then returns immediately into the river, and drinks upon these dry peas large draughts of water, which suddenly causes his death; for the peas soon begin to swell with the water, and not long after the Egytians find him dead on the shore, blown up, as if killed by the strongest poison. 5, the oftener the River-Horse goes on shore, the better hopes have the Egyptians of a sufficient swelling or increase of the Nile. 6, the Egyptians say, that they can almost distinguish the food of this animal in his excrements." Some parts of this relation (that regarding the peas, for instance) may be considered as bordering upon the marvellous, but there are others which there seems to be no good reason for doubting. The alleged enmity to the Crocodile can hardly be considered to be well founded.

In Professor Smith's 'Journal' (Tuckey's 'Narrative of an Expedition to explore the River Zaire, usually called the Congo, in South Africa') we find it stated that they "landed in a beautiful sandy cove at the opening of a creek behind a long projecting point. It is called Sandi-Sundi. An immense number of Hippopotami were seen here. In the evening a number of Alligators were also seen." This association would be hardly consistent with hostility. Captain Tuckey also says, "The Hippopotamus and Alligator seem to be numerous." The usual mode of capturing the animal is by a pitfall, by the natives at least, but the colonists near the Cape use the rifle. The two killed by Zerenghi, in the year 1600, frequented the neighbourhood of the Nile, near Damietta. He stationed men upon the Nile, who, having seen two of these animals go out of the river, made a large ditch in the way through which they passed, and covered it with thin planks, earth, and herbage. In the evening, when returning to the river, they both fell into the ditch. Zerenghi immediately hastened to the place with his janizary, and they killed both the beasts by pouring three shot into the head of each with a large arquebus. They almost instantly expired, he adds, after uttering a cry which had more resemblance to the bellowing of a buffalo than to the neighing of a horse. Captain Tuckey observed Hippopotami with their heads above the water, "snorting in the air." In another part of his 'Narrative,' he says, "Many Hippopotami were visible close to our tents at Condo Yanga, where we were obliged to halt, and to wait some time for a canoe to pass. No use firing at these animals in the water; the only way is to wait till they come on shore to feed at night. During the night they kept a continual grunting like so many hogs, but none of them came on shore, though we had a constant watch on the beach." Sparrman, who gives a ludicrous account of the terror which seized him and some of his companions on the rush of one of these animals towards him from the river, thus describes the noise made by one of these 'sea-cows' at Great Fish River:—"At half an hour after eight, it being already very dark, a sea-cow began at intervals to raise its head above the water, and utter a sharp, piercing, and, as it were, very angry cry, which seemed to be between grunting and neighing. Perhaps this cry may be best expressed by the words 'heurb, hurb, heoh-heoh:' the two first being uttered slowly, in a hoarse but sharp and tremulous sound, resembling the grunting of other animals; while the third, or compound word, is sounded extremely quick, and is not unlike the neighing of a horse. It is true, it is impossible to express these inarticulate sounds in writing to any great degree of perfection; but perhaps one may make nearer approaches to it than one can to the gutturopalatial sounds of the Hottentot language." Le Vaillant had an opportunity of watching the progress of a hippopotamus under water at Great River. "This river," says he, "contained many hippopotami; on all sides I could hear them bellow and blow (mugir et souffler). Anxious to observe them, I mounted on the top of an elevated rock which advanced into the river, and I saw one walking at the bottom of the water (marcher et se promener au fond de l'eau). But I remarked that its colour, which when it is dry is grayish, and when it is only humid and moist appears bluish, seemed then to be of a deep blue. I killed it at the moment when it came to the surface to breathe. It was a very old female, and my people in their surprise, and to express its size, called it the 'grandmother of the river.'" ('Second Voyage.') Mr. Barrow, in his journey into the interior of Southern Africa, when he reached the mouth of the Great Fish River, saw towards the evening a vast number of Hippopotami (Sea-Cows of the Dutch) with their heads above the surface. Several paths made by these animals led from various parts of the river to a spring of fresh water about a mile distant. To this spring they went in the night to drink; the water of the river for some distance from the mouth being salt. According to Dampier and others, the Hippopotamus, when wounded or irritated, is violently ferocious, and has been known to sink a boat by its bite.

For a long time it was considered that there was but one species of living Hippopotamus; but some naturalists are of opinion that there are at least two. Before we enter into this part of the subject we shall give a slight sketch of the history of the Hippopotamus from the time of the ancients.

If the Hippopotamus be the Behemoth of Job (ch. xl.), we must refer to the well-known verses 15 to 19, both inclusive, as the earliest description of the animal. But the identity is by no means satisfactorily ascertained. The vulgate uses the term Behemoth, and the Zürich version translates the word by 'Elephas.' In the edition of the Bible, 'imprinted at London by Robert Barker, printer to the King's most excellent Majestie' (1615), Behemoth is the word in the text, with the following annotation:—"This beast is thought to bee the elephant, or some other which is unknowen." Bochart, Ludolph, Scheuchzer, and many others hold that the Hippopotamus is the animal meant; while not a few of the learned have written in support of the Elephant. Cuvier and others think that though we may believe with Bochart that the Hippopotamus is intended, the description in the book of Job is too vague to characterise it. Good comes to the conclusion that some extinct pachydermatous genus was probably represented by the term; and some have lately even gone so far as to contend that Behemoth and the Iguanodon of geologists are identical!

Herodotus (ii. 71) gives a most incorrect description of what must be regarded, from the context and other evidence, as the Hippopotamus. This description is borrowed almost entirely by Aristotle, who has not however given to the animal a horse's tail, which Herodotus bestowed upon it; adding, correctly enough, that its size was that of the largest oxen.

Aristotle ('Hist. Anim.,' book ii. chap. vii.) thus describes the Hippopotamus:—"The Hippopotamus of Egypt has a mane like a horse; a bifurcated hoof like the ox; a flat visage or muzzle; an astragalus like the animals with cloven feet; projecting teeth which do not show themselves much; the tail of a hog; the voice of a horse; and in size it resembles an ass. Its skin is of such a thickness that spears are made of it." Now, there is enough in this curious description to lead to the conclusion that Aristotle meant no other than the Hippopotamus; there is also quite sufficient to show that he never saw the animal, and that he trusted to the wild accounts of others. We trace however the descriptions of Herodotus and Aristotle in many of the figures of the animal which were published after the revival of letters; for it is worthy of remark that notwithstanding the highly erroneous descriptions of ancient authors, some of whom must, one would think, have had an opportunity of seeing the animal, the portraits of it by ancient artists on coins, &c., are, almost without exception, far from bad representations of the animal. But to return to the ancient authors.

Diodorus (book i.) comes much nearer to the truth in his description, at least as to the size of the Hippopotamus; for he says that it is five cubits in length, and in bulk approaches to that of the Elephant. The teeth are not badly characterised by the same author; but he still leaves to the animal the cloven hoof and the horse's tail.

Pliny says of it (book viii. 25), after treating of the Crocodile and *Scincus*, "Major altitudine in eodem Nilo belua hippopotamus editur," and he gives it the bifid hoofs of the ox, the back, mane, and neigh of the horse, a flattened muzzle, the tail and teeth of the boar, adding, that though they are hooked they are less noxious—"ungulis bifidi quales bubus, dorso equi, et jubâ, et hinnitu, rostro resimo, caudâ et dentibus aprorum, aduncis, sed minus noxiis." In short he seems to have followed with very little exception the account given by Aristotle, without attending to that of Diodorus. Pliny adds, that helmets and bucklers are made of its skin, which are impenetrable unless they are softened by moisture, and he speaks of its feeding on the crops "depascitur segetes," and its caution in avoiding snares. In his 9th book and 12th chapter, on the covering of aquatic animals ('Tegmenta Aquatilium'), the varieties of which he enumerates, he says, "Alia corio et pilis teguntur, ut vituli et hippopotami;" thus making it hairy like the seals, which we take to be meant by 'vituli;' and yet, with all this monstrous error, he himself (book viii. 26) speaks of M. Scaurus as being the first who had shown the hippopotamus, together with five crocodiles, at Rome, during his ædileship; finishing the account however by making the former animal a master of one department in the art of healing, in consequence of his habit of letting blood by pressing the vein of his leg against some very sharp stake when his obesity requires such relief. We know moreover that Augustus exhibited one of these animals on occasion of his triumph over Cleopatra. (Dion., book li.). We shall only further refer to the account of Achilles Tatius (book iv. 2), which is, notwithstanding some errors, perhaps the most correct; and shall proceed to notice that, under the later emperors, a considerable number of Hippopotami were introduced into the Roman shows. Thus Antoninus exhibited some, with crocodiles, tigers, and other

* That it was found in Lower Egypt in the year 1600 appears by Zerenghi's account above given. Hasselquist travelled in the years 1749-52.

animals. Commodus showed five on one occasion, and killed some of them with his own hand. Heliogabalus and the third Gordian also exhibited Hippopotami. These demands seem to have produced their effect; for according to Marcellinus Ammianus (book xxii. 15) and others, the race of Hippopotami had disappeared from Egypt since the time of the emperor Julian. Favourable circumstances however must have operated to restore it, as we collect from the account of Zerenghi above alluded to and others. That the animal was sacred, in some parts at least, appears from Herodotus (book ii., 'Euterpe'): "Those which are found in the district of Papremis are sacred, but in other parts of Egypt they are not considered in the same light." * Sonnini ('Travels in Upper and Lower Egypt'), who quotes this passage, and also one from Pausanias (book iv. 33), goes on to state that these animals laid waste whole countries by ravages as fearful as their size was enormous, and that they were equally formidable to man with the crocodile. From the terror which they inspired, they were, he asserts, generally looked upon as the symbol of Typhon, that giant who had spread death and destruction among the deities which were worshipped in that quarter; they were, he adds, of course the emblem of mischance and of cruelty, and the particular worship of them at Papremis must have been practised solely with the view of appeasing or averting their rage.

We have mentioned that with few exceptions, if not with one only, the representations of the ancient artists have been found faithful to nature when compared with the descriptions of ancient naturalists and authors. The exception is the figure copied by Hamilton ('Ægyptiaca,' pl. xxii.) from one of the caves of Beni-Hassan, in which the feet are represented as cloven, and the lower tusks are so enormous as to render it impossible that they should be covered by the lips, whereas the largely developed muzzle and its consequent concealment of the tusks are portrayed upon most of the ancient figures and coins. We do not consider the figure found by Belzoni as an exception, because, as the author of the amusing book on Egyptian Antiquities observes, the designer sometimes placed on one animal a part taken from another, and that mentioned by Belzoni was a calf with the head of a Hippopotamus. Though the details of the teeth and feet are not correct in the figure on the plinth of the statue of the Nile formerly in the Vatican, and afterwards taken to the French Museum, its general contour is good; and the animal occurs in other sculptures and in mosaics very characteristically represented. Some of these, that of the Vatican above mentioned, for instance, may have given rise to the story of the enmity borne towards the crocodile by the Hippopotamus, which in that sculpture holds a crocodile in its mouth. On medals and coins of the Roman emperors the Hippopotamus often appears, sometimes with the crocodile, sometimes without. Those of the emperors Trajan, Hadrian, and Philip, or rather of Marcia Otacilia Severa, Philip's wife, will occur to some of our readers.

In more modern times we have the descriptions of Isidore of Seville, Vincent de Beauvais, Albertus Magnus, James of Vitry, and all more or less fabulous; but Abdallatif gives a very good account of the animal. Belon and Gillius however seem to have been the first among the moderns who actually saw, or at least who have recorded that they saw the animal alive. They both saw it at Constantinople, and perhaps they saw the same. Sonnini seems to doubt whether the animal which Belon saw was a hippopotamus ('Travels in Upper and Lower Egypt,' vol. iii.), and quotes Matthiolus, who speaks very slightingly of Belon; but a perusal of that accurate observer's account will, we think, satisfy the most scrupulous that he saw a living Hippopotamus; he even alludes to the differences between the figures of that animal on ancient works of art and the specimen which he had before his eyes, and rectifies the error in the figure on the plinth of the statue of the Nile, which has five toes instead of four. Of the teeth indeed he only remarks that they approach to those of a horse. Gesner does little but quote Belon; and without detaining the reader with the descriptions of Zerenghi, who is above alluded to, which were good, or the compilation of Aldrovandus, who did not use the figure of Zerenghi, but another sent to him from Padua (Cuvier thinks, by Prosper Alpinus), or the good description and more accurate representation given by Fabius Columna, we come to Ludolph, who, in his "History of Ethiopia,' gives an entire figure on a large scale. This is the best which had been hitherto published; but the teeth are exaggerated, and a great deal too much exposed, and the ears are rather long. Below this is a figure of "the sea-horse, putting up his head above the water; thence called the river-horse by the Greeks." The head and neck alone are visible; but the exaggeration and exposure of the teeth are continued, and the draftsman, by lengthening the neck, head, and ears has given a much more horse-like character to the figure. Thevenot, in his 'Voyage to the Levant,' very fairly describes an individual killed in his time (1658) near Girgeh, and taken to Cairo.

The date of the last of these authors is 1689, but in 1735 the work of Prosper Alpinus was published, and obscured the subject again by giving a representation of two stuffed skins, the one of a large female animal, and the other of her fœtus, which he had seen in the house of the Pasha of Cairo. These were the skins of two Hippopotami, but the skulls had been withdrawn, and the absence of the projecting teeth led Prosper to the conclusion that he had at last found in this, which he took for a distinct creature, the animal represented by the ancient artists, forgetting, or more probably not knowing, that when the Hippopotami of the present day keep their mouths closed no tooth is visible.

We need not detain the reader with a reference to the figures and descriptions given by other zoologists, as Grew, A. Jussieu, Daubenton, Pallas, Buffon, &c., but shall come at once to Linnæus, and this will bring us to the question of the geographical distribution of the genus, and of the number of species.

Linnæus, in his last edition of his 'Systema Naturæ,' gives only one species, *Hippopotamus amphibius*, and places its habitat "in Nilo et Bambolo Africæ, et ad ostia fluviorum Asiæ."

Africa appears to be the only quarter of the globe in which this form exists; and though Onesicritus (Arrian, 'Indic.,' c. 6) places the Hippopotamus in the Indus, Strabo (690, 707, Casaub.) seems to prefer the testimony of Aristobulus in contradiction of the fact, and Pausanias (iv. 34) agrees with Strabo. Cuvier, who has collected almost all the learning on this subject, well observes that no traveller of credit has reported that it has been found on the continent of India. He remarks that Buffon gave no credence to the testimony of Michael Boyn, who states China to be one of the localities; he observes that it is nearly without authority that Linnæus supposes the animal to occur at the mouths of the rivers of Asia, and is of opinion that M. Faujas appears to be well authorised in denying that it is to be found on the continent of India.

Marsden includes the Hippopotamus among the animals of the islands of Sumatra and Java; but Cuvier ('Ossemens Fossiles') enters into an interesting discussion, well worthy of the perusal of the reader, to show that Marsden is mistaken; and in addition to his arguments, he brings forward the fact that Messrs. Diard and Duvaucel, who travelled over a considerable part of Java and Sumatra in different directions, could not find a Hippopotamus, though they succeeded in obtaining two species of Rhinoceros and a Tapir. Upon the whole evidence at present known, it seems to be established that the geographical distribution of this pachydermatous form is confined to the great rivers and lakes of Africa.

We now come to the question of how many species of Hippopotamus at present exist.

M. Desmoulins ('Journal de Physiologie,' &c., par F. Magendie, tome v.) gives osteological reasons, drawn principally from the differences in the skull, for distinguishing at least two species of Hippopotamus. And upon the whole it must be allowed that he appears to be borne out in his position that the distinctions between the two species, one of which he designates as the Hippopotamus of the Cape (*H. Capensis*), and the other as the Hippopotamus of Senegal (*H. Senegalensis*), are as strong as those on which Cuvier founded his specific separation of the Fossil Hippopotamus from that of the Cape. M. Desmoulins is further of opinion that it is not impossible that the Hippopotamus of the Nile differs specifically from the other two. The external differences do not appear to be considerable, if any. M. Desmoulins indeed remarks, that of 40 Hippopotami seen by M. Caillaud in the Upper Nile, two or three were bluish-black, all the others reddish; and M. Desmoulins even hints that there may be two species in that river. The latter adds that of the two Hippopotami of the Cape possessed by the Paris Museum, one is black, the other reddish; but he considers that the numerical disproportion observed between the individuals of the two colours in the Nile can hardly admit of a sexual solution. We have examined several skulls of Hippopotami, and some of them certainly present many striking differences; but it should be remembered that safe inferences as to specific distinction can only be drawn from a very extensive examination of skeletons, combined with unquestionable data as to the locality, age, and sex of the subjects examined.

With regard to the supposed two Nilotic species, there is reason for considerable doubt; nor is much weight to be attached to the alleged difference of colour. The animal in the water and out of it presents a very different appearance; and, to say nothing of the possibility of a difference in the case of sex, there is every probability that some change in the colour may take place as the animal advances in age. We have seen the remark of Le Vaillant as to the difference of colour when the skin is dry, when it is only moist, and when the animal in full life is walking at the bottom of the river.

It need hardly be observed that the Romans must have derived their Hippopotami from Northern Africa; and as we have given Sparrmann's description, among others, of the noise made by the southern animal, we may be excused perhaps for remarking that Burckhardt ('Travels in Nubia') describes the voice of the Hippopotamus as a harsh and heavy sound, like the creaking or groaning of a large wooden door. This noise, he says, is made when the animal raises its huge head out of the water and when he retires into it again. We may also add, with regard to the alleged disappearance of the Hippopotamus from Lower Egypt, that, as Cuvier remarks, the French

* The following is the entire passage:—"Hippopotami are held sacred in the Nome of Papremis; but they are not held sacred by the rest of the Egyptians. Their nature and form are these: the animal is four-footed, bisulcated, with hoofs like those of an ox, a flat nose, a horse's mane, prominent teeth, and the tail and voice of a horse. In size it is as large as the greatest ox. The skin is so thick that when dried the shafts of darts are made of it."

savans attached to the expedition to Egypt, who ascended the Nile above Syene, did not meet with one.

We now come to an interesting period in the history of the Hippopotamus, its arrival in Europe in modern times, and its appearance for the first time within the historical period in Great Britain. On the 11th of December 1849 Mr. Mitchell communicated to the Zoological Society, at its evening meeting, the fact that a live Hippopotamus had been secured for the Gardens in Regent's Park. He then read the following extract from a letter, addressed to him by the Hon. C. A. Murray, dated Cairo, November 16th, 1849:—

"It is with the greatest satisfaction that I communicate to you the intelligence that I have succeeded in obtaining for the Society a live Hippopotamus. It is now in a yard at the back of my house, and apparently in perfect health: you cannot be more anxious than I am that I may be able to keep it through the winter, and send it to you safe in the spring. It is only five or six months' old, and still lives entirely on milk. I think a fresh importation of cows will be necessary in Cairo, as our little monster takes about thirty quarts of milk daily for his share already. H. H. Abbas Pasha has been most liberal in having the animal brought here at his own expense from the White Nile. A lieutenant and a party of ten Nubian soldiers formed his escort; a boat was built on purpose for him, and the viceroy sent him to my house in charge of the chief officer of his palace. I may also mention that, by his Highness's orders, another officer with a party of soldiers, is still out on the White Nile charged with the duty of securing a young female for us, so that I am not without hope of sending you the pair together."

In another letter the same gentleman writes—

"The Hippopotamus is quite well, and the delight of every one who sees him. He is as tame and playful as a Newfoundland puppy; knows his keepers, and follows them all over the court-yard: in short, if he continues gentle and intelligent, as he promises to be, he will be the most attractive object ever seen in our garden, and may be taught all the tricks usually performed by the elephant."

had then been born about two days. It was so small that, in his delight at having accomplished the pasha's order, he seized it in his arms, and would have carried it to the boat, which waited on him, had not the slimy exudation which is lavishly poured forth from innumerable pores in the skin of the young Hippopotamus rendered it so slippery, that he was entirely unable to retain his hold. The animal, having thus slipped from his grasp, all but escaped into the Nile, where the mother doubtless was lying near at hand. The hunter, however, with the presence of mind which characterises a good sportsman, seized his spear, and with the sharp side-hook, which has been in fashion in Egypt for three thousand years or more, he succeeded in arresting the headlong plunge of his prize, without inflicting greater injury upon him than a skin-wound, which is marked by the scar upon his ribs to this day.

"The long voyage down the river was successfully accomplished in a boat which had been built for the purpose by the viceroy's order, and 'Obaysch,' as they named the Hippopotamus from his birth-place, was safely delivered, in November 1849, after a journey of four months, into the care of the Hon. C. A. Murray, through whose powerful influence the viceroy had been prevailed on to exert his power and assist the Society in an object for which all exertions of their own had failed.

"Obaysch spent his first winter in Cairo, under the charge of his present intelligent keeper, Hamet Saaffi Canaana, a Nubian Arab whom Mr. Murray engaged for the purpose. In May 1850 proper preparations were made, with the obliging co-operation of the directors, in the Peninsular and Oriental Steam Navigation Company's ship Ripon, for the transport from Alexandria, and on the 25th of that month the first Hippopotamus which had breathed on English soil since the deluge was landed successfully on the quay at Southampton, and liberated in the Gardens, from his travelling house, at ten o'clock the same evening. On emerging from the door of it he followed Hamet, who has scarcely ever left him during the whole voyage from Cairo, into the building which had been prepared for him, and instantly

Hippopotamus.

The animal referred to in the above letter arrived in England on the 25th of May. The following account of its capture and habits in the Gardens is taken from Mr. Mitchell's 'Popular Guide' to the menagerie of the Society. A house and two tanks have been expressly built for the accommodation of this animal:—

"Since the imperial exhibitions in the Circus at Rome, no living Hippopotamus has been imported into Europe, except the young male which the Society possesses. The difficulty of obtaining such an animal may be conjectured from the fact, that after the viceroy of Egypt had determined to present one to the Society, it became necessary for his Highness to despatch an expedition to the Upper Nile for the purpose of making the capture, and that success was only achieved after two thousand miles of the river had been ascended. In the month of July, 1849, the chief huntsman of the party, in searching the reedy margin of an island in the White Nile, called Obaysch, at last discovered a little Hippopotamus calf, which, as he conjectured,

indulged in a long-continued bath. The ten hours which elapsed between his removal from the steamer at Southampton, and his arrival in the Regent's Park, is the longest period during which he has ever been without access to water.

"The slow respiration of the Hippopotamus enables him to remain for long intervals beneath the surface, and the organisation both of the ears and nostrils are beautifully adapted for this condition of his existence. The enormous size to which these animals grow has been recorded by every African traveller, and is sufficiently indicated by the skulls which are found in almost every museum. An adult male in good condition, measuring five feet at the shoulder, would certainly have three times the present bulk of Obaysch, who has most probably grown quite as fast under the treatment he has experienced as he would have done in his native river.

"The principal food of the Hippopotamus in his natural state appears to be young grass, green corn when it is to be obtained, browse of shrubs, and probably some of the great water-plants which abound in the African rivers.

"Obaysch consumes about one hundred pounds weight daily of hay, chaff, corn, roots, and green food. For the first year he was fed almost entirely on cow's milk and Indian corn-meal finely ground; and there is no doubt whatever that any of the great animals, technically called Pachyderms, such as the Elephants and Rhinoceros, might be reared by residents in Africa with perfect success in the same manner. The African Elephant and the African Rhinoceros are still wanted for the Society's collection.

"The Hippopotamus now only exists in Africa; it is found in the rivers of the south and west, as well as in the Nile; and there is also in some of the western rivers a pigmy species, of whose skull a cast was presented to the Society by the late Dr. Morton of the United States."

A hippopotamus has also been recently exhibited in the Jardin des Plants in Paris, but it died a few months after its arrival.

On Saturday, July 22nd, 1854, a second specimen, a female, of this interesting animal was safely deposited in the Gardens of the Zoological Society. At this date it was about four months old, and weighed above a ton. It was fed by its keeper opening its mouth with his hand, which he thrust down its throat, covered with milk and corn-meal. It was ascertained that this creature was not insensible to music, and when any one of the musicians on board the vessel in which it was brought, played his instrument near it, she invariably raised her head in the attitude of listening. The keeper, also an Arab snake-charmer, was in the habit of exciting the attention of his charge by a kind of musical call, which it answered by vibrating its great bulk to and fro with evident pleasure, keeping time to the measure of his keeper's song.

The uses of the Hippopotamus to man are certainly not many, but when we look at the enormous ripping chisel-like canines of the lower jaw, and the lower incisors formed for uprooting, we cannot but think that such an animal must be an active agent in clearing rivers from the greater water-plants which might in time, if left undisturbed, go far to convert the running stream into a sluggish swamp. With regard to minor details, the flesh of this Wasser Ochs is much esteemed as an article of food. In the first catalogue of the African Museum we read that it is much in request both among the natives and the colonists, and that the epicures of Cape Town do not disdain to use their influence with the country farmers to obtain a preference in the matter of Sea-Cow's Speck, as the fat which lies immediately under the skin is called when salted and dried. Nor are the whips which are made of the skin of the Hippopotami of the Nile thought lightly of in the neighbouring countries. They are said to be made by cutting the fresh skin into triangular strips some five or six feet in length: one extremity of the strip is pointed, and it gradually widens till the breadth at the opposite extremity is equal to the intended circumference of the bulk of the whip. The strip is then rolled up so as to form a sort of conical pipe, is firmly tied to keep it in place, and dried in the sun. When all is finished a light and elastic whip is produced. But there is no part of the hippopotamus in more request than the great canine teeth, the ivory of which is so highly valued by dentists for making artificial teeth. No other ivory keeps its colour equally well;* and these canine teeth are imported in great numbers to this country (where more are sent in the first instance than anywhere else perhaps) for this purpose, and sell at a very high price. From the closeness of the ivory, the weight of the tooth, a portion only of which is available for the artificial purpose above mentioned, is heavy in proportion to its bulk; and the article fetches, or did fetch, upon an average, about thirty shillings, more or less, per pound. One of the specific distinctions pointed out by M. Desmoulins is the comparative abrasion of the canines in the supposed two species; and we would call the attention of the curious who deal in these teeth to this circumstance and the papers above quoted.

Fossil Hippopotami.

The remains of several species of Hippopotamus have been found which are now extinct. Amongst others, the following have been recorded:—*H. antiquus*, *H. minor*, *H. medius*, and *H. minimus*. These have been found in the tertiary beds of Europe. A larger species than any of these has been found in Great Britain, and identified by Professor Owen with *H. major*, Cuv. The following notice of this species occurs in his 'History of British Fossil Mammals:'—

"In glancing retrospectively towards the dawn of the scientific investigation of fossil remains, one is struck with the early introduction of the idea that the Hippopotamus had contributed to those found in the temperate latitudes of Europe: this amphibious quadruped seems in fact to have been the first to which large fossil bones and teeth were referred, after the notion that they were relics of giants of the human species began to be exploded.

"Thus the learned Saxon scholar Somner acquaints us that some who had seen the Chatham fossils were of opinion that they were bones of a river-horse; and the antiquarian Douglas misinterpreted in like manner the jaw and teeth of a rhinoceros, much of the ingenious speculations in his 'Dissertation on the Antiquity of the Earth' being based on the assumption that the fluviatile deposits at Chatham, in the instance which he describes, had yielded 'hippopotamic remains.' 'When we consider,' he says, 'the great distance from the Medway to the Nile, or other rivers near the tropics where these kind of animals are now known to inhabit, and when we have no authority from the Pentateuch to conclude that any extraordinary convulsion of nature had impelled animals at that period from their native regions to countries so remote, so we have no natural inference for concluding that the deluge was the cause of this phenomenon. Taking into consideration the geological features of the stratum of the river soil, he concludes 'that, as the hippopotamus is known to be the inhabitant of muddy rivers like those of the Nile and the Medway, it should therefore argue that this animal was the inhabitant of those regions when in a state of climature to have admitted of its existence.'

"This conclusion is essentially correct, though based in the present instance on wrong premises: neither the organic remains from Chatham, any more than those from Chartham, having appertained to a 'river- or sea-bred creature.' The genus of land-quadrupeds to which these fossils actually belonged is nevertheless at the present day as much confined to the tropics as the hippopotamus. No long time elapsed before true hippopotamic remains were found in the same deposits which had yielded the bones and teeth of the rhinoceroses. It was most probably from fresh-water marl that the entire skull of the hippopotamus was obtained, which is stated in Leo's 'Natural History of Lancashire' to have been found in that county under a peat-bog, and from which work Dr. Buckland has copied the figure given in plate xxii., fig. 5, of the 'Reliquiæ Diluvianæ.' From the indication of the second pre-molar in this figure we may, I think, discern the greater separation of that tooth from the third pre-molar, which forms one of the marks of distinction between the fossil and recent hippopotamus. Mr. Parkinson, in the third volume of his 'Organic Remains,' 4to., 1811, p. 375, treating of the Hippopotamus, says, 'In my visits to Walton, in Essex, I have been successful in obtaining some remains of this animal.' These fossils are now in the museum of the Royal College of Surgeons, and are referrible to the extinct species subsequently determined by Cuvier in the second edition of the 'Ossemens Fossiles,' under the name of *Hippopotamus major*. The first specimen, cited by Mr. Parkinson as 'an incisor of the right side of the lower jaw,' is the great median incisor, which when entire must have been 18 inches in length. It has lost much of its original animal matter, and is considerably decomposed. This tooth may be distinguished from the straight inferior tusk of the Mastodon by its partial investment of enamel; or when this is lost, as in the decayed specimen from the till at Walton, by the fine concentric lines on the fractured surface of the ivory, the corresponding surface in the tusk of the Mastodon presenting the decussating curvilinear striæ. The second specimen from Walton is thus described by Mr. Parkinson:—'The point of an inferior canine tooth or tusk, measuring full nine inches in circumference, and having seven inches in length of triturating surface.' From the great size of this tooth it is very likely to have belonged to the same animal to which the preceding tooth belonged. Besides the longitudinal striæ and grooves observable in the enamel of its sides and inferior parts, it is characterised by strong transverse rugous markings, which are placed at nearly regular distances of about two inches, and are observed to exist in the same manner on the fragment which joins to it. The third specimen described in that work is a fragment of the left lower canine tusk of a young hippopotamus; it had scarcely come into use, and the pulp cavity extends to near the apex of the conical and unworn crown. From the absence of the transverse rugous markings in the enamel, and the roundness of the circumference of this first-formed portion of the tusk, Mr. Parkinson was induced to suspect that it might have belonged to the small hippopotamus; but similar modifications are observable in the recently-protruded tusk of the young African hippopotamus, and are doubtless due to the immaturity of the individual of the fossil species which yielded this small tusk.

"Mr. Parkinson says, 'Remains of the Hippopotamus have been found, I am informed, in some parts of Gloucestershire,' and prior to the publication of the third volume of the 'Organic Remains,' Sir Everard Home had deposited in the museum of the College of Surgeons a tooth—the third pre-molar, right side upper jaw—of the *Hippopotamus major*, Cuv., which had been dug up in a field called Burfield, in the parish of Leigh, five miles west of Worcester. Mr. Strickland's valuable observations on the fluviatile deposits in the valley of the Avon, have confirmed these indications of the remains of the hippopotamus in that locality, and have thrown much light on the conditions under which the extinct species of that now tropical genus of Pachyderms formerly existed in the ancient waters that deposited those sands. Mr. Parkinson lastly cites the remarkable discovery by Mr. Trimmer of the remains of the hippopotamus in the fresh-water deposits at Brentford, an account of which Mr. Trimmer afterwards communicated to the Royal Society, with excellent figures of the principal fossils of the hippopotamus and of those of the mammoth, rhinoceros, and a large deer therewith associated.

"These specimens were collected in two brick-fields; the first about half a mile north of the Thames at Kew Bridge, and with its surface about 25 feet above that river at low water. The strata here are:—1st, sandy loam, from six to seven feet, the lowest two feet slightly

* Pausanias (viii. 46) mentions the statue of Dindymene, whose face was formed of these teeth instead of elephant's ivory.

calcareous; this yields no organic remains. 2nd, sandy gravel a few inches thick, with fluviatile shells and a few bones of land animals. 3rd, loam, slightly calcareous, from one to five feet; between this and the next stratum peat frequently intervenes in small patches of only a few yards wide and a few inches thick: here bones and horns of ox and deer occur, with fresh-water shells. 4th, gravel containing water; this stratum varies from two to ten feet in thickness, and is always deepest in places covered by peat; in it were found the remains of the mammoth, teeth of the hippopotamus, and horns and teeth of the aurochs. This stratum like the fresh-water deposits at Clacton, with similar mammalian fossils, rests upon the Eocene London clay, the fossils of which are, as Mr. Trimmer correctly observes, 'entirely marine.'

"The first stratum in the second brick-field is a sandy loam, calcareous at its lower part, eight or nine feet thick, in which no organic remains were observed. In the second stratum, consisting of sand, becoming coarser towards the lowest part, and ending in sandy gravel from three to eight feet, 'were found always, within two feet of the third stratum, the teeth and bones of the hippopotamus, the teeth and bones of the elephant, the horns, bones, and teeth of several species of deer and ox, and the shells of river fish. The remains of hippopotami are so extremely abundant, that in turning over an area of 120 yards in the present season,' (1812) 'parts of six tusks have been found of this animal.' Mr. Trimmer adds, that 'the gravel stones in this stratum do not appear to have been rounded in the usual way by attrition, and that the bones must have been deposited after the flesh was off, because in no instance have two bones been found together which were joined in the living animal; and farther, that the bones are not in the least worn, as must have been the case had they been exposed to the wash of a sea-beach.'

"When the flesh and ligaments of dead hippopotami decomposing in African rivers have been dissolved and washed from its bones, these will become detached from one another, and may be separately imbedded in the sedimentary deposits at the bottom of the river without becoming much water-worn in their course previous to entombment. Although therefore the bones of the Brentford hippopotamus were imbedded after the flesh was off, the individual to which they belonged might not have been transported from any great distance, the phenomena being perfectly in accordance with the fact that the animal had lived and died in the stream with the fresh-water mollusks, the shells of which characterise the sedimentary deposit in which its bones were subsequently buried.

"All the well-observed phenomena attending the discovery of hippopotamic remains, have concurred in establishing the truth of the conjecture of Douglas, that such animals, though now tropical, were formerly inhabitants of these regions. Additional arguments, as novel as ingenious, in support of the same conclusion have been deduced by Dr. Buckland, from his examination of the cave of Kirkdale, and of the remains of the quadrupeds, including the hippopotamus, which he discovered in that remarkable depository of organised fossils. Of the great amphibious Pachyderm, he cites six molar teeth, and a few fragments of canine and incisor teeth, 'the best of which are in the possession of Mr. Thorpe of York.'

"'These teeth of the hippopotamus therefore, like the teeth of the mammoth, associated with them in the Kirkdale Cave, prove that they were young and inexperienced individuals that had fallen into the clutches of the co-existing predatory *Carnivora*, which made that cave their lurking place, and perfectly coincide with the conclusions which Dr. Buckland thus enunciates:—'The facts developed in this charnel-house of the antediluvian forests of Yorkshire, demonstrate that there was a long succession of years in which the elephant, rhinoceros, and hippopotamus had been the prey of the hyænas, which, like themselves, inhabited England in the period immediately preceding the formation of the diluvial gravel; and if they inhabited this country, it follows as a corollary that they also inhabited all those other regions of the northern hemisphere in which similar bones have been found under precisely the same circumstances, not mineralised, but simply in the state of grave-bones imbedded in loam, or clay, or gravel, over great part of northern Europe, as well as North America, and Siberia. Fossil remains of the hippopotamus have been found in some abundance, and in a more perfect state than those in the fluviatile deposits of the valley of the Thames and Avon, in the formation of clay and sand with lignite beds, also of fresh-water origin, that overlie the Norwich Crag upon the eastern coast of Norfolk.'"

Remains of the extinct Hippopotamus have been found in other caves in England besides Kirkdale, as at Kent's Hole, Torquay, and at Durdham Common. The shells which were found by Mr. Strickland with the remains of this animal, indicate that no great difference of temperature existed from that which we find at the present day. The remains of *H. major* are not uncommon along the European shore of the Mediterranean. No remains of it have been found in any part of Asia. In the fossils from the Sewalik Hills, found by Dr. Falconer and Captain Cautley, there is a representative of the hippopotamus with six incisive teeth in the lower jaw. For this form the subgeneric name *Hexaprotodon* has been proposed. We have no evidence of the Hippopotamus having existed upon our planet anterior to the pliocene division of the tertiary period; and the ancient extinct species, like that of the recent form, seems to have been confined to the eastern hemisphere.

HIPPOPUS. [TRIDACNIDÆ.]

HIPPOTHE'RIUM, the name of an extinct species of *Mammalia* allied to the Horse, found and described by Professor Kaup, from the strata of sand at Epplesheim, near Altzey, about 12 leagues south of Mayence, referrible to the second or Miocene period of the Tertiary Formation.

HIPPOTHOA, a genus of Animals belonging to the family *Polyzoa*. It is characterised by a confervoid polypidom, adherent, and creeping, calcareous, irregularly branched, the branches frequently anastomosing, formed of elliptical cells linked to each other at the extremities; aperture lateral near the distant end. Dr. Johnston enumerates three British species, *H. catenularia*, *H. divaricata*, and *H. sica*. They are found encrusting shells and other objects in deep water.

HIPPOTIGRIS. [EQUIDÆ.]

HIPPU'RIS (from ἵππος, a horse, and οὐρα, tail, from the resemblance of the stem to a horse's tail), a genus of Plants belonging to the natural order *Haloragaceæ*. [HALORAGACEÆ.] It has the calyx-limb very minute, obsoletely 2-lobed; no petals; one stamen; a filiform style lying in a channel of the anther; the stigma simple, acute; the fruit nucumentaceous, 1-celled. Three species of this genus have been described. Of these, *H. vulgaris*, the Common Mare's-Tail, is found abundantly throughout Europe and North America. It has linear leaves, 6-12 in a whorl, and callous at the point. It is found in ditches and lakes. In deep water the submersed leaves are flaccid and pellucid, and not callous at the points. This plant is very common in Great Britain in stagnant waters and slow streams. (Babington, *Manual of British Botany*.)

HIPPURITES, a name given by Knorr and Schroeter to a Fossil Coral (*Cyathophyllum ceratites*, Goldfuss) of the Eifel Transition Limestone. Guettard also used this title for a lamelliferous coral.

By Lamarck, Defrance, and other writers, this name is given to a somewhat problematical group of fossils found in limestones of the Oolitic age which flank the Alps in the Untersberg, near Salzburg, at Regensburg, &c., in the Chalk of Perigord, Alet, &c.

Lamarck places *Hippurites* with *Belemnites*, and *Orthoceratites* among the *Cephalopoda*. ('Conchyliologie: Nouv. Dict. des Sciences Nat.') Latreille takes nearly the same view as Lamarck. ('Familles Naturelles' du 'Règne Animal.') Rang, referring to *Batolites* and *Raphanistes* of Montfort, and *Amplexus* of Sowerby (which is certainly a lamelliferous coral), introduces the genus among the acephalous *Rudista*, according to the views of De Blainville.

The structure of the *Rudista* has been studied by M. Ch. Desmoulins and M. Deshayes, and the location of *Hippurites* in that group may, on their competent authority, be definitively adopted. Considered as a bivalve shell, whose valves are excessively unequal, one may be described as cylindrical, conical, or curved; the other as flat, or tumid externally, and operculiform. The laminæ of the large valve are sometimes separated, as in some spondyli, and subject to such convolutions on one part of the circumference as to cause the appearance of longitudinal siphons immersed in the shell. Those are arguments, but very insufficient ones, for comparing *Hippurites* with *Cephalopoda*. The shell is fibrous, or rather formed of prismatic cells, of a 6-sided figure, in a longitudinal direction, which have been compared to the cellular structure of the shells of *Balanus*. The shells are sometimes attached side by side, as two portions of a coral. The internal cavity is far from corresponding to the external figure of the shell, and the cast in this cavity has been called *Birostrites*.

The abundance of these fossils in certain calcareous bases of the Chalk or top of the Oolitic formation in the Pyrenees, the Untersberg near Salzburg, the Bellunese, &c. is extraordinary, so that particular strata receive from the circumstance the name of Hippurite Limestone.

HI'PTAGE, a genus of Plants of the family of *Malpighiaceæ*, better known by the name *Gærtnera*, given it by Schreber in honour of the celebrated Gærtner; though the name assigned by himself, as prior, is now alone admitted. The genus contains only two species: one, *H. Madablota*, figured by Sonnerat under the latter name ('Voy.' ii. t. 135), which is common in the forests of many parts of India; the other, *H. obtusifolia*, is found in China, but commonly cultivated as an ornamental plant in India. Both species are remarkable for their great size as climbers, ascending to the tops of the loftiest trees, and hanging down in elegant festoons of white flowers.

HIRCUS. [CAPREÆ.]

HIRLING, a local name for the Salmon Trout. [SALMONIDÆ.]

HIRUDINE'LLA, a name given by M. Bory to a genus of *Microzoaria*.

HIRUDINIDÆ. [ANNELIDA.]

HIRUNDINIDÆ, a family of Birds belonging to the order *Insessores*, and the division *Fissirostres*. They include the species of birds known by the name of Swallows and Martins. Many of these are inhabitants of the British Islands. The following are the forms described in Yarrell's 'History of British Birds:'—

Hirundo.—Beak very short, depressed, and very wide at the base;

upper mandible curved downwards at the point; the culmen elevated; nostrils basal, oval, partly covered by membrane; legs short; toes slender, three in front, one behind; claws curved; wings long and pointed.

H. rustica, the Swallow, the Chimney-Swallow.

H. urbica, the Martin, the Martin-Swallow, the House-Martin.

H. riparia, the Sand-Martin, the Bank-Martin.

Cypselus.—Beak very short, triangular at its base, wide, concealed, depressed, gape extending beyond the eyes; upper mandible hooked at the point; nostrils longitudinal, near the ridge of the beak, open, the edges raised, and furnished with small feathers; tarsi very short; toes four, all directed forwards and entirely divided; claws short, strong, and curved; wings very long; the first quill-feather a little shorter than the second.

C. apus, the Swift, the Swift Swallow, the Common Swift.

C. alpinus, the Alpine Swift, the White-Bellied Swift.

For an account of the other members of the family, see SWALLOW TRIBE.

HISINGERITE. [THRAULITE.]

HISTOLOGY (ἱστὸς and λογὸς), that department of science which embraces the facts relating to the ultimate structure of the parts of plants and animals. These facts have been usually comprehended under the term General Anatomy, but more recently it has been found convenient to use the term Histology. It is only recently that this word could be needed, for the observations upon which the science is founded have only been made since the extensive employment of the microscope. It may be said to have originated with Marcellus Malpighi (1628-94) and Anton von Leeuwenhoek (1622-1723) at the time when magnifying glasses were first constructed of such a kind as to be useful in observing the structure of plants and animals. The ultimate composition of organised bodies was unknown to ancient observers, as well as those who lived in the middle ages. It is true that Aristotle and Galen speak of homogeneous and heterogeneous parts of the body; and Fallopius, at the beginning of the 16th century, defined still more accurately the idea of what are now called the tissues of the body, yet the more minute structure of these parts was entirely hidden from these observers. Even after the time of Malpighi and Leeuwenhoek little was done towards unravelling the intimate structure of the tissues till the beginning of the present century. We can only point to such men as Fontana, Muys, Lieberkühn, Hewson, and Prochaska, as having engaged in isolated observations upon the structure of various parts of the body. It was not till the year 1801 that a connected view of the tissues of the human body was given to the world, in such a form as to lay the foundations of what is now called the science of Histology. The 'Anatomie Generale' (Paris, 1801) of Bichat was in fact the first attempt to treat the subject of Histology scientifically. It was not so much that Bichat contributed new observations on this subject, as that he systematically arranged what had hitherto been done, and called attention to the importance of the subject, and to the fact that it lay at the foundation of all physiological and pathological inquiries.

In the direction of botany, the present century witnessed the observations of Robert Brown, who was the first to draw the attention of botanists to the importance of minute observations on the tissues of plants. One of the earliest attempts at a systematic arrangement of the tissues of plants was made by Slack, in the 39th volume of the 'Transactions of the Society of Arts,' in a paper on the Elementary Tissues of Plants and on Vegetable Circulation. Observations upon the cellular and vascular structure of plants multiplied, and a greater value and interest was given to these than they had before possessed by the observations of Schleiden on the origin and development of the cells of plants in his paper on Phytogenesis, published in Müller's 'Archiv fur Anatomie und Physiologie,' Part ii., 1838. He here pointed out, that in the formation of vegetable cells, small sharply-defined granules are first generated in a granulous substance, and around them the cell-nuclei (cytoblasts) are found, which appear like granulous coagulations around the granules.

The results of these observations were communicated in 1837 to Schwann, who, struck with the resemblance between the cells of animals and those of plants, conceived the idea that the same history of development would be found true of the parts of animals that had been discovered by Schleiden in the parts of plants. From this time the science of Histology made rapid progress, and we cannot more appropriately present its present condition than in the language of Professor Kolliker, in his introduction to his 'Manual of Human Histology:'—

"In the year 1838 in fact the demonstration by Dr. Th. Schwann of the originally perfectly identical cellular composition of all animal organisms, and of the origin of their higher structures from these elements, afforded the appropriate conception which united all previous observations, and afforded a clue for further investigations. If Bichat founded Histology more theoretically by constructing a system and carrying it out logically, Schwann has by his investigations afforded a basis of facts, and has thus won the second laurels in this field. What has been done in this science since Schwann has been indeed of great importance to physiology and medicine, and in fact of great value in a purely scientific point of view, inasmuch as a great deal which Schwann only indicated or shortly adverted to, as the genesis of the cell, the import of the nucleus, the development of the higher tissues, their chemical relations, &c., has received a further development, but all this has not amounted to a step so greatly in advance as to constitute a new epoch. If, without pretensions to prescience, it be permitted to speak of the future, this condition of Histology will last as long as no essential advance is made towards penetrating more deeply into organic structure, and becoming acquainted with those elements of which that which we at present hold to be simple is composed. If it be possible that the molecules which constitute cell-membranes, muscular fibrils, axile fibre of nerves, &c., should be discovered, and the laws of their apposition and of the alterations which they undergo in the course of the origin, the growth and the activity of the present so-called elementary parts, should be made out, then a new era will commence for Histology, and the discoverer of the law of cell-genesis, or of a molecular theory, will be as much or more celebrated than the originator of the doctrine of the composition of all animal tissues out of cells.

"In characterising the present position of Histology and of its objects, we must by no means forget that, properly speaking, it considers only one of the three aspects which the elementary parts present to observation, namely, their form.

"Microscopical anatomy is concerned with the understanding of the microscopic forms, and with the laws of their structure and development, not with any general doctrine of the elementary parts.

"Composition and function are only involved so far as they relate to the origin of forms and to their variety.

"Whatever else respecting the activity of the perfect elements and their chemical relations is to be found in Histology, is there either on practical grounds, in order to give some useful application of the morphological conditions, or to complete them, as, from its intimate alliance with the subject, it is added only because physiology proper does not afford a due place for the functions of the elementary parts.

"If Histology is to attain the rank of a science, its first need is to have as broad and certain an objective basis as possible. To this end the minuter structural characters of animal organisms are to be examined on all sides, and not only in fully-formed structures, but in all the earlier periods from their first development.

"When the morphological elements have been perfectly made out, the next object is to discover the laws according to which they arise, wherein one must not fail to have regard also to their relations of composition and function. In discovering these laws, here as in the experimental sciences generally, continual observation separates more and more, among the collective mass of scattered facts and observations, the occasional from the constant, the accidental from the essential, till at last a series of more and more general expressions of the facts arises, from which in the end mathematical expressions or formulæ proceed, and thus the laws are enumerated.

"If we inquire how far Histology has satisfied these requirements, and what are its prospects in the immediate future, the answer must be a modest one. Not only does it not possess a single law, but the materials at hand from which such should be deduced are as yet relatively so scanty, that not even any considerable number of general propositions appear well founded. Not to speak of a complete knowledge of the minuter structure of animals in general, we are not acquainted with the structure of a single creature throughout, not even of man, although he has been so frequently the object of investigation; and therefore it has hitherto been impossible to bring the science essentially nearer its goal. It would however be unjust to overlook and depreciate what we do possess; and it may at any rate be said that we have acquired a rich store of facts, and a few more trustworthy propositions. To indicate only the more important of the former, it may be mentioned that we have a very sufficient acquaintance with the perfect elementary parts of the higher animals; and that we also understand their development, with the exception of the elastic tissue, and of the elements of the teeth and bones. The mode in which these are united into organs has been less examined; yet on this head also much has been added of late, especially in man, whose individual organs, with the exception of the nervous system, the higher organs of sense, and a few glands (the liver, blood-vascular glands), have been almost exhaustively investigated. If the like progress continue to be made, the structure of the human body will in a few years be so clearly made out, that, except perhaps in the nervous system, nothing more of importance will remain to be done with our present modes of investigation. With Comparative Histology it is otherwise: hardly commenced, not years but decades will be needed to carry out the necessary investigations. Whoever will do good work in this field must, by monographs of typical forms embracing their whole structure from the earliest periods of development, obtain a general view of all the divisions of the animal kingdom, and then by the methods above described strive to develop their laws.

"As regards the general propositions of Histology, the science has made no important progress since Schwann; however, much has been attained by the confirmation of the broad outlines of his doctrines. The position, that all the higher animals at one time consist wholly of cells, and develop from these their higher elementary parts, stands firm; though it must not be understood as if cells, or their derivatives, were the sole possible or existing elements of animals. In the same way, Schwann's conception of the genesis of cells, though considerably modified and extended, has not been essentially changed, since the cell-nucleus still remains as the principal factor of cell-development and of cell-multiplication. Least advance has been made in the laws which regulate the origin of cells and of the higher elements; and our acquaintance with the elementary processes which take place during the formation of organs must be regarded as very slight. Yet the right track in clearing up these points has been entered upon; and a logical investigation of the chemical relations of the elementary parts and of their molecular forces, after the manner of Donders, Dubois, Ludwig, and others, combined with a more profound microscopical examination of them, such as has already taken place with regard to the muscles and nerves, and further, a histological treatment of embryology, such as has been attempted by Reichert, Vogt, and myself, will assuredly raise the veil, and bring us step by step nearer to the desired though perhaps never-to-be-reached end."

In accordance with the plan of this work, the Histology of each separate organ of the body will be found in the general article devoted to that organ.

The tissues or textures of the body enumerated in the article ANATOMY will be found under their respective names; and in the articles TISSUES, VEGETABLE, and TISSUES, ANIMAL, will be found an account of the relations and general physiology of the textures of the body.

Necessary aids to the study of Histology are the microscope and books. Under the article MICROSCOPE, in ARTS AND SC. DIV., the nature of that instrument and the mode of using it will be described, as well as the various forms adapted for histological purposes.

We refer here to some of the more important works and papers to be consulted on this subject.

Kölliker, *Manual of Human Histology*; Sharpey, *General Anatomy*, in Quain's *Elements of Anatomy*; Beale, *The Microscope, and its Application to Clinical Medicine*; Todd and Bowman, *Physiological Anatomy*; Gerber, *Elements of the General and Minute Anatomy of Man and the Mammalia*; Goodsir, *Anatomical and Pathological Observations*; Hassall, *Microscopic Anatomy*; Bowman, *On the Structure of Voluntary Muscle* (*Phil. Trans.*, 1840); Kiernan, *On the Structure of the Liver* (*Phil. Trans.*, 1835); Mandl, *Manuel d'Anatomie Générale*; Mohl, *On the Vegetable Cell*; Owen, *Lectures on Comparative Anatomy*; Quekett, *Lectures on Histology*; Schleiden, *Principles of Scientific Botany*; Schleiden and Schwann, *Microscopical Researches* (Sydenham Society); *Cyclopædia of Anatomy and Physiology*; Robin, *Histoire Naturelle des Végétaux Parasites*; Carpenter, *Principles of Physiology, General and Comparative*.

HOAZIN. [CRACIDÆ.]

HOBBY. [FALCONIDÆ.]

HOCCO, a name employed by Buffon, Latham, and others, to designate some of the Curassow Birds. [CRACIDÆ.]

HOE. [SQUALIDÆ.]

HOG. [SUIDÆ.]

HOG-MEAT. [BOERHAAVIA.]

HOG-PLUM. [SPONDIACEÆ.]

HOLASTER, a genus of Fossil *Echinidæ*, proposed by M. Agassiz to include species once ranked as *Spatangi*. *Spatangus subglobosus* (Leske), *S. planus* (Mantell), and *S. hemisphericus* (Phillips), are examples. The species occur almost exclusively in the Chalk Formation. [ECHINODERMATA.]

HOLCUS, a genus of Grasses belonging to the tribe *Avenew*. It has 2-flowered glumes, the lower perfectly awnless, the upper usually stameniferous, with a dorsal awn; the paleæ hardening on the fruit. There are two British species of this genus. *H. lanatus* has the upper glume obtuse, apiculate; the awn smooth, except for a short distance from the tip. It grows in meadows and pastures. *H. mollis* has the upper glume acute, and the awn rough throughout its whole extent. It grows in thickets or open places on a light soil. The *H. cernuus* of Willdenow, and the *H. sorghum* of Linnæus are now referred to the genus *Sorghum*. [SORGHUM.] Fraas refers the Μέλινη of Theophrastus ('Hist. Plant.,' viii. 1, 3, 7, 10) to these grasses, and not to the *Setaria Italica*, as had been done by previous authors.

(Babington, *Manual of British Botany*; Fraas, *Synopsis Plant. Floræ Classicæ.*)

HOLETUA. [TRACHEARIA.]

HOLIBUT. [HIPPOGLOSSUS.]

HOLIGARNA, a genus of Plants belonging to the natural order *Anacardiaceæ*. The berries of *H. longifolia* are manufactured in India into a well-known black varnish.

HOLLY. [ILEX.]

HOLLY, SEA. [ERYNGIUM.]

HOLLYHOCK. [ALTHÆA.]

HOLMESITE. [CLINTONITE.]

HOLOCANTHUS. [CHÆTODON.]

HOLOCENTRUM (Agassiz), the name of a genus of Fossil Ctenoid Fishes from Monte Bola. [FISH.]

HOLOCENTRUS, a genus of Fishes belonging to the family *Scomberidæ*. *H. niger* of Lacépède is the *Centrolophus pompilius* of Cuvier and Valenciennes. [CENTROLOPHUS.]

HOLO'PTYCHIUS (Agassiz), the name of a genus of Fossil Ganoid Fishes from the Carboniferous Limestone of Burdie House near Edinburgh, and other localities. [FISH.]

HOLO'STEUM (from ὅλος, all, and ὀστέον, a bone, an antiphrasis applied to this plant because it is soft and unlike bone), a genus of Plants belonging to the natural order *Caryophyllaceæ*, and the sub-order *Alsineæ*. It has 5 sepals; 5 petals, toothed at the end; 3, 4, or 5 stamens; 3 styles; a subcylindrical many-seeded capsule, opening at the end, with 6 teeth. The species of this genus are herbs with nothing to recommend them for use or cultivation. One species, *H. umbellatum*, is British. It has umbellate flowers, pubescent viscid peduncles, the pedicels reflexed after flowering, the leaves acute, elliptical, or elongate. It is not a common plant, but has been found on old walls and dry places at Norwich, Bury St. Edmunds, Eye, and Yarmouth. (Babington, *Manual of British Botany.*)

HOLOTHURIA. [HOLOTHURIADÆ.]

HOLOTHU'RIADÆ, a family of Animals belonging to the order *Echinodermata*.

Linnæus, in his last edition of the 'Systema Naturæ' (the 12th), gives the following definition of his genus *Holothuria*, which he places under his *Vermes Mollusca*, between *Tethys* and *Terebella*:—"Body free, naked, gibbous; vent (anus) terminal. Tentacles numerous at the other extremity (tentacula plura in alterâ extremitate). Mouth situated among the tentacles." He records 9 species. Gmelin, in his edition (13th), increases the species to 23.

The following is Lamarck's definition of *Holothuria*:—"Body free, cylindrical, thick, soft, very contractile; with a coriaceous skin, which is most frequently papillose. Mouth terminal, surrounded with tentacula divided laterally, subramose, or pinnated. Five calcareous teeth in the mouth. Vent at the posterior extremity." He gives 10 species of *Holothuria*; but he separates other *Holothuriæ* of authors into the genera *Fistularia* and *Priapulus*. These three genera are preceded by *Actinia*, and followed immediately by *Sipunculus*. The place therefore assigned by Lamarck to *Holothuria* is among the Radiated Animals, in his third section of which, the Fistulides, he has arranged the tribe.

Cuvier gives the *Holothuriæ* a position among the Pedicillated Echinoderms, making them follow the *Echinidæ*. *Priapulus* is placed by him in the next order, the Footless Echinoderms. He gives a good outline of the anatomy, referring to the excellent work of Tiedemann.

M. De Blainville's *Echinodermata* form the first class of his *Actinozoa*, and the first order of that class consists of the *Holothuridea*, which are followed ('Actinologie,' 1834) by the *Echinidea*, his second order. M. De Blainville thus defines the *Holothuridea*:—

"Body more or less elongated, sometimes subvermiform, soft or flexible on all sides, provided with tentaculiform suckers, often numerous, very extensible, completely retractile, and pierced by a great orifice at each extremity. Mouth anterior, at the bottom of a sort of funnel or prebuccal cavity, sustained in its circumference by a circle of fibro-calcareous pieces, and provided with a circle of arbuscular appendages, more or less ramified. Vent terminating in a sort of cloaca opening externally by a large terminal orifice. Generative organs terminating externally by a single mesial orifice at a little distance from the anterior extremity, and nearly marginal."

M. De Blainville observes that Bianchi appears to have been the first who came to the conclusion that this form ought to be approximated to the *Echini*, and in fact names one species, *Echinus coriaceus*; an opinion which was adopted by Blumenbach and most of the modern zoologists, when they made the *Holothuriæ* a division of their Echinoderms with the *Echini* and *Asteriæ*; some however, following the idea of Pallas, consider that they should be placed near the *Actiniæ*.

The author last quoted remarks that the organisation of these animals is not yet completely known, notwithstanding the labours of Bohatsch, Müller, Vahl, Forskahl, Monro, Tiedemann, and Delle Chiaje. In addition to these names we would call the attention of the reader to the drawing and description of *Holothuria tremula*, Linn., left by John Hunter. The drawing is beautifully engraved, and, with the description, will be found in the 1st vol. of the Descriptive and Illustrated Catalogue of the 'Physiological Series of Comparative Anatomy, contained in the Museum of the Royal College of Surgeons in London,' pl. iii. The following parts are distinctly made out, namely:—1, The mouth, in which the bristle is introduced. 2, Appendicula cæca, which surround the mouth, or fauces, into which they enter, and which Mr. Hunter supposes to be salivary glands and ducts. 3, A large one, lower down, just at the beginning of the intestinal canal. 4, The whole tract of the intestinal canal, which is of considerable length. 5, The dilated part of the intestine, or rectum, or what seems to answer the same purpose as the dilated part of the gut at the anus in a bird. 6, The anus. The use of the parts to which we next have to advert, though the parts themselves are most clearly demonstrated, seems to have been more the subject of conjecture with Mr. Hunter. 7, Two branching bodies almost like a tree, which consist of a duct with its branches, and which open into the dilated part of the rectum. These Mr. Hunter suspects to be the kidneys, from their opening similar to the kidneys in birds, turtles, &c. There are small oblong bodies near the opening of the principal trunk into the rectum. 8, A vast number of hollow round tubes, all entering into one duct, which opens at the head. These will be best seen in another plate which will be published in the fasciculus of the catalogue relating to generation. 9, Vessels which seem to have neither beginning nor end, somewhat like the vena portarum: "they appear," adds Mr. Hunter, "to be collecting at one end while they are ramifying at the other; but which is the collecting end, and which the ramifying, I do not know; however it is possible one end is the absorbing system, the other the arterial. Whenever there is a heart one commonly can make out the motion of the blood from and to that viscus; but where we are deprived of that guide it becomes difficult to determine." 10, A distinct vessel from the former. These parts are indicated in the plate.

The preparation No. 984 (Physiological Series—Gallery) in the museum of the Royal College of Surgeons, is the specimen of *Holothuria tremula* laid open, and the alimentary canal and generative tubes turned aside to show the respiratory organs, which have been injected. These organs consist of two elongated, hollow, ramified processes, commencing by a common orifice from the closed cavity, and extending towards the opposite end of the body. One of them is in more immediate connection with the alimentary canal, and is abundantly supplied by ramifications of the intestinal vessel, the contents of which are thus brought into necessary communication with the sea-water introduced into the tubular branchia from the cloaca. The other gill is more closely attached to the parietes of the body, and probably serves to aërate the vessels of that part. ('Cat.,' vol. ii.) To this Professor Owen adds, that in the description of the *Holothuria* above quoted, Mr. Hunter attributes to these organs a more limited share in the great excretory functions than they undoubtedly perform, regarding them, from their connection with the cloaca, as analogous to the kidneys of the higher animals. Distinct urinary organs are not however, observes the Professor, developed until we arrive at a much higher point in the scale of organisation than the *Holothuria* and its congeners attain to; the preparation is therefore placed in the respiratory series.

In his 'British Star-Fishes,' Professor E. Forbes makes the following general observations on this family:—

"A *Holothuria* may be regarded in one light as a soft Sea-Urchin, in another as a radiated animal, approximating the Annelides. The radiation of the surface is more or less complete in all the genera of *Holothuriadæ*: the internal organisation is mostly bilateral. The skin is usually soft and leathery; in a few genera strengthened by calcareous or horny spines. Five avenues of suckers separate the body into as many longitudinal segments, which in the majority are of equal or nearly equal dimensions. In some the suckers are developed only on one side, so that the animal when creeping presents in a manner a back and a belly. The suckers are similar to those of the true star-fishes and sea-urchins. Besides progression by means of these suckers, the *Holothuriadæ* move as Annelides, by the extension and contraction of their bodies. They have a mouth and an anus, each terminal, and placed at opposite extremities of their bodies. The mouth is surrounded by plumose tentacula, the number of which, when they are complete, is always a multiple of five; but as these animals are singularly subject to the loss or absence of parts in individuals of the various species, much confusion has arisen from the establishment of supposititious species from characters founded on abnormal numbers of the parts.

"The tentacula are ramose cirrhi; they can be retracted within the mouth, and sometimes when in captivity the animal will not exsert them for days together, though otherwise active. They are drawn in with the skin, and when we cut open a *Holothuria* having its tentacula retracted, we find them in the centre of a dental circle. The circle of teeth is analogous to that of the *Echini*. The œsophagus passes through it, and opens into a more or less muscular stomach, from which an intestine, often very complicated, proceeds to the posterior extremity of the body, where it opens into a funnel-shaped cloacum, into which also open the two tree-like respiratory organs. There is a vascular circle (and some say a nervous cord) surrounding the mouth, and vessels are distributed from it to various parts of the body and organs. One or more sacs of a pyriform shape depend from a vessel surrounding the pharynx, and are by many believed to be salivary organs. Mr. Goodsir has found a sac containing calcareous concretions on one side of the mouth in certain species. This he regards as a madreporiform tubercle or nucleus. The ovaries are in many species very numerous, in others very few, and unite to form a tube which opens at one side towards the upper extremity of the animal. The inner surface of the animal's skin is lined with powerful longitudinal and transverse muscles, by means of which the creature contracts its body and lengthens it out in many directions, changing its form in a wonderful manner. Sometimes the creature ejects all its viscera, or bursts the body with its convulsive contractions. It is usually stated that the *Holothuriæ* do so whenever they are taken, but such is not the case. I have never seen the animal disgorge its intestines, but specimens of many species have I seen in which there was not a trace left of the creature's bowels and other internal organs, though it seemed, when taken, alive and healthy. It is astonishing how long they can live deprived of the most essential parts of their organism. Sometimes they are found wanting the respiratory organs, and sometimes the generative tubes are deficient, and these deficiencies so frequently occur that we should be extremely shy of proclaiming differences in the internal structure of species; and when we see genera and species (as has been the case) anatomically defined from the want of respiratory trees or genital tubes, we should be extremely cautious about admitting such, and rather regard such wants as accidental deficiencies in a few specimens than as organic peculiarities.

"The *Holothuriadæ* are generally distributed through the seas of the globe, but are congregated in greatest numbers in the Eastern seas. On our shores they are rare and unattractive animals, not often seen even by the zoologist; but abroad they are very abundant and in some places used as food. Of one genus, the Trepang, many species are eaten. In Mr. F. D. Bennett's interesting 'Account of a Whaling Voyage round the World,' we are told that there are two kinds of Trepang abundant on the rocks at Raialia, and that they are very indolent animals. 'When handled,' says Mr. Bennett, 'the Trepang contracts its body in a longitudinal direction, and should its tentacles be expanded they are instantly concealed; but no noise or agitation of the surrounding water will excite these symptoms of alarm, or cause any attempt to escape. They usually lie exposed in the shallow waters, though we have very often seen them buried in beds of coral-sand, their plumy tentacles being alone exposed, and floating in the water above, apparently as a lure for prey. Some may also be observed lying on the rocks, their bodies completely encrusted with coral-sand, which may either have been accumulated by a previous burrowing, or thus used as a disguise. It would appear to be partly the instinct of the animal to take its prey in ambush, but what that prey is, as well as the entire economy of these molusca, remains a perplexing mystery. Their intestines invariably contain many hard and solid masses of madreporic rock or tree-coral, some of them more than an inch in length, and all moulded as pellets to the calibre of the intestinal canal.

"It is difficult to say how these stony bodies have been obtained by the Trepang, though it is easy to conceive that they may be rendered serviceable as nutriment, by the assimilation of the animal matter they contain. It is this animal which the Malays of the Oriental Isles seek so diligently for the supply of the China market, where it obtains a good price if well preserved.

"It is employed by the Chinese in the preparation of nutritious soup, in common with an esculent sea-weed, sharks' fins, edible birds'-nests and other materials, affording much jelly." Jæger says the intestines are extracted, the animal then boiled in sea-water and dried in smoke.

The British *Holothuriadæ* belong to four families, namely:—

1st. The *Psolidæ*, or Ascidian *Holothuriadæ*, animals approaching the *Mollusca* in their form, and having a soft circumscribed disc like the foot of a Gasteropodous Mollusc, on which the suckers are placed for progression. [PSOLIDÆ.]

2nd. The *Pentactæ*, which have the suckers arranged in five regular rows, and are more or less angular in form. [PENTACTÆ.]

3rd. The *Thyones*, which have the suckers scattered all over the surface of the body. [THYONES.]

4th. The *Synaptæ*, in which there are no suckers on the body, the oral tentacula being the only representatives of those organs. [SYNAPTÆ.]

De Blainville refers the difficulty of the distinction of the species of *Holothuriadæ* to the following, among other causes:—

1. The general form is extremely variable. When the animal is in a state of tranquillity in the enjoyment of all its faculties at the bottom of the water, it is, in the greatest number of cases at least, very much elongated, often cylindrical, and almost vermiform: on the contrary, when in a state of repose, it becomes much shorter and ordinarily more convex in the middle than at the extremities. When it is irritated, whether in or out of the water, the contractile action becomes stronger, and the animal can no longer be recognised. But it is especially when it has been plunged in spirit, that the form differs totally from that which the living animal exhibits.

2. The size, the form, and distribution of the more or less mammillated tubercles which are numerously spread over the skin, appear to M. De Blainville to offer too great a number of variations to permit of their being employed in distinguishing specific character.

3. The tentaculiform suckers, which have their exit through the pores or holes in the skin, and by means of which these animals attach themselves to submarine bodies, are, in a certain number of species, spread nearly equally over the whole superficies of the body; but in others they are accumulated on the lower surface, without order, in a determinate order, or are disposed in double series upon five longitudinal lines, as in *H. pentacta*.

4. The more or less terminal position of the two orifices may, M. De Blainville thinks, be taken into consideration advantageously.

5. Some zoologists, and among others M. Lesueur, says M. De Blainville, attach a great importance to the number of the tentacular appendages of the mouth, and to their form and mode of division; but, M. De Blainville fears, erroneously, for he has been positively assured that the most common species of the Mediterranean, *H. tubulosa*, which is found in hundreds at Toulon, varies much, both as to the number and terminal divisions of those organs.

6. It seems to M. De Blainville that a better character may be drawn from the form of the circle of the solid pieces of the mouth, which is constant, as he believes, in each species; it is however difficult to employ this test.

7. To judge from a considerable number of *Holothuriæ tubulosæ* seen by M. De Blainville, colour in these animals is very variable, in intensity at least, passing from a nearly deep black to a reddish bordering upon whitish.

8. With regard to dimensions, besides the difficulty of measuring the animals when captured, it appears that they vary considerably in size, doubtless from age.

M. De Blainville finally, after a careful analysis of the different species described by authors, joiued to his own observations upon seven or eight species in a living state, distributes these animals into the following five sections, which he considers to be sufficiently natural, and some of which may be established as genera :—

Body	Flattened, with suckers below	*Cuvieria.*
	Subprismatic, with inferior suckers . . .	*Holothuria.*
	Fusiform, with scattered suckers	*Thyone.*
	Vermiform, with pinnated tentacles . . .	*Fistularia.*
	Subpentagonal, with ambulacriform suckers .	*Cucumaria.*

A. Species whose rather short body, more convex and harder above than below, is provided with tentaculiform suckers only on that side, and with fairly developed buccal appendages; the two apertures more or less superior. (*Cuvieria*, Péron; *Psolus*, Oken.)
Ex. *H. Phantapus.* Scarborough *Ascidia* of Pennant. ('Brit. Zool.')

B. Species whose coriaceous and rather elongated body is subprismatic; tho belly sufficiently distinct from the back, and alone provided with tentaculiform suckers, scattered throughout its whole extent; the buccal appendages in general but little ramified; the mouth snb-inferior. (*Holothuria*, Lam.)
Ex. *H. tubulosa.*

C. Species whose body, in general elongated, but little coriaceous, cylindrical, or fusiform, is entirely covered with retractile papillæ, aud whose buccal appendages are very large. (*Thyone*, Oken; *Mulleria*, Fleming.)
Ex. *H. papillosa.*

D. Very soft species, but little or not at all coriaceous, very long and vermiform, cylindrical or subpentagonal, provided with cirrhiform papillæ, which are very small, scattered, and with the buccal appendages usually regularly pinnated.
Ex. *H. vittata.*

E. Species sufficiently coriaceons, smooth, in general short or moderately elongated, regularly pentagonal, with tentaculiform suckers in 10 rows, two at each ambulacral angle. (*Cucumaria*, Sea-Cucumbers.)
Ex. *H. Cucumis.*

More recently Messrs. Jæger and Brandt have given a classification of the *Holothuriadæ.* The characters upon which the system of Messrs. Jæger and Brandt rests are the following :—

1. The absence or the presence of tentaculiform suckers, which M. Braudt, as well as M. Jæger, calls fect, in common with mauy zoologists.

2. Tho resemblance or dissemblance of those organs.

3. Tho existence or absence of the posterior and internal aquiferous, branchial apparatus, which they name lungs, with good reason, because the ambient fluid penetrates therein.

4. The disposition of the tentaculiform suckers at the surface of the body, all ronnd it or on certain parts only, in regular series, of variable number or irregularly scattered.

5. The freedom or the adhesion of the respiratory aquiferous tree, divided by M. Jæger into the intestinal lung and the locomotive lung.

6. The last and least important character is drawn from the form of the tentacles which surround the buccal aperture, which leads M. Jæger to his sub-genera and tribes, and M. Brandt to his genera and sub-genera. M. Jæger forms, says M. De Blainville, in fact three groups only, which he considers as sub-genera, *Cucumaria*, *Tiedemannia* (*Fistularia*), and *Holothuria*, which he separates into six tribes, *Mulleria*, *Bohatschia*, *Cuvieria*, *Psolus*, *Holothuria*, and *Trepang*, this last being in truth held doubtful in the system of M. Braudt, as M. Jæger himself considered it.

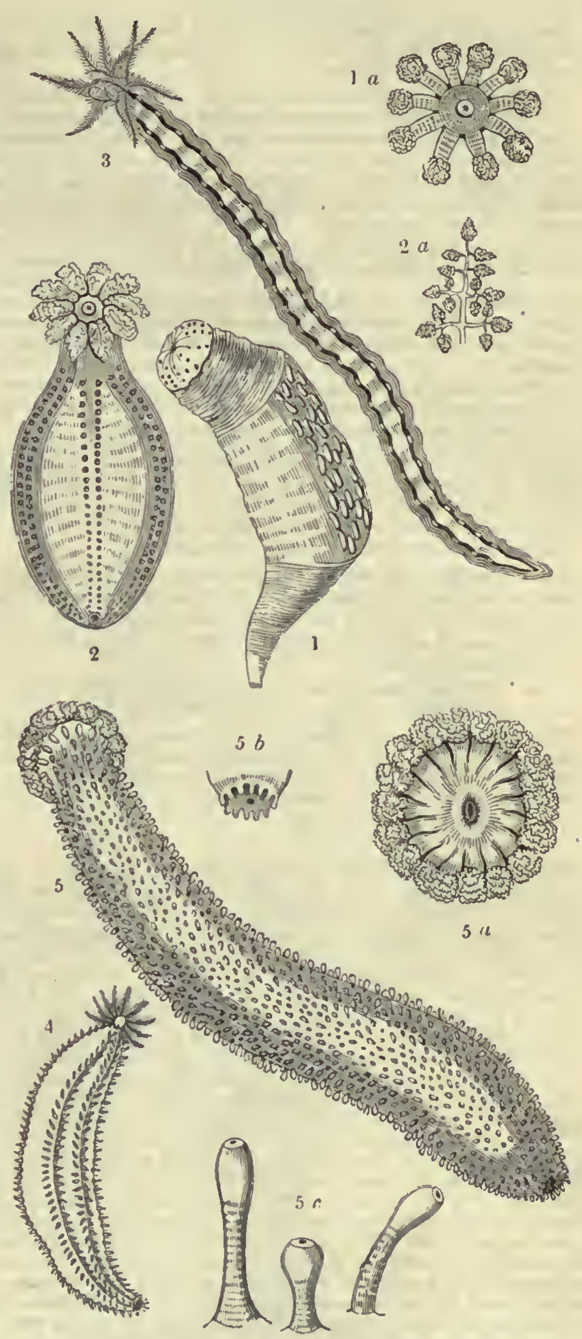
M. Brandt's divisions resolve themselves into seven groups :—

1. *Pentastichoæ*, answering to M. De Blainville's division *E* (*Cucumaria*), and subdivided according to the free or fixed state of the aquiferous tree.

2. *Sporadipodæ*, confounded by M. De Blainville with the *Holothuriæ* properly so called, from which he says they do not differ really, excepting that the tentaculiform suckers with which the body is covered are similar both above and below. This division coutains only two genera, established upou the distinction of having the tentacula sheathed or not.

3. *Hippopodæ*, comprising M. De Blainville's division *A*, separated into two genera, *Cuvieria* and *Psolus*, containing each two species.

4. The *Apneumones*, which were regarded by M. De Blainville as belonging to the genus *Fistularia* of Lamarck, to the number of four



1, *Holothuria Phantapus*; 1 *a*, its buccal appendages. 2, *Holothuria papillosa*; 2 *a*, a branch of its buccal appendages isolated. 3, *Holothuria vittata.* 4, *Holothuria Cucumis.* 5, *Holothuria tubulosa*; 5 *a*, its oral extremity; 5 *b*, its anal extremity; 5 *c*, some of the cirrhi, of the natural size.

or more, the half of which are doubtful, and coutaining only, for M. Brandt, the genus *Oncinolabes.*

5. *Schizopodæ*, which are diversiform species more or less elongated, in which the tentaculiform suckers are disposed in three or five longitudinal rows; these form but two genera, each containing one species only.

6. *Heteropodæ*, corresponding to M. De Blainville's divisions *B* and *C*, that is to say, to his *Holothuriæ* properly so called, and to his *Mulleriæ*, of which M. Brandt forms seven geuera.

All these are *Holothuriæ pedatæ*, but

7. consists of the *Non pedatæ*, forming a great part of M. De Blainville's division *D*, that is to say, the geuus *Fistularia* of Lamarck, separated into three principal genera, two of which, provided with aquiferous trees, are distinguished by the form of their body, and the third has beeu named *Synapta* by Escholtz.

M. De Blainville, iu his 'Nouvelles Additions et Corrections' to his 'Actinologie,' published in 1834, gives the followiug amended divisions, which he subdivides, retaiuing many of the generic uames of Jæger and Brandt.

A. The *Vermiform Holothuriæ* (*Fistularia*), which have the body elongated, soft, vermiform, and the tentacular suckers very small or even null. Three divisions.

1. Without suckers, tentacula pinnated. (*Synapta*, Escholtz.)
2. Without suckers, tentacula pinnatifid. (*Chirodota*, Escholtz.)
3. Very small suckers disposed in five bands. (*Onciolabes*, Brandt.)

B. The *Ascidiform Holothuriæ* (*Psolus*), whose body is, on the contrary, short, coriaceous, convex above, flattened below, with superior rather than terminal orifices.

1. Skin as it were squamous. (*Cuvieria*, Péron.)
2. Skin rugose, but soft. (*Psolus*, Oken.)

C. The ordinary or *Vertilliform Holothuriæ*, whose body is sufficiently elongated, sufficiently soft, subcylindrical, and covered throughout with tentaculiform suckers, the lowest of which are longest.

1. Vent (anus) largely open. (*Holothuria*.)
2. Vent plaited. (*Bohadschia*, Jæger.)
3. Vent closed with five teeth. (*Mulleria*, Jæger.)

D. *Holothuriæ*, whose body is more or less elongated; the lower tentacular suckers longer than the upper ones, and disposed in longitudinal series in a determined number.

1. Suckers in three rows. (*Stichopus*, Brandt.)
2. Suckers in five rows. (*Diploperideris*, Brandt.)

E. The *Cucumiform Holothuriæ*, whose body is but little elongated, more or less fusiform, pentagonal, with tentaculiform suckers forming five ambulacra, one on each angle. (Brandt.)

1. Tentacular suckers very small or null. (*Liosoma*, Brandt.)
2. Suckers very visible.
   a. Tentacles pinnated, ramose. (*Cladodactylus*, Brandt.)
   b. Tentacles pinnatifid. (*Dactylota*, Brandt.)

F. The *Sipunculiform Holothuriæ*. Body more or less suddenly attenuated backwards, of an ill-defined pentagonal form, without either ambulacra or suckers (?). Tentacles simple, short, and cylindrical, as in the *Actiniæ*. (*Molpadia*, Cuvier.)

1. *M. Holothuroides.* (Cuvier.)
2. *M. musculus.* (Risso.)

When M. De Blainville says that he has never heard that any of these animals were of much utility to mankind, but that M. Delle Chiaje does indeed inform us that the poor inhabitants of the Neapolitan coasts eat them, he appears to have forgotten the great oriental traffic carried on with some of the species, as an article of food, under the name of Trepang or Tripang, Biche-de-Mer or Beche-de-Mer. Captain Flinders fell in with a fleet of Malay proas at the English Company's Islands, north coast of Australia, near the Gulf of Carpentaria (1803), and was informed that sixty proas belonging to the raja of Boni, and carrying one thousand men, had left Macassar with the north-west monsoon, two months before, on an expedition to that coast. "The object of their expedition," writes Captain Flinders ('Voyage to Terra Australis'), "was a certain marine animal called Trepang. Of this they gave me two dried specimens; and it proved to be the Beche-de-Mer, or Sea-Cucumber, which we had first seen on the reefs of the east coast, and had afterwards hauled on shore so plentifully with the seine, especially in Caledon Bay. They got the Trepang by diving, in from three to eight fathoms water; and where it is abundant, a man will bring up eight or ten at a time. The mode of preserving it is this :—the animal is split down one side, boiled, and pressed with a weight of stones, then stretched open with slips of bamboo, dried in the sun, and afterwards in smoke, when it is fit to be put away in bags, but requires frequent exposure to the sun. A thousand trepangs make a 'picol' (of about 125 Dutch pounds); and one hundred picols are a cargo for a prow. It is carried to Timor, and sold to the Chinese, who meet them there; and when all the prows are assembled, the fleet returns to Macassar. By Timor seemed to be meant Timor-laoet; for when I inquired concerning the English, Dutch, and Portuguese there, Pobassoo (Captain Flinders's informant) knew nothing of them : he had heard of Coepang, a Dutch settlement, but said it was on another island. There are two kinds of Trepang : the black, called Baatoo, is sold to the Chinese for forty dollars the picol; the white or gray, called Koro, is worth no more than twenty. The Baatoo seems to be what we found upon the coral reefs near the Northumberland Islands; and, were a colony established in Broad Sound or Shoal-Water Bay, it might perhaps derive considerable advantage from the Trepang. In the Gulf of Carpentaria we did not observe any other than the Koro, or Gray Slug."

Captain Phillip Parker King, who quotes a part of the above passage ('Survey of the Intertropical Coasts of Australia'), found a fleet of Malay proas in the bay at Coepang (1818): it had just returned from an unsuccessful voyage on the south coast of Timor in search of trepang. Dramah, the principal raja of the fleet, gave Captain King the following information respecting the coast of Australia, which the raja had frequently visited in the command of a fleet that annually frequents its shores. The coast is called by them 'Marega,' and has been known to them for many years. A fleet to the number of 200 proas (but Captain King thinks that this number is perhaps very much exaggerated) annually leaves Macassar for this fishery; it sails in January, during the western monsoon, and coasts from island to island, until it reaches the north-east end of Timor, when it steers south-east and south-south-east, which courses carry them to the coast of Australia; the body of the fleet then steers eastward, leaving here and there a division of 15 or 16 proas, under the command of an inferior raja, who leads the fleet, and is always implicitly obeyed. His proa is the only vessel which is provided with a compass; it also has one or two swivels, or small guns, and is perhaps armed with muskets. Their provisions chiefly consist of rice and cocoa-nuts; and their water, which during the westerly monsoon is easily replenished on all parts of the coast, is carried in joints of bamboo. "After having fished along the coast to the eastward until the westerly monsoon breaks up, they return, and by the last day of May each detached fleet leaves the coast, without waiting to collect in one body. On their return they steer north-west, which brings them to some part of Timor, from whence they easily retrace their steps to Macassar, where the Chinese traders meet them, and purchase their cargoes. At this time (1818) the value of the trepang was from forty to fifty dollars a picol; so that if each vessel returns with 100 picols of trepang, her cargo will be worth 5000 dollars. Besides trepang, they trade in sharks' fins and birds' nests, the latter being worth about 3000 dollars the picol." [SWALLOW TRIBE.] To this Captain King appends a note, stating that in 1822 the value of the trepang was much less, the price having fallen to 25 dollars the picol.

In Crawfurd's 'Indian Archipelago' it is stated that the Slug, or Trepang, is sometimes as much as two feet in length and from seven to eight inches in circumference; a span long and two or three inches in girth is however the ordinary size. But the quality and value do not depend upon its size, but upon properties not discernible by those who have not had much experience in the trade. In shallow water the animal is taken out by the hand, but in deeper water it is sometimes speared. When taken, it is gutted, dried in the sun, and smoked over a wood-fire. The fishery is carried on from the western shores of New Guinea and the southern shores of Australia, to Ceylon inclusive. Indeed within the last few years it has been successfully prosecuted on the shores of the Mauritius. The whole produce goes to China. In the market of Macassar, the great staple of this fishery, not less than thirty varieties are distinguished, varying in price from 5 Spanish dollars a picol (133⅓ lbs.) to fourteen times that price, each variety being distinguished by well known names. The quantity of trepang sent annually to China from Macassar is about 7000 picols, or 8333 cwt.; the price usually varying from 8 dollars a picol to 110 and 115 dollars a picol, according to quality. There is also a considerable export of trepang from Manilla to Canton.

(M'Culloch, *Dictionary of Commerce*, article *Tripang*.)

HOMALIA'CEÆ, a small natural order of shrubby Exogenous Plants with polypetalous flowers, a row of glands in front of the segments of the calyx, many perigynous stamens, and a 2-5-styled ovary, with as many parietal placentæ as styles. The species chiefly inhabit tropical countries; they have small starry flowers, and are of no known utility. Brown considers them nearly related to *Passifloraceæ*. Lindley places them near *Cucurbitaceæ*, *Loasaceæ*, *Cactaceæ*, and *Onagraceæ*. There are 8 genera and 30 species.

1 *Homalium racemosum.* 2

1, an expanded flower; 2, an ovary with its two styles.

HO'MARUS (Milne-Edwards), a genus of Animals belonging to the order *Crustacea*. It embraces the true Lobsters. Milne-Edwards has noticed certain differences which induce him to separate the true

Lobsters (*Homarus*) from the Crawfishes (*Astacus*), and to combine the genera *Astacus*, *Homarus*, and *Nephrops* in one small group, which he designates as the family of the Astacians (*Astacidæ*). These he considers as forming the passage between the Cuirassed Macrurous Crustaceans and the Salicoques, or Shrimps, but as differing sufficiently to require separation. In the general form of the body the *Astacidæ* approximate very nearly to the Salicoques, but they have not, he remarks, like them, branchiæ composed of laminæ piled one on another; these organs being formed by an assemblage of small cylinders more or less long, and brush-like, as in the greater part of the Cuirassed *Macrura*, which the Astacians also resemble in the hardness of their tegumentary skeleton; but their sternum is not enlarged into a plastron, and the nervous ganglions corresponding with the two thoracic rings are distant, and united by rather long double cords.

The body of the Astacians is elongated and a little compressed; the abdomen is very large, but at the same time less developed in proportion to the thorax than it is in the Shrimps. The carapace terminates anteriorly by a moderate rostrum, which overhangs the base of the ocular peduncles. The antennæ are inserted nearly on the same transversal line; those of the first pair are of moderate length, their peduncle is straight, and their terminal filaments two in number. The external or second pair are much longer, and their peduncle is furnished above with a moveable plate, which is analogous to the spiniform appendage in the *Paguri*, as well as to a similar but much larger plate which is found in the Salicoques. In the Astacians this appendage is hastiform, and never entirely covers the last peduncular joint situated below, and it is even rudimentary. The buccal apparatus presents nothing remarkable; the external jaw-feet are elongated, but bent back upon the mouth; their second joint is much larger than those which succeed, and they do not assist in locomotion. The first pair of feet are very large, and terminated by a large didactylous claw; the last four pairs are of moderate length, and nearly of the same general form, excepting that the second and third pairs are provided with a small didactylous claw, and that the last four are monodactylous. The abdomen is nearly of the same size throughout, and presents on each side a lamellar prolongation, which descends so as to incase more or less completely the base of the false feet. The last segment is very wide, and forms, with the two plates of each of the appendages of the sixth ring, a great caudal fin, all the pieces of which are nearly of the same length. The external plate of this fin has a transverse joint towards its posterior third part. The false natatory feet are elongated; in the male the first pair are styliform, nearly as in the *Brachyura*, while the others are terminated by two large foliaceous plates with ciliated borders, a condition which belongs to the whole of these feet in the female. The branchiæ amount to twenty on each side. They are disposed in three rows, so as to form vertical bundles separated by flabelliform appendages, fixed to the base of the feet. These last-mentioned appendages are very large, and are only wanting in the posterior feet.

This family corresponds to the genus *Astacus* of Fabricius; and M. Milne-Edwards, adopting the division established by Dr. Leach in founding his genus *Nephrops*, further separates the Crawfishes properly so called, from the true Lobsters thus:—

Astacians.	Rostrum depressed, and armed with one tooth at most on each side. Last thoracic ring moveable.		*Astacus* (Crawfishes).
	Rostrum straight, and armed with many teeth on each side.	Eyes spherical. Last ring of the thorax soldered to the preceding.	*Homarus* (Lobsters).
		Eyes reniform. Last ring of the thorax preserving a little mobility.	*Nephrops*.

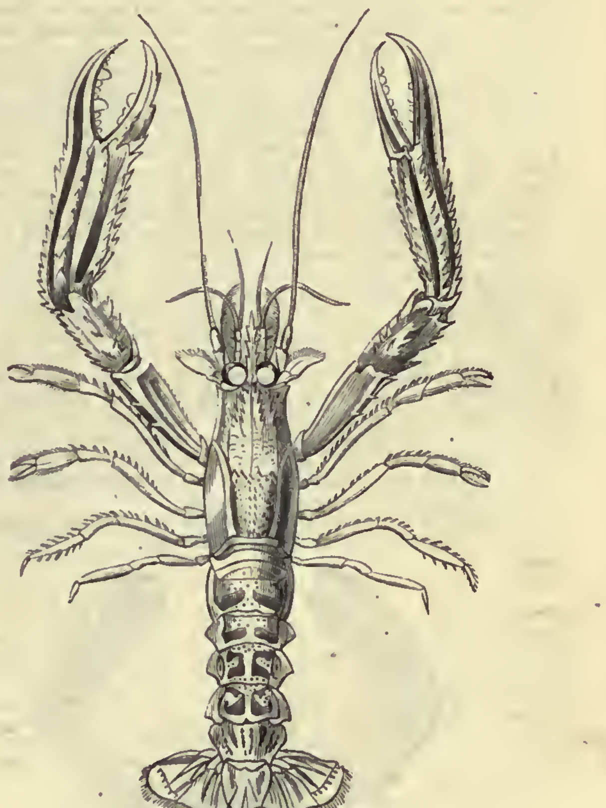
But the separation thus further carried out by M. Milne-Edwards does not depend on external distinctions only; for there are great differences in the conformation of the internal organs of generation and digestion, as compared with that of those essential parts of the animal economy in the other *Astacidæ*. Thus M. Milne-Edwards remarks, that in the Crawfishes the duodenal portion of the intestine presents on its internal surface a great number of small villosities, and is not clearly separated from the rectum, which is smooth internally; while in *Homarus* the duodenum is smooth within, the rectum is plaited internally, and there exists between these two parts of the digestive tube a kind of circular valvule; the posterior cæcal appendage of the intestine, which is seen at the extremity of the duodenum of the true Lobsters, is wanting in the Crawfishes. The liver is composed in the Crawfishes of small cæcal tubes, which are comparatively much more elongated, and its anterior lobes are less developed; the testicle is very small, and is composed of three lobes, whence spring the very long and tortuous deferent vessels, whilst in the true Lobsters these secreting organs are very much elongated, extending from the head into the abdomen, presenting no mesial lobe, but a simple commissure, and only giving rise to very short deferent canals.

The *Astaci*, which are all fluviatile, consist of the species *A. fluviatilis* [ASTACUS], *A. Bartonii*, *A. affinis*, *A. Australasiensis*, *A. Chilensis*, and *A. Blandingii* (?).

The *Homari*, which are all marine, consist of the species *H. vulgaris*, the Common Lobster [ASTACUS], *H. Americanus*, with its immense claws, and *H. Capensis*, according to M. Edwards, who considers the *Astacus scaber* of Fabricius as identical with *H. Capensis*. The species *A. cærulescens*, *A. fulgens*, *A. fulvus*, are unknown to M. Edwards, and considered doubtful by Latreille.

Nephrops (Leach).—Body more elongated than that of the Crawfishes; rostrum slender and rather long, armed with lateral teeth like that of *Homarus*. Eyes large and reniform. Lamellar appendage of the external antennæ wide, and long enough to extend beyond the peduncle situated below. Feet, first pair long and prismatic; succeeding pairs with a compressed manus. Nothing remarkable either in the abdomen or in the buccal appendages. Branchiæ disposed as in *Homarus*.

N. Norvegicus, the Norway Lobster, *Cancer Norvegicus* of Linnæus, is occasionally taken in the seas around the British Islands. It is one of the most beautiful of the larger *Macroura*. Its general colour is pale-flesh, rather darker in parts; the pubescence is light brown. It is generally considered a northern species, but Mr. Bell says he has received specimens from the Mediterranean. It is found on the coast of Norway in large quantities, and is also frequently taken on the coasts of Scotland, and sold in the Ediuburgh and other markets. It is taken in Dublin Bay, and is very common in the Dublin markets. It may also be occasionally seen in the London shops. It is said to be the most delicate-flavoured of all the *Crustacea*. Forms of the *Astacidæ* are found fossil. [CRUSTACEA.]



Norway Lobster (*Nephrops Norvegicus*).

HOME. [RAIIDÆ.]

HOMELYN. [RAIIDÆ.]

HOMOCERCAL. Fishes with symmetrical forms of tails are thus named by M. Agassiz, in contradistinction to Heterocercal. [HETEROCERCAL.]

HOMOLA. [HOMOLIDÆ.]

HO'MOLIDÆ, *Homola Tribe*. The Homolians, according to the system of M. Milne-Edwards, are the second tribe of the Apterurous family of the Anomurous Crustaceans, and their place is between the Dromians and the Raninians.

The carapace is spiny, and armed with a rostrum. Internal pair of antennæ without a pit, and incapable of being bent back upon the front. Jaw-feet pediform. Feet of the second, third, and fourth pairs very long; fifth pair very short, and of no service in progression. Sternal plastron enlarged. Claw terminating the anterior feet, composed of two fingers in the ordinary form. Tarsi of the three following feet styliform. Posterior feet more or less completely prehensile.

M. Milne-Edwards thus divides the tribe into three genera :—

Homolians having the posterior feet.	Sub-cheliform and exposed; carapace quadrilateral.		*Homola.*
	Cheliform, and hidden under the lateral parts of the carapace.	Carapace triangular; rostrum very much elongated.	*Lithodes.*
		Carapace circular; rostrum rudimentary.	*Lomis.*

Homola (Leach).—Carapace longer than wide, nearly quadrilateral; the stomachal region occupying the whole breadth of it anteriorly, and the branchial regions, though not prolonged above the base of the feet, very large; lateral portions of carapace vertical. Front narrow, and advancing so as to form a small rostrum; on each side of its base a large conic tooth directed forwards. Orbits extremely incomplete, even within, where the articulation of the ocular peduncles is naked; they are scarcely limited without, and are continued with a large oblique and very superficial pit, against which the eyes are applied. Ocular peduncles cylindrical, and divided into two portions—one internal, slender, and elongated; the other stout, short, and terminated by the eye. Internal antennæ not lodged in pits; their basilary joint nearly globular and advancing below the insertion of the ocular peduncles; the two succeeding joints very long, the third, as in the *Brachyura*, supporting two very small multiarticulate filaments. External antennæ inserted nearly on the same line as the internal; at their base a large auditory tubercle, which is sometimes extremely projecting; their first joint cylindrical, rather stout, and moderately long; the second slender and very long; the third very short; the terminal filament very long. Buccal frame quadrilateral. External jaw-feet nearly pediform, their three last joints being large, and nearly as long as the two preceding, which are hardly flattened. Sternal plastron much resembling that of the Dromians, and not containing the genital parts. Feet very long; first pair terminated by a nearly cylindrical hand, fifth pair raised upon the back and subcheliform. Abdomen very wide in the male as well as the female, and composed of seven distinct joints; in the female the first ring carries a pair of very short appendages; those of the four succeeding segments are of the same form as in the *Brachyura;* the penultimate ring has no vestige of any appendage. The vulvæ, instead of occupying a place in the sternal plastron, as in the *Brachyura*, are hollowed in the basilary joint of the third pair of feet. The disposition of the branchiæ is equally remarkable: there are 14 on each side; the first is laid across (en travers) under the base of the succeeding ones, and fixed to the base of the second jaw-foot; but the others are all directed obliquely up, and are fixed to the circumference of the vault of the sides. One is inserted at the ring which carries the jaw-feet of the second pair, two above the base of the external jaw-foot, three on each of the two succeeding rings, and two to the penultimate ring.

The species inhabit the seas of Europe.

H. spinifrons has its body covered with yellow hairs; length about 18 lines. It is found in the Mediterranean Sea.

Homola spinifrons. a, left external jaw-foot.

H. Cuvierii is the *Hippocarcinus hispidus* of Aldrovandus, and is also an inhabitant of the Mediterranean Sea.

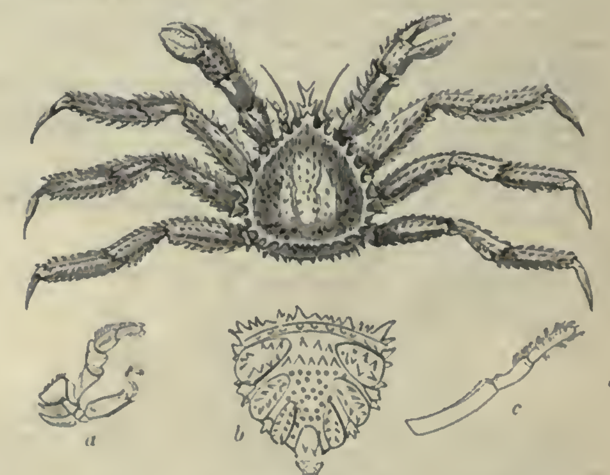
Lithodes (Latreille).—M. Milne-Edwards remarks that up to the present time the *Lithodes* have been arranged among the *Oxyrhynchi* on account of the form of the rostrum; but he asserts that it is not their place, and that they evidently belong to the *Anomura*. They bear, he says, the greatest analogy to the *Apterura*, and especially to *Homola;* but they establish the passage between these crustaceans and *Birgus*.

Carapace triangular or rather heart-shaped, its upper surface distinctly limited by a thick and spiny border. Rostrum horizontal and very long; its base covers the insertion of the eyes, and the anterior border of the carapace is very short. No orbits; but a stout conic tooth is seen at the place ordinarily occupied by the external angle of those cavities. Ocular peduncles very short. Internal antennæ inserted far from the mesial line, below and within the eyes; their first joint nearly cylindrical; the two succeeding of moderate length, and the terminal filaments of the same conformation as in the *Brachyura*. External antennæ inserted more backwards and outwards than the preceding; their basilary joint entirely mortised between a prolongation of the lateral border of the buccal frame and the anterior border of the carapace; the second carries a conic tooth externally, the last joint of the peduncle is long and slender, and finally the multiarticulate stem is rather long. The buccal frame is not distinct, except laterally, where its borders are straight. The external jaw-feet are pediform, and their second joint, which is stout and short, carries internally a strongly-toothed prolongation. The thorax presents a disposition different from that of the crustaceans which precede this genus in the system, but which is general in the succeeding family (*Pterygura*); its last ring is not soldered to the preceding, but free, and even moveable. The sternal plastron is linear between the first pair of feet, but becomes very wide afterwards, and presents complete transverse sutures between the last three segments; in the interior of the thorax there is no posterior sella turcica nor mesial apodeme, nor sternal canal. The feet of the first pair are moderate and cylindrical; the three succeeding pairs are very long and equally cylindrical; finally, those of the fifth pair are extremely small, and bent back in the interior of the branchial cavities; they are cylindrical, and terminated by a small claw with flattened and extremely short fingers. The abdomen is large, triangular, and bent back against the plastron; its basilary part is completely solidified below, but in the terminal half it is only furnished with corneo-calcareous isolated plates, which appear to represent the six last rings. In the female, oviferous filaments seem to exist only on one side of the abdomen.

As in the other Anomurous Crustaceans, the vulvæ are not situated on the sternal plastron, but occupy the basilary joint of the third pair of feet. The branchiæ are disposed as in the rest of the tribe.

L. arctica.—Length of carapace about 5 inches; colour, reddish-yellow.

It inhabits the northern seas.



Lithodes arctica (female).
a, left external jaw-foot; b, abdomen; c, foot of the fifth pair.

Lomis (Milne-Edwards).—M. Milne-Edwards remarks that the small crustacean on which he has founded this new genus has been confounded up to the present time with the *Porcellanæ*, to which it in fact bears a resemblance in its general form, but from which it differs in many important particulars, such as the conformation of the tail, the antennæ, &c. He gives the following generic character:—

Carapace depressed, narrowed anteriorly, and truncated posteriorly, it does not reach beyond the middle of the base of the third pair of feet, and the rest of the dorsal surface of the body is occupied by the base of the abdomen. The front is truncated, and armed with a small mesial tooth; there are no orbital pits, and the ocular peduncles have the form of two great triangular joints, which touch each other on their internal edge, and carry the eyes at their external angle. The internal antennæ are moderate; their first three joints are cylindrical, and terminate by two small filaments. The external antennæ are inserted on the outside of the eyes, and nearly on the same line; they are large, and terminated by a stout multiarticulate stem furnished with long hairs at its lower border. The external jaw-feet are pediform; their third joint has no noticeable dilatation, and the three succeeding joints are very stout. The sternum is large, and the last thoracic ring is not soldered to the preceding. The first pair of feet are very large, very wide, and extremely depressed; the carpus is as large as the arm, and nearly quadrilateral; the claw is stout, short, and nearly horizontal. The three succeeding pairs are short, stout, and terminated by a nearly conical joint; the fifth pair are very slender, and bent back above the others in the branchial cavity. The abdomen is very wide but lamellar, bent back below the sternum, as in the *Porcellanæ*, and presents no vestiges of appendages belonging to the penultimate ring.

M. Milne-Edwards says that he knows nothing of the manners of these small crustaceans, of which only one species is known, namely, *Lomis hirta* (*Porcellana hirta* of Lamarck). The above only is covered by very short and close-set hairs, and the hands are nearly as large as the carapace.

It is supposed to inhabit the seas of Australasia.

HOMOLONO'TUS, the name of a group of *Trilobites*, as they are generally called (*Palæaderna*, Dalman); in which the tripartite character of the dorsal crust is almost lost; for which reason Mr. Miller called it *Monolobite*. *H. Knightii* occurs in the Upper Silurian Rocks of England, aud a similar species at the Cape of Good Hope. [TRILOBITES.]

HOMO'PTERA, one of the sections into which the class *Insecta* is divided. According to Leach, Stephens, and some other authors, the section *Homoptera* is regarded as an order; but in Latreille's arrangement it forms the second of the two great sections into which the order *Hemiptera* is divided. The insects of this group are thus characterised by Latreille:—Rostrum arising from the lowest part of the head near the chest; the elytra, almost always tectiform, are of the same consistence throughout, semi-membranous, and sometimes resembling the wings; the three segments of the thorax are blended, and the first is often shorter than the following.

In the typical *Homoptera* the head is large, broader than long; the eyes are large, and there are ocelli, or simple eyes, between them; the antennæ are minute, composed of but few joints, and terminated by a seta; the rostrum is a slender jointed process, which, like that of the *Hemiptera*, lies close to the chest; the legs are of moderate size; the hinder tibiæ are usually spined; the body is convex above and flattish beneath; the wings are semi-membranous, the anterior pair often opaque, sometimes transparent, aud always of a uniform texture throughout. The larvæ are active, and resemble the perfect insect, excepting that they possess no wings; the pupæ are also active, but possess rudimentary wings.

These insects feed upon vegetable juices. The females are furnished with an ovipositor, composed of three denticulated blade-like processes, which are lodged in a groove in the abdomen. By means of this ovipositor they pierce holes in vegetables, in which they deposit their eggs. Many Homopterous Insects possess the power of leaping by means of their posterior pair of legs.

The section or order *Homoptera* may be divided into the following families, most of which are analogous to Linnæan genera, or nearly so:—

Family 1. *Cicadiidæ* (Leach) comprises those species in which the antennæ are 6-jointed, where there are three ocelli on the upper surface of the head, and where the tarsi are 3-jointed.

In these insects the wings are usually transparent, and have dark nervures; the males are furnished with an apparatus, situated at the base of the abdomen on each side, by means of which they create a monotonous musical sound. They are usually of large size (some measuring as much as 7 inches in width when the wings are expanded), and for the most part inhabit hot countries. But one species is found in England, the *Cicada hæmatodes* of authors, an insect about 2 inches in width, with transparent wings having black nervures, and their basal portion red; the anterior margin of the fore wing is also red; the body is black, but with the margin of each segment red; the legs are red, varied with black. This, which is the largest Homopterous Insect found in England, is not uncommonly met with in the New Forest, in Hampshire.

Family 2. *Fulgoridæ* (Stephens).—Antennæ 3-jointed, inserted beneath the eyes; ocelli two in number; tarsi 3-jointed.

The insects of this family have generally the fore part of the head produced, aud varying in form according to the species. They do not possess the power of creating a sound, nor do those of the following families. [FULGORA.]

The above two families constitute the section *Cicadariæ* of the 'Règne Animal.' The *Fulgoria laternaria* (Linn.) will serve as an illustration of the second. This curious insect is an inhabitant of Brazil. It is about 5 inches wide, and 2½ inches long, of a yellowish colour mottled with black, and having a large ocellated spot on each of the under wings.

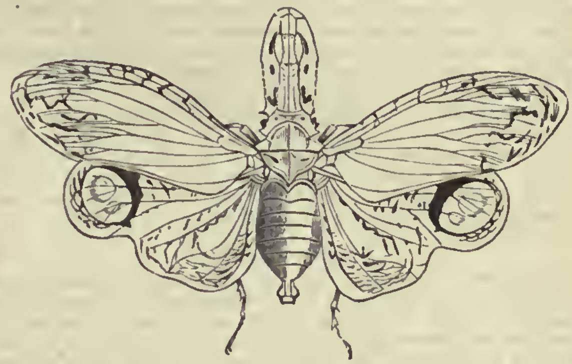
Family 3. *Cercopidæ* (Leach).—The antennæ 3-jointed; tarsus 3-jointed; ocelli two in number; antennæ situated between the eyes. [CICADELLA.]

Family 4. *Psyllidæ* (Stephens).—Antennæ with 10 or 11 joints, of which the last is terminated by two setæ; legs formed for leaping; tarsi 2-jointed; both sexes winged.

Family 5. *Thripidæ* (Stephens).—Antennæ 8-jointed; rostrum minute; tarsi terminated by a vesicular joint, and without claws.

Family 6. *Aphidæ* (Leach).—Tarsi 2-jointed; antennæ with seven joints; rostrum, in both sexes, with three distinct joints; females generally apterous. [APHIS.]

Family 7. *Coccidæ* (Leach), *Gallinsecta* (Latreille).—Tarsus with but one joint and one claw; the male sex destitute of rostrum, and possessing but two wings; the female apterous, and furnished with a rostrum; antennæ generally 11-jointed. [COCCIDÆ.]



Fulgoria laternaria, half the natural size.

HOMOPUS. [CHELONIA.]
HONEY, HONEYCOMB. [BEE.]
HONEY-BUZZARD. [FALCONIDÆ.]
HONEY-GUIDE. [INDICATORINÆ.]
HONEY-LOCUST. [GLEDITSCHIA.]
HONEY-STONE. [MELLITE.]
HONEY-SUCKER. [NECTARINIDÆ.]
HONEYSUCKLE. [CAPRIFOLIACEÆ; LONICERA.]
HONEYSUCKLE, FRENCH. [HEDYSARUM.]

HONEY-WARE, a name given to *Alaria esculenta*, known in Scotland as Badderlocks.

HONKENEJA, a genus of Plants belonging to the natural order *Caryophyllaceæ*, and the sub-order *Alsineæ*. It has 5 sepals, 5 large petals, 10 stamens alternating with glands, 3 styles and valves, aud very few large seeds.

H. peploides is a British species found on sandy sea-coasts. It has ovate-acute sessile leaves, fleshy, glabrous, and 1-nerved; the petals obovate; sepals ovate-obtuse, 1-nerved, shorter than the petals; the stems are dichotomous, procumbent, rhizomatous; the flowers proceed from the forks of the stem frequently diœcious; capsules large, globose; seeds few, and large.

HOOD-CAP. [PHOCIDÆ.]
HOODED-CROW. [CORVIDÆ.]
HOOPER. [CYGNINÆ.]
HOOPOE. [PROMEROPIDÆ.]
HOP. [HUMULUS.]
HOPEITE. [ZINC.]

HO'RDEUM, the genus of Plants to which the corn called Barley belongs. It is distinguished from *Triticum*, or the Wheat genus, by its spikelets having only one perfect floret in each, and by its glumes being somewhat unilateral and bearded; Rye, or Secale, differs in having two perfect florets to each spikelet, and in the same additional circumstances as *Triticum*. As many as 15 species of *Hordeum* are distinguished by Professor Kunth, the latest writer upon the subject; in addition to which there are many varieties. The species are found wild in various places in both the Old and New World: as many as eight inhabit America. In the application of their botanical names to the cultivated barleys there is some confusion, one writer distinguishing four species, another six, and some a greater number. It does not appear possible to determine, upon existing evidence, which of these opinions is most correct; the probability however seems to be that there are not more than four, or at the utmost six species, which may be readily distinguished by attention to the following circumstances:—The 1-flowered spikelets of Barley grow in threes, on opposite sides of the ear. If all the spikelets are perfect, the grains of corn are therefore necessarily arranged in six lines or rows; these rows may be very distinctly arranged, as in *H. hexastichum*, or they may be disposed in an irregular manner, as in *H. Ægiceras*. But if the lateral spikelets of each parcel are imperfect all along the ear, the middle spikelet alone producing a grain of corn, the grains in that case will be in two rows only, as in *H. distichum* and *H. Zeocriton*. Of these two distinct forms there are some in which the grain adheres to the paleæ, or husk, as in Common Barley, and others in which the grain is free from the husk, as in Naked Barley. It is generally supposed that barleys of the second kind are mere varieties of those of the first kind; but there is no proof of the correctness of the opinion, and probability is against it. These characters and a few others being attended to, cultivated barleys may be arranged under the following heads:—

* Two-Rowed Barleys.

1. *H. distichum* (Linn., 'Sp. Pl.,' 125). Ear cylindrical; awns almost parallel with the ear; grains adhering to the husk. This is the Common Summer-Barley of England, and that which cultivators seem to prefer; its ears are not so large as those of *H. hexastichum*, but the grains are heavier. It is commonly stated to be a native of Tartary. Colonel Chesney found it wild in Mesopotamia, upon the banks of the Euphrates.

2. *H. gymnodistichum* (Lowe's 'Elements of Agriculture,' p. 238.) Ear cylindrical; awns almost parallel with the ear; grains loose in the husk. Naked Barley, a species but little cultivated now, is of unknown origin. It is said to have been introduced into England in the year 1768; but it is reported to have preserved its characters unaltered from time immemorial in some parts of Europe.

3. *H. Zeocriton* (Linn., 'Sp. Pl.,' 125). Ears conical; awns spreading away from the ear, in a flabelliform manner; grains adhering to the husk. From the spreading direction of the awns, the ears of this barley acquire a much broader figure at the top than at the bottom, on which account it has been called Battledore Barley; it also bears the name of Sprat-Barley. It is little cultivated in England, because of the shortness of its straw; its native country is unknown.

** Six-Rowed Barleys.

4. *H. hexastichum* (Linn., 'Sp. Pl.,' 125). Ears cylindrical; awns very long, rough, and rigid, rather spreading away from the ear; grains adhering to the husk. It does not appear in what way the *H. vulgare* of Linnæus differs from this. Professor Lowe has justly remarked that there is no such thing as a barley with the grains growing in four rows, the circumstance by which Linnæus defined his *H. vulgare*, and that all such appearances are merely imperfect states of *H. hexastichum*. The native country of this species is unknown: it is the Bere, Bigg, or Winter Barley of farmers, and is particularly valuable for ripening quicker than the Common Two-Rowed Barley; its grains are however lighter, and it is considered an inferior species to the last. To northern nations with short summers it is however invaluable.

5. *H. gymno-hexastichum* (Lowe's 'Elements of Agriculture,' p. 238). Ear cylindrical; awns very long, rough, and rigid, rather spreading away from the ear; grains loose in the husk. The origin of this, the Naked Six-Rowed Barley, is unknown. It is extremely productive, and in some parts of Europe it is reckoned the most valuable of all. The French call it, on account of its good qualties, Orge Céleste.

6. *H. Ægiceras* (Royle's Manuscripts). Ears cylindrical; florets arranged in a confused manner, not in rows; awns soft, short, hooded, and bent downwards; grains loose in the husk. A most curious species, found in the northern parts of India, and probably in Tartary, as its grains have been sent to England under the name of 'Tartarian Wheat.' Its appearance is more that of wheat than of barley, and its naked grains assist the resemblance. It is however a genuine species of *Hordeum*. It appears to be a productive plant, but little is as yet known of its quality in this climate.

Of most of the species there are many varieties, the most striking of which are those called 'Black Barleys,' on account of the dark colour of their husks. They are not of sufficient importance to require particular notice, except in works treating of agriculture in great detail. [Barley, in Arts and Sc. Div.]

HOREHOUND. [Marrubium.]

HORNBEAM. [Carpinus.]

HORNBILLS, a family of Birds named after the genus *Buceros*—*Bucerida*. They constitute a family of birds, the construction of whose bill arrests the attention at first sight, and ornithologists have not been entirely agreed as to the situation which the form ought to occupy in the series.

It is not at all improbable, from the geographical distribution of the species, that some of the species were known to the ancients; but whether the *Tragopan** of Pliny and Solinus, or the *Tragopomenes* of Pomponius Mela, belonged to this genus is not clear. That the Rhinoceros Bird of Hesychius and Varinus was one of the species is not unlikely. Aldrovandus, Jonston, and Bontius† give the form the same name, as do Ray and Willughby‡, the latter of whom gives two good figures of heads. Bontius also describes one of the species under the appellation of *Corvus Indicus*, and another as *Corvus rostro-cornuto*. Petiver received the bill of one (which he figures) from Kamel, under the name of *Calao*. The description of the bird said by Jonston and others to have been killed as it was flying, when the Christians beat the Turks at the battle of Lepanto (Naupactum), agrees well with the characters of the genus.

Brisson gives the Hornbills the name of *Hydrocorax*, following, not improbably, Clusius, who speaks of one of them under the title of *Corvi Marini genus*.

Linnæus, in his last edition of the 'Systema Naturæ' (12th), places the Hornbills, genus *Buceros*, under the *Picæ*, between the Toucans (*Ramphastos*) and *Buphaga*. The feet he defines to be gressorial. Gmelin leaves *Buceros* in the same position.

Latham also places the Hornbills among the *Picæ*, Pies, with walking feet.

Lacépède removes the form far from the Toucans, placing it at the head of his *Platypodes* and in his 16th order (bill dentilated), with the Momots, in his second division of his first sub-class of birds, or those which have three anterior toes, and sometimes a hind toe, sometimes none.

M. Duméril's second family of his second order, Passereaux, or Passerine Birds, consists of the *Dentirostres*, or *Odontoramphes*, including two of the Hornbills, Momots, Plant-Cutters (*Phytotoma*).

Illiger's *Dentirostres* come between the Passerine Birds and Crows, and belong to his second order, *Ambulatores*, or Walking Birds.

Cuvier places the *Buceridæ* at the end of the Syndactylous Passerine Birds; they are immediately preceded by the Todies (*Todus*). Next to the *Buceridæ*, in his system, come the Scansorial Birds (Les Grimpeurs), headed by the Jacamars (*Galbula*, Briss.), which are followed by the Woodpeckers. He speaks of the *Buceridæ* as large birds of Africa and the Indies, whose enormous bill renders them so remarkable, and connects them with the Toucans, while their carriage and habits bring them near to the Crows, and their feet are those of the Bee-Eaters and Kingfishers.

M. Vieillot arranges the Hornbills and Momots in his family of *Prionotes*, in the second tribe (*Anisodactyli*) of his second order of birds (*Sylvicolæ*).

M. Temminck introduces the Hornbills among the Omnivorous Birds, the second order in his arrangement.

Mr. Vigors places the *Buceridæ* in the aberrant group of his *Conirostres*. *Fregilus*, in the opinion of that ornithologist, by its curved and slender bill, leads immediately to the Birds of Paradise, which, in conjunction with the *Epimachus* of Cuvier, terminates Mr. Vigors's family of *Corvidæ*, and here, Mr. Vigors thinks, we shall find the passage from the *Corvidæ* to the *Buceridæ*. He speaks indeed with considerable hesitation as to the situation of *Epimachus*, but observes that, being more united in its front toes than the *Corvidæ* in general, it holds a middle station, in respect to that character, between the two groups; while in the length and curvature of its bill it approaches, in conjunction with many of the *Paradiseæ*, to some of the extreme species of the *Buceridæ*, among which, he remarks, the *Buceros nasutus* of Dr. Latham may be instanced.

"We thus," says Mr. Vigors, "arrive at the singular family of *Buceridæ*, which seems to draw near to the preceding groups in its food and habits, as far at least as we can conclude from the very imperfect accounts which are transmitted of them. From the strength also of the formation of these birds, and the powers with which they are endowed, they seem to assert a title to a place in the vicinity of the group which is typical in the tribe. In one particular however we may detect a deviation from the more perfect structure of that type. The fore toes of all are strongly united at the base, the external being joined to the middle as far as to the second articulation; an impediment which must considerably interfere with the free action of the member. This deficiency is, on the other hand, retrieved by the superior robustness and muscular conformation of the whole limb. An analogous defect, and an analogous mode of compensating for it, is observable in the Ostrich, a bird also, it is to be observed, closely allied to the typical group of its own family; and in both instances we may pronounce the deviation from the more regular or perfect conformation to be a defect rather to the eye of the observer, an infringement upon what he would conceive to form the 'beau-idéal' of the typical character, than a defect in reality. We may here delay a moment to observe upon the causes that assign so totally remote a station from the present to the *Todidæ*, *Meropidæ*, and *Halcyonidæ*, whose gressorial feet, as they are technically called, are of precisely the same structure as those of *Buceros*. In them, the deficiency, accompanied by a corresponding weakness of the whole member, is real, and of sufficient consequence to deprive the bird of the means of using its legs and feet to advantage. The force and powers of these parts are in fact transferred to the wings, which are thus endowed with a more than usual share of strength, in order to afford the bird a more than usual assistance in the aërial mode of seeking its food which it is assigned by nature. In the *Buceros*, on the other hand, the gressorial feet are accompanied by a superior robustness, which counterbalances their inferiority in form. And hence the family may consistently maintain its station in the vicinity of the more perfectly formed and typical groups of the *Insessores* which are now before us. The tendency, already observed, which opposite points of the circle in which a series of affinities is united have to approach each other, accounts for the resemblance here pointed out between these otherwise discordant groups, and serves to explain the reason why the analogous relation between them has been mistaken for a relation of affinity by systematic writers, so far as to induce them to arrange all the gressorial birds in one connected group. Besides the genus *Buceros*, Linn., the protuberance on the bill of which varies in almost every possible shape in which fancy can embody it, the present family includes the *Momotus* of M. Brisson, which accords with the entire of that genus in its gressorial feet, and with several species of it, as the genus now stands,

* The *Tragopan* of modern zoologists is a gallinaceous bird, considered by many to be intermediate between *Meleagris* and the typical Pheasants.

† "Corvus Indicus cornutus, seu Rhinoceris Avis."

‡ Willughby terms the Hornbill "The Horned Indian Raven, or Topau, called the Rhinocerot Bird."

in the curved but somewhat shorter and more attenuated bill." [MOMOT.]

In his remarks on the succeeding order, *Scansores*, Mr. Vigors observes, that besides the deviation from the more perfect formation of the foot in the *Buceridæ*, which prepares us for the more considerable deviation that takes place in the same particular among the Scansorial Birds, the large and disproportionate bill of that family is carried on to the *Ramphastidæ*, the first family of the *Scansores*, according to Mr. Vigors.

M. Latreille arranges the Hornbills among the *Syndactyles*, the fifth family of his second order (Passereaux, or Passerine Birds), in company with the Bee-Eaters, Momots, Kingfishers, &c.

In the method of M. De Blainville, as carried out by his pupil M. Lherminier, the Hornbills appear among the Normal Birds (first sub-class), and as the 14th family, between the Kingfishers and the Toucans.

M. Lesson, in his 'Projet,' places the *Buceridæ* as the last family of his *Insessores*, or Grimpeurs, arranging it in the third tribe (*Syndactyles*) of that his first order. The other families of the tribe are the Bee-Eaters, *Meropidæ;* Kingfishers, *Halcyonidæ;* and Cocks of the Rock, *Rupicolidæ*.

Mr. Swainson arranges the *Buceridæ* among the *Conirostres*, together with the *Corvidæ*, *Sturnidæ*, *Fringillidæ*, and *Musophagidæ*. After noticing the peculiar conformation of the bill in the *Buceridæ*, he observes that in some of the species that organ is without the basal protuberances, so that they bear the nearest affinity to the Toucans, belonging to the Scansorial tribe, which is joined to the Conirostral. He considers that we have no bird which actually unites the two families in so perfect a manner as that by which the Toucans are blended with the *Fissirostres* through *Prionites;* and he remarks, that we should expect that a bird which might conduct us from the Toucans to the Hornbills would be of large size, and that it would present us with some of the gay colours peculiar to the Toucans, both in its bill and plumage; but that its feet should no longer exhibit the scansorial structure, inasmuch as that, as he has before remarked, we see, in the little power possessed by the Toucans of climbing, that nature is about to quit the scansorial structure. There is good reason to believe, he thinks, that such a bird is in existence, although at present only known to modern writers by a drawing executed in India, in the collection of Mr. Smith. Both Dr. Latham and Dr. Shaw, he adds, describe this bird under the name of the Crimson Hornbill, and he considers that the figure published by the latter carries internal evidence of its authenticity. Mr. Swainson sees in this bird the crimson colour, the long tail, and the dorsal collar, so prevalent in the genus *Pteroglossus*, joined to a miniature Toucan's bill, with a distinct band at the base, like the *Ramphastos Tucanus*, yet with the feet of a Hornbill. That this bird, and probably other annectant species, will hereafter be discovered in the vast and still unexplored regions of Central Asia, Mr. Swainson does not doubt. He speaks of the Hornbills as a small family, of which perhaps the typical form is now only known; and he looks upon them as being as much isolated as the Toucans and the Parrots. He adverts to their enormously large bills, generally furnished with an appendage or excrescence on their top, the use of which, he says, is unknown; nor has, he adds, the internal structure of this member been fully ascertained. The feet, he remarks, are generally so very short as to appear calculated only for perching. "United," continues Mr. Swainson, "to the Scansorial Birds by means of the Toucans, they would seem to represent the *Rasores;* but the structure of their feet, more imperfect than any of the families in this order, forbids the supposition. This opinion we had long entertained from theory, but it has recently been confirmed by a singular fact in their economy, communicated by an officer long resident in India. It seems that all the species of *Buceros* he has met with in a live state are constantly in the habit of throwing their food up in the air and catching it before it is swallowed." This propensity Mr. Swainson considers to be an incipient development of the fissirostral economy. We have only to add, that Mr. Swainson does not admit into the family of the *Buceridæ* the Momots (*Prionites*), which he places under a line drawn at the end of the family of *Trogonidæ*. ('Classification of Birds.')

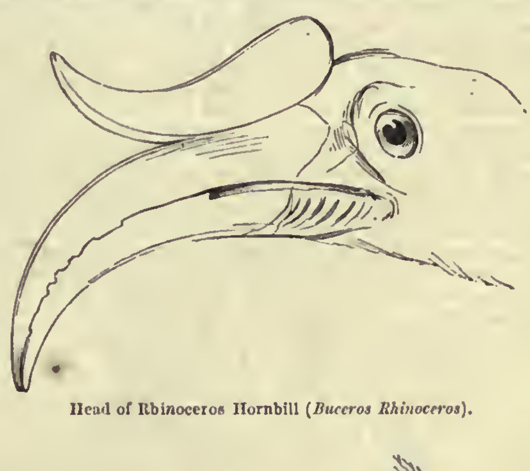
Some light will be thrown on the proper place of the bird in the animal series by the following account of the anatomy of a young *Buceros cavatus* by Professor Owen:—The tongue was very short, of a triangular form, and very smooth. The air-cells were very large, and that in front of the neck contained the œsophagus and the trachea. The œsophagus, as in the Toucan, was very wide, and of nearly equal diameter as far as the gizzard. The gizzard was thicker in its coats and of a more elongated form than that of the Toucan: its cuticular lining was very tough, and disposed in longitudinal ridges. After the duodenal fold the remainder of the intestinal canal was disposed in two similar folds, and then extended along the middle line of the back to the cloaca. There were no cæca. The coats of the intestines were stronger than is usual in birds, and the diameter of the canal was more considerable, diminishing however gradually from the commencement of the ilium, as far as the beginning of the rectum, and thence becoming wider to its termination. The whole length of the intestines was 5 feet; that of the bird, from the end of the bill to the vent, being 2 feet 2 inches, of which the bill measured 7 inches. The liver had the usual two lobes, of which the right was the largest. The gall-bladder was of considerable size. The pancreas, of an elongated slender form, had a small oval enlargement at its commencement at the lower end of the spleen, and a flattened oblong mass or head at the bottom of the duodenal fold: it accompanied the duodenum throughout its length, being folded on itself similarly to the intestine. Its secretion was conveyed into the intestine by three ducts; one from its head, which entered the duodenum at the head of the fold; the others from the elongated lobes, which terminated close together at the end of the fold between the insertions of the hepatic ducts; an arrangement corresponding with that which exists in the Heron. In the cloaca the rudimentary bladder was little more than a line in width, and the ridges bounding it above and below were confined to the back part of the cavity. The bursa Fabricii (which Professor Owen regards as analogous to the glandular pouch found in so many other classes) was of a triangular form, large, and surrounded, as usual, by a capsule of muscular fibres.

The muscles of the mandibles consisted of a digastricus, or of a muscle analogous to it, destitute, as is usual in birds, of a middle tendon, a temporal muscle of moderate size, and pterygoidei externi and interni, proportionally more developed. There is also a strong ligament occupying the place of the masseter, and a second, destined to prevent dislocation backwards, which passes from the zygoma directly backwards to the condyle, or articulate depression of the lower jaw. Disproportionate as this apparatus seems to the moving of so large a body as the bill of the Hornbill, it is yet fully adequate, the weight of that organ by no means corresponding with its size. The cavities in the bones, the arrangement of the columns supporting their parietes, and the air-cells, produce at the same time lightness and strength.

With respect to the other parts of the skeleton, Professor Owen particularly noticed the extension of the air-cells into the distal bones of the extremities. He remarked that Mr. Hunter observes how, in the Pelican, the air passes not only into the ulna and radius, but "into those bones which answer to the carpus and metacarpus of quadrupeds." In the Hornbill the air passes also into the bones corresponding to the phalanges; and in the posterior extremity that it permeates the tibiæ, tarsi, and phalanges.

Professor Owen concludes by some remarks on the affinities of the Hornbill as deducible from its anatomy. Its nearest approach is to the Toucan. The Toucan however, in the want of a gall-bladder, agrees with the Parrots; the presence of that organ in the Hornbill places the bird in more immediate relation with the Crows. The disposition of the intestines in long and narrow loops also agrees with the Raven. The tongue, so remarkably varied in form and use among the *Scansores*, resembles in the Hornbill that of the Carnivorous Birds. ('Proceedings of the Zoological Society of London,' 1833.)

Buceros.—Bill long, very large, compressed, more or less curved or falcated; base smooth, elevated, or rather surmounted by a casque or



Head of Rhinoceros Hornbill (*Buceros Rhinoceros*).

Foot of *Buceros cavatus*.

helmet-like protuberance; edges of the mandibles smooth or notched; point smooth; interior of the bill, especially the upper mandible and casque, very cellular; nostrils basal, on the surface of the beak, in a furrow, small, somewhat round, open, pierced in the corneous substance of the bill, covered at the base by a membrane. Feet short, strong, muscular; sole of the foot large. Wings moderate; the first three quills graduated; the fourth or fifth the longest. [BIRDS.]

The species of *Buceros* are found in the Old World, Africa, India and its islands, and New Guinea.

Bontius, in his description of his *Corvus Indicus* (*Buceros Hydrocorax* of Linnæus), a native of the Moluccas and Banda, says, "More Corvi nostratium graditur, indole a nostris corvis differt, quod non cadavere, sed potissimum nucibus myristicis avide vescatur; iisque insigne damnum infert. Caro eorum quoque delicata est, et assa saporem a pastu plane aromaticum habet (It walks like the crow of our countries, but differs much in disposition from our crows, inasmuch as it feeds not on carcasses, but most especially on nutmegs, and that greedily, doing a great deal of damage to them. Their flesh also is delicate, and when roasted has an aromatic flavour from their food)." Of the 'Corvus rostro cornuto' (*B. Rhinoceros* of Linnæus) he says that it lives on the carcasses and intestines of animals, and that it waits upon the hunters who kill wild cattle, boars, and stags, to gorge itself with the entrails of those animals. Willughby, in his account of 'Bontius his Indian Raven,' says, "It walks after the manner of our Raven, but differs from it in nature and disposition, in that it feeds not upon carrion or dead carcasses, but chiefly upon nutmegs, of which it is very greedy, making great destruction of that fruit, to the no small detriment of the owners. Its flesh is very delicate, and being roasted hath a plain aromatical relish, contracted from its food." Of 'The Horned Indian Raven, or Topau, called the Rhinocerot Bird,' he says, "This horned bird, as it casts a strong smell, so it hath a foul look, much exceeding the European Raven in bigness. . . . . It lives upon carrion and garbage, that is, the carcasses and entrails of animals." Both these passages are taken from Bontius, as the reader will perceive. Cuvier considers them as omnivorous—"Ils prennent toute sorte de nourriture;" and he states that they eat tender fruits, hunt mice, small birds, and reptiles, and do not even disdain carcasses. The late Major-General Thomas Hardwicke, who contributed so largely to our acquaintance with Indian animals, in treating of *B. galeatus* ('Linn. Trans.,' vol. xiv.), gives the following description of the habits of the Hornbills:—"The progressive motion of the birds of this genus, although their feet are formed for walking, is always by jumping or hopping. I have kept several species alive, and they all moved in the same manner. In a state of nature these birds, in this part of India (Malacca), live on wild fruits. In confinement they feed freely on plantains and on boiled rice. At night they perch with great security, though the largeness of the foot seems better suited to rest on the ground." M. Lesson sums up the habits of the Hornbills thus:—Those of Africa live on carrion; those of the East Indies seek for fruits, especially nutmegs, and their flesh acquires from them a delicious flavour. Their flight is performed by repeated strokes of the wings, and the air which they displace, joined to the clattering of their mandibles, occasions a great and very disquieting noise in the forests, when the cause is unknown. This noise, capable of inspiring terror, does not ill resemble those flaws of rough and sudden winds ("grains de vent brusques et subits") which arise so unexpectedly between the tropics, and blow so violently. The Europeans established at the Moluccas think that the furrows which are seen on the bill of the Hornbills are the result of age, and that each furrow signifies a year; whence the name of Jerarvogel, which they give to these birds. Mr. Swainson remarks that the Hornbills are gregarious noisy birds, generally of a very large size, and are restricted to the Old World; that they are omnivorous, feeding both on animals and vegetables; that some however seem only to partake of the latter food; while others, upon the authority of Le Vaillant, feed upon carrion. The *B. cavatus* dissected by Professor Owen was observed to be more attached to animal than to vegetable food, and would quit any other substance if a dead mouse were offered to it. This it would swallow entire, after squeezing it twice or thrice with the bill; and no castings were noticed. Professor Owen however adds that Petiver has borne testimony to its regurgitating habits.

Before we proceed to give examples of the family as it here stands, that is, as consisting of the true Hornbills alone, we may remark that if it should be clearly made out that some species live entirely on vegetable food, while others live on carrion, as has been asserted, there may be good grounds for elevating such species to the rank of genera; for such a total difference of food must in all probability be accompanied by a corresponding difference of internal structure and of general habits. M. Temminck may be considered as the author who has most successfully dissipated the obscurity in which the species were involved; and to his elaborate and beautiful works we refer the reader. We shall select as examples the following two species.

B. Rhinoceros, Rhinoceros Hornbill. This species is to be found in most collections, and though there may be some variety from age and circumstances, the bill will be generally found to be about 10 inches long and of a yellowish-white, the upper mandible red at the base, the lower black. The horn, or casque, varied with black and white.

The body black, of a dirty white below and posteriorly; tail about 12 inches, the feathers white at the base and tip, black in the middle; feet and claws obscure gray.

Rhinoceros Hornbill (*Buceros Rhinoceros*).

It is a native of India and the Indian Islands (Sunda, for instance).

B. cavatus. Throat, ear-coverts, circle round the eye, and a narrow band at the occipital edge of the protuberance of the beak, black; neck dirty straw-colour, the feathers of the back of the neck elongated; body and wings black, greater coverts and quill-feathers tipped with white; thighs, upper and under tail-coverts, white; as is the tail also, with the exception of a broad black band about three inches from the tip; beak yellowish, inclining to scarlet at the tip, under mandible black at the base; tarsi black. (Gould.)

Buceros cavatus.

The food of the *Buceros cavatus*, like that of other Hornbills, consists of fruits, berries, flesh, and even carrion; in short, it may be considered as strictly omnivorous. (Gould.)

It is a native of India, the Himalaya Mountains, Java, and most of the islands of the Indian Archipelago.

The species of *Buceros* are very numerous.

HORNBLENDE, a Mineral belonging to the group of the Anhydrous Silicates of Magnesia. An account of its general characters and formation is given under AUGITE. It is subject to numerous varieties differing much in appearance, arising from isomorphism and crystallisation. Alumina enters into the composition of some of them, and replaces part of the other ingredients.

The varieties are divided into light and dark coloured.

To the light coloured varieties belong *Tremolite* or *Grammatite.* It comprises the white, grayish, and light-greenish slender crystallisations, usually in blades or long crystals, penetrating the gangue, or aggregated into coarse columnar forms. It is sometimes nearly translucent. The specific gravity is 2·93.

The light-green varieties are called *Actinolite. Glassy Actinolite* includes the bright glassy crystals of a rich green-colour, usually long and slender, and penetrating the gangue like tremolite. *Radiated Actinolite* includes olive-green masses, consisting of aggregations of coarse acicular fibres, radiating or divergent. *Asbestiform Actinolite* resembles the radiated, but the fibres are more delicate. *Massive Actinolite* consists of angular grains instead of fibres. The specific gravity is 3·02 to 3·03. [ACTINOLITE.]

Asbestus is also included under this division. [ASBESTUS.]

To the dark-coloured varieties belongs *Pargasite,* a term which is applied to dark-green crystals, short and stout, of bright lustre, of which Parga in Finland is a notable locality.

The term *Hornblende* is applied to the black and greenish-black crystals and massive specimens. It contains a large per-centage of oxide of iron, and to this owes its dark colour. It is a tough mineral. Pargasite and Hornblende both contain alumina.

The varities of Hornblende fuse easily with some ebullition, the pale varieties forming a colourless glass, and the dark a globule more or less coloured with iron. Hornblende is an essential constituent of certain rocks, as syenite, trap, and hornblende-slate.

Actinolite is usually found in magnesian rocks, as talc, steatite, or serpentine. *Tremolite* occurs in granular limestone and dolomite; *Asbestus* occurs in the above rocks, and also in serpentine.

(Dana, *Manual of Mineralogy.*)

HORNBLENDE-SCHIST. Under this term M'Culloch ranks a variety of mineral aggregates in which hornblende abounds, and which are mostly but not universally of laminated structure. Hornblende-Schist is commonly associated with gneiss, less frequently with mica-schist, and seldom forms alone any considerable mountain masses. It follows the contortions of gneiss, and is traversed like it by granite veins. (Glen Tilt.) Hornblende is rarely associated with argillaceous slate, as in Ben Lair, in Skiddaw, Cader Idris, and near the granites of Cornwall. In these cases its origin may perhaps be due to the action of the contiguous heated granitic masses, and such rocks may be considered 'metamorphic.' They are considerably different from the Hornblende-Schists of Glen Tilt, Iona, and Ross-shire. (M'Culloch on 'Rocks.')

HORN-EEL. [AMMODYTES.]

HORNE'RA, a genus proposed by Lamouroux to include a small recent stony Polypifer, which Solander ranked among the Millepores, and Lamarck among the Retepores. Like the latter genus, it has cells on one side only: they are arranged almost in quincunx, on diagonal lines; the opposite side is slightly furrowed. (Lamouroux, 'Tableau Méthodique.')

HORNET. [VESPIDÆ.]

HORNET-MOTH. [SPHINGIDÆ.]

HORN-FISH. [SYNGNATHIDÆ.]

HORN-POPPY. [GLAUCIUM.]

HORNSTONE. [QUARTZ.]

HORSE. [EQUIDÆ.]

HORSE-CHESTNUT, the *Æsculus Hippocastanum* of botanists: it is said to derive its name from the practice among the Turks of feeding their horses on the seeds of this tree. [ÆSCULUS.]

HORSE-RADISH. [COCHLEARIA.]

HORSE-TAIL. [EQUISETUM.]

HORTIA, a genus of Plants belonging to the natural order *Rutaceæ. H. Braziliana* possesses in its bark properties resembling those of *Cinchona,* but in a less degree.

HORTULIA. [BOIDÆ.]

HOT-SPRINGS. [GEYSERS.]

HOTTO'NIA, a genus of Plants belonging to the natural order *Primulaceæ.* It has a 5-parted calyx, divided almost to its base; the seeds, with the hilum, close to one end; the stamens, 5, inserted and included in the tube of the corolla; the capsules many-seeded and 5-valved, with 10 teeth.

H. palustris has the flowers whorled, stalked, and seated upon a long solitary cylindrical common peduncle, the corolla longer than the calyx, the leaves pectinated. It is a native of Great Britain in ponds and ditches, and is called the Water-Violet. The leaves are submerged and crowded; the flowers rising above the water are of a purple and yellow colour. It is a pretty plant, but possesses no useful available properties.

(Babington, *Manual of British Botany.*)

HOUND (from the German Hund), a name generally applied in the British Islands to those varieties of the Dog which are employed in hunting the Deer, the Fox, the Hare, and the Otter, by scent. The hound employed for following depredators, and used so much in the old Border times, was called a Blood-Hound. [BLOOD-HOUND.] The Grayhound, which follows its four-footed game by the eye [GRAYHOUND], is not a hound in the proper acceptation of the term adopted by sportsmen; for that appellation is confined to those varieties of the Dog which are trained to that species of chace called Hunting, which implies that the dogs so employed follow their four-footed game by the scent principally.

In addition to the Blood-Hound,—the Stag-Hound, the old Southern Hound, the Fox-Hound, the Harrier [HARRIER], and the Beagle [BEAGLE], were the hounds of greatest note. Some of these varieties, the old Southern Hound for instance, which was slow but very sure, and with a fine deep-toned voice when it gave tongue in earnest, are gradually disappearing; and indeed the pace required now in most kinds of hunting, except otter-hunting, but especially in fox-hunting, has brought into demand a breed of hounds whose fleetness requires the best and fastest horses. The old fox-hunter of the early part of the last century would find himself 'nowhere' on a good day in Leicestershire, could he now be present. His horses and hounds were bred with a view to endurance rather than speed; and if he were to appear at a modern 'meet,' he would see that an entire revolution has taken place in the system. Whether this is an improvement is a question which will be answered differently, according as the respondent may prefer the old-fashioned slow hunting, where all the sagacities of the hound were minutely developed, not without a good deal of 'music,' or the rapidity which makes a good run now-a-days very like a race. The young, bold, and well-mounted rider will generally prefer the latter.

The Southern Hound, which is supposed to have been of very high antiquity in Britain, is large in size, strong, and of majestic aspect, long but round in the body, deep in the chest, and his ears are long and sweeping. The tone of his cry is deep, rich, and mellow. He will hunt the coldest scent, and persevere long after lighter hounds have given it up; but he is very slow. The author of 'Rural Sports' saw a pack of these hounds in Lancashire, where they were kept to hunt hares, and the least of them stood twenty-two inches. The huntsman went with a pole on foot.

As a contrast we may notice the celebrated match made between Mr. Barry and Mr. Meyuell to run a couple of each other's fox-hounds a drag, from the rubbing-house at Newmarket town-end, to the rubbing-house at the starting-post of the Beacon-course, for five hundred guineas. The match came off on the last day of September, and was won by Mr. Barry's Bluecap and Wanton, which came in very close to each other; Mr. Meynell's nearest hound, Richmond, being beat by upwards of a hundred yards. The ground was crossed in eight minutes and a few seconds; and of sixty horses that started with the hounds only twelve were up. Cooper, Mr. Barry's huntsman, came in first, but it is asserted that the mare that carried him was completely blind at the conclusion of the run. The famous Will Crane, who rode Rib, a king's-plate horse, was only in the twelfth. Colonel Thornton's Merkin, which was sold in 1795 for four hogsheads of claret, the seller to have two couple of her whelps, ran a private trial of four miles in seven minutes and half a second.

Our limits will not permit us to go into the details of this, to many, interesting subject; and we must refer the reader to Somerville's 'Chace,' Beckford's 'Thoughts upon Hunting,' 'The Sportsman's 'Cabinet,' Daniel's 'Rural Sports,' the Sporting Magazines, and, most especially, 'Nimrod,' for further information.

HOUND'S-TONGUE. [CYNOGLOSSUM.]

HOUSE-LEEK. [CRASSULACEÆ; SEMPERVIVUM.]

HOUSE-MARTIN. [HIRUNDINIDÆ.]

HOUSE-SPARROW. [PASSER.]

HOVINIA, a genus of Plants belonging to the natural order *Rhamnaceæ.* The peduncles of *H. dulcis* become extremely enlarged and succulent, and are in China in much esteem as a fruit, resembling in flavour, it is said, a ripe pear. Some species are astringent.

HOWLET. [STRIGIDÆ.]

HOYA, a genus of Plants belonging to the natural order *Asclepiadaceæ.* It has a 5-cleft rotate corolla. Coronet of appendages depressed, 5-leaved; leaflets spreading, fleshy, with the inner angle extended into a tooth lying upon the anther. Anthers terminated by a membrane. Pollen-masses fixed by the base, converging, compressed. Stigma not pointed, or scarcely so. Follicles smooth.

H. viridiflora is a native of Coromandel, Sylhet, and the Nilgherry Hills. It has opposite, stalked, broad, cordate, or ovate leaves, not sinuate at the base, pointed, membranous, smooth, from 3 to 4 inches long; petioles from 1 to 2 inches long; umbels lateral or axillary, simple, many-flowered. Flowers numerous, green, with pedicels as long as the peduncle. Corolla flat; crown of appendages turbinate, truncate. Anthers reflected over the stigma. Follicles horizontal, obtuse, about 3 or 4 inches long, and 4 inches in circumference. The root and tender stalks produce nausea, and promote expectoration. The leaves peeled and dipped in oil are used by the natives of India as a discutient in the early stages of boils; when the disease is more advanced they are employed in the same way to promote suppuration.

Several species of this genus are cultivated in our gardens on account of their elegant flowers, which, from their curious wax-like appearance, give rise to the name of Wax-Plants.

HUANUCO-BARK. [CINCHONA.]

HUMAN SPECIES. [MAN.]

HUMBLE-BEE. [BOMBUS.]

HUMBOLDTILITE. [SOMERVILLITE.]

HUMBOLDTINE, a mineral Oxalate of Iron. This substance occurs crystalline and massive; the crystalline form is undetermined. Fracture uneven, earthy. Colour brightish-yellow; devoid of lustre; opaque. Specific gravity variously stated from 1·3 to 2·13. Hardness sufficient to scratch gypsum, but is scratched by mica.

It is insoluble in water, but dissolves in nitric acid without effervescence, and imparts a yellow colour to it.

The massive variety occurs in small flattish reniform pieces, of a fine earthy structure; colour greenish-yellow.

Analysis by Rivero:—

Oxalic acid	46·14
Protoxide of iron	53·86
	—— 100.

HUMBOLDTITE. This mineral is a Boro-silicate of Lime, and is therefore a variety of *Datholite*, unless indeed it be identical with it, which has been supposed to be the case. It occurs crystallised. Primary form an oblique rhombic prism. Cleavage parallel to the oblique diagonal of the prism; fracture conchoidal. Hardness 4·5 to 5·0. Colour white and yellowish-white; streak white. Lustre vitreous, transparent, translucent; opaque. Specific gravity 2·99.

Found in the Tyrol, in the Harz, in North America, and near Edinburgh.

HUMIRIA'CEÆ, *Humiriads*, a natural order of Plants belonging to the Syncarpous group of Polypetalous Exogens. It has the following essential characters:—The calyx is in 5 divisions; the petals alternate with the lobes of the calyx and equal to them; the stamens hypogynous, four or many times as numerous as the petals, monadelphous; the anthers 2-celled, with a fleshy connective, extended beyond the two lobes; the ovary superior, usually surrounded by an auricular or toothed disc, 5-celled, with from one to two suspended ovules in each cell; the style simple, the stigma lobed; the fruit drupaceous, with five or fewer cells; the seed with a membranous integument, the embryo straight, oblong, lying in fleshy albumen; the radicle superior. The plants belonging to the order are trees or shrubs abounding in a resinous juice, with alternate simple coriaceous exstipulate leaves, and axillary corymbs of flowers.

The affinities of this order are not well made out. In their albuminous seeds and slender embryo they agree with *Styraceæ*, as also in their balsamic wood. They resemble *Meliaceæ* very much in habit and in their fructification, but the anthers and seeds of *Humiriaceæ* differ very much from those of *Meliaceæ*. Von Martius compares this order with *Chlenaceæ*, whilst Lindley thinks that their real affinity is with *Aurantiaceæ*; "an affinity," he observes, "indicated by their inflorescence, the texture of their stamens, their disc, their winged petioles, and their balsamic juices." There are three genera belonging to this order, *Humirium*, *Helleria*, and *Saccoglottis*. All are natives of the tropical parts of America.

Humirium (from Oumiri, the Guyanese name of one of the species) has 20 stamens joined into a tube, the alternate ones shortest, ciliated above, an annular disc 20-lobed, the stigma 5-lobed, the fruit containing a 5-celled nut, the cells 2-seeded. *H. balsamiferum* is a tree 40 feet in height, with ovate oblong leaves half-clasping the stem, with a decurrent nerve on the back, the inflorescence longer than the leaves, the peduncles smooth as well as the petals. This tree is a native of Guyana. Its bark is thick, and abounds with a red balsamic fluid, which resembles styrax in smell; after it has exuded from the tree it becomes hard and transparent, and when burnt affords an agreeable odour. The negroes and natives of Guyana use the bark in slips for the purpose of flambeaux; they also use the wood in building their houses. We have no account of the composition of this resinous juice, but Aublet suggests that it might be used as a substitute for the Peruvian Balsam. The Creoles call this tree Red-Wood, on account of the colour of the wood. *H. floribundum* is a tree 20 or 30 feet high; the trunk when wounded yields a fragrant yellow liquid balsam, known by the name of Balsam of Umiri, resembling the properties of Copaiva and Balsam of Peru. The other species of *Humirium*, and also those of *Helleria* and *Saccoglottis*, yield resinous juices.

(Lindley, *Natural System*; Burnett, *Outlines of Botany*; Don, *Dichlamydeous Plants*.)

HUMITE. This mineral occurs in attached crystals, the primary form of which is a right rhombic prism. Cleaves readily parallel to the base of the primary form. Fracture uneven. Hardness 6·5 to 7. Scratches glass readily. Colour, various shades of yellow and brown, sometimes nearly colourless. Translucent, transparent. Streak white. Lustre vitreous. Heated by the blow-pipe it becomes opaque, but is not fusible; with borax it gives a transparent glass.

HUMMING BIRDS, the name of a brilliant family which includes the smallest of Birds. [TROCHILIDÆ.]

HU'MULUS, a genus of Plants belonging to the natural order *Urticaceæ*. It has the following characters:—Flowers diœcious. Males with the perianth parted; stamens 5; females with the perigone scale-like, open, hidden by the scales of an oval catkin; stigmas 2, elongated.

H. Lupulus, the Hop, twines round hedges in many parts of Europe. It is truly wild in England, and is also found apparently wild in the United States of America. It has rough opposite cordate lobed leaves, and numerous greenish-white flowers, of which the sexes are distinct. In the male the flowers form loose drooping panicles, and each consists of 5 sepals, 5 stamens, and a convex centre representing the ovary. In the female the flowers are arranged in little axillary stalked scaly tufts; each consists of a naked ovary, with two spreading downy stigmas, and is inclosed by a concave bract. These bracts increase in size after the flowering is past, are collected into a loose head of imbricated scales, within which are placed the small seed-vessels, or seeds, as they are usually called.

The female flowers, termed cones, strobuli, or catkins, of this plant, when ripe, constitute the Hops, which, independent of their employment in brewing, are of considerable utility in medicine. The mature hops consist of a number of imbricated membranous scales, having the fruit at their base: the surface both of the scales and of the fruit is studded with aromatic glands, which prepare a material bearing considerable resemblance to the pollen of the anthers, and termed Lupuline. This is the most valuable part, as in it reside the essential properties of the Hop: it possesses a cellular structure, and in the cells are contained volatile oil, resin, a bitter principle, with tannin, and a trace of malic acid, with acetate, hydrochlorate, and sulphate of ammonia.

The Hop (*Humulus Lupulus*).

1, a branch of the female plant; 2, a branch of the male plant; 3, a male flower; 4, a head of young female flowers; 5, a head of ripe flowers and fruit in the state of Hops.

The superiority of the Hop, as an ingredient in our malt-liquors, depends upon the fact of its containing within itself several distinct and independent elements of activity, which the bitter herbs that have at different times been employed as a substitute do not possess. The bitter principle imparts to the beverage a tonic quality and an agreeable flavour; while at the same time an aromatic ingredient adds a warmth and stimulating property, and modifies the bitterness: it likewise contains an astringent principle (tannin), the effects of which are to precipitate the vegetable mucilage, and thus to remove from the beer the active principle of its fermentation: every attempt therefore to substitute an ordinary bitter for that of the Hop must necessarily fail, unless a compound can be so artfully constructed as to contain in due proportions the principles of bitterness, astringency, and aroma.

The aromatic bitter gives to the Hop a very marked power over the digestive organs when debilitated. A narcotic property has also been ascribed to this article, which is denied to it by some writers, who attribute the intoxicating power of beer entirely to the alcohol and carbonic acid which it contains. Yet there can be no doubt that tincture of hops, and even extract of hops, possess sedative powers, and often procure quiet and sleep, where opium cannot be borne. Decoction does not seem to be a judicious mode of preparation, and should not be practised. Lupuline has been administered alone, but this does not possess any advantages over the common plan. [HOPS, in ARTS AND SC. DIV.]

HURA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has monœcious amentaceous flowers; the male flowers have a truncate calyx; numerous stamens united into a solid column; female flowers with 1 style; stigma with 12 or 18 rays; capsule with 12 or 18 cocci.

H. crepitans, Sandbox-Tree, is a native of the West India Islands, Mexico, and Guyana. It is a tree abounding in milky juice. Leaves cordate, acuminate, entire, or very slightly toothed, stalked, smooth, coriaceous, with simple veins passing from the midrib to the margin in a curved direction, within a quarter of an inch or so of each other, and connected by numerous oblique veinlets; stipules large, ovate, leafy, deciduous; petioles as long or rather longer than the leaves, with 2 glands at the apex. Male flowers arranged in an erect long-stalked axillary conical catkin, composed of imbricated 1-flowered scales; calyx short, urceolate, truncate; column of stamens surrounded in the middle by 2 or 3 rows of tubercles, each of which bears an anther on its under side. Female flower solitary at the base of the male peduncle, or near it; calyx urceolate, entire, or dividing eventually into 3 parts; stigma very large, discoidal, peltate. Fruit a depressed umbilicated woody capsule, about the size of a middling apple, with from 12 to 18 furrows, which separate into as many cocci, which fly asunder, each opening into two valves with great elasticity when dry and fully ripe. The milk is so venomous as to produce blindness in a few days after touching the eye. Seeds a violent drastic dangerous purgative. Aublet states that negro slaves to whom one or two seeds had been administered in the form of an emulsion, were nearly killed by them.

HURAULITE. [MANGANESE.]

HURO'NIA, the generic name assigned by Mr. C. Stokes to certain remarkable articulated bodies, of a partially radiated structure, found in the transition limestone of Lake Huron by Dr. Bigsby. Until lately these fossils were referred to the group of *Polypiaria*, but from a careful study of specimens more complete than those which he first observed, Mr. Stokes has found that the parts represented as lamelliferous corals are really only the siphuncular portions of shells of *Cephalopoda*, which may be included in the family of Orthoceratites. The structure of the siphuncular parts in these and other chambered shells from the limestone of various parts of North America, has led Mr. Stokes to propose two other new genera, namely *Actinoceras* and *Ormoceras*, whose characters, as well as those of *Huronia*, can only be well traced in comparison with the ordinary structure of *Orthoceras*. [ORTHOCERAS.]

HU'RRIA, Daudin's name for certain Indian Colubers, the scales or plates on the base of whose tails are constantly simple, and those of the point double.

HUTCHINSIA, a genus of Plants belonging to the natural order *Cruciferæ*, named in honour of Miss Hutchins. It has an entire elliptical pouch; boat-shaped valves, keeled, not winged at the back; seeds 2 in each cell; petals equal; filaments simple.

H. petræa is a rare plant, found on limestone rocks in Great Britain. It has pinnate leaves; a branched leafy stem; petals scarcely longer than the calyx; pouch obtuse at both ends. The stem is from 2 to 4 inches high. Flowers small.

(Babington, *Manual of British Botany*.)

HYA-HYA. [TABERNÆMONTANA.]

HYACINTH, a Mineral, consisting of silica and zirconia, transparent, and of a red colour. [ZIRCON.]

HYACINTHUS, a genus of Plants belonging to the natural order *Liliaceæ* and the tribe *Scilleæ*. One of the most common of our garden plants is the *H. orientalis*. The genus formerly included two species of British plants, which are now referred to the genera *Endymion* and *Muscari*. [ENDYMION; MUSCARI.] For the culture of these plants see HYACINTH, in ARTS AND SC. DIV.

HYÆNA. [HYÆNINA.]

HYÆNA-DOG, an animal found in the south of Africa, more especially the Cape. In size and form it is smaller and more slender than either the hyæna or the wolf. It is the Wild Dog of the settlers at the Cape. M. Temminck first described it as a hyæna (*Hyæna picta*), but subsequently regarded it as a species of dog. Desmarest considered it a species of *Canis*, and recorded it as *Canis pictus*. Brookes gave it the generic appellation of *Lycaon*; and Fischer, in his 'Addenda et Emendanda,' quotes it as *Canis Lycaon*, and, in his 'Index Nominum,' refers to it as *Lycaon tricolor* of Brookes. Cuvier places it among the dogs. Dr. J. E. Gray places it among the *Canina* in his order *Felidæ*. He calls it *Lycaon venaticus*, and gives the following synonyms in addition to the above:—*Canis aureus*, Thunberg; *Canis Hyænoides*, Cuvier; *Hyæna venatica*, Burchell; *Kynos pictus*, Rüppell; *Lycaon typicus*, A Smith. It is also known by the common names Simir and Melbia.

In the number and form of its teeth the Hyæna-Dog agrees with the dogs, as well as in its general osteological structure, which presents a remarkable difference from that of the hyæna. Externally it is distinguishable from both the hyænas and the dogs in the proportional length of its legs and the form and proportions of the body. There is no mane as in the hyænas, and the tail resembles that of some dogs. The head is hyæna-like, and, like the hyænas, it has only four toes to each foot.

Its colour is reddish or yellowish-brown, variously mottled in large patches along the sides of the body and on the legs, with black and white intermixed. Nose and muzzle black, with a strong black line passing from them up the centre of the forehead to between the ears, which are very large, black within and without, and furnished with a broad and expanded tuft of long whitish hairs arising from their anterior margin, and filling up a considerable part of their concavity. Beneath each of the eyes a lighter patch. Tail moderate, covered with long bushy hair, and divided in the middle by a ring of black, below which it is nearly white, as are also the fore parts of the legs below the joint. Mr. Bennett, who thus describes the animal, had an opportunity of seeing a living specimen in the Tower of London; but he observes that their colours and markings are subject to variation in different individuals, though their general disposition and appearance are similar.

Mr. Burchell, who brought to this country the first specimen, and pointed out the distinguishing characters, describing it under the name of *Hyæna venatica*, states that it hunts in packs, at night by preference, but frequently in the day. He describes it as swift, fierce, and active, so that only those animals which are gifted with great fleetness can escape from it. It attacks sheep openly and fearlessly; it approaches oxen and horses more cautiously, advancing upon them by stealth, biting off the tails of the oxen, and injuring the horses, especially young colts, so severely that they rarely survive.

Mr. Burchell's specimen continued ferocious though he kept it chained up in his stable-yard for more than a year, and the man who fed it "dared never to venture his hand upon it." It however became familiar with a dog, its companion. The Tower specimen arrived with a young Cape lion, with which it agreed perfectly till the lion became too strong and rough in his play, when the Hyæna-Dog was associated with a Striped Hyæna and two Spotted Hyænas, and all lived tolerably well together in the same den.

Mr. Swainson gives the name of Hyæna-Dog as the English synonym of *Proteles*. [AARD-WOLF.] The animal which is the subject of this article he describes under the name of *Lycaon*, the Hunting Dog. He arranges both under the family *Felidæ*, where they had been previously placed by Dr. Gray.

Two very fine specimens of this animal are now living (1854) in the Zoological Gardens, Regent's Park. They are young, and excessively playful, seldom allowing each other to rest a single moment.

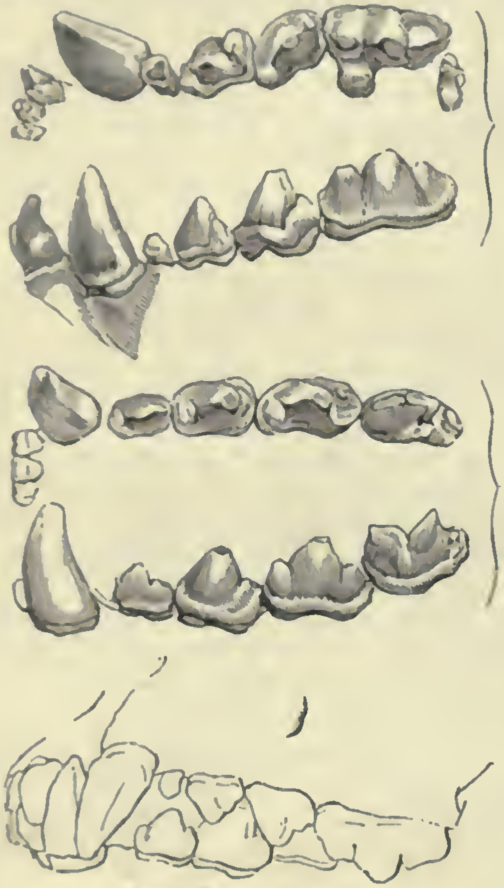
HYÆNANCHE, a genus of Plants belonging to the natural order *Euphorbiaceæ*. *H. globosa* yields a fruit which is collected by the Cape Colonists, and when powdered is used as a poison for hyænas by being rubbed over meat.

HYÆNINA, the name of a family of Digitigrade Carnivorous *Mammalia*, distinguished by having their fore legs longer than their hind legs, by their rough tongue, great and conical molar, or rather cutting-and-crushing teeth, projecting eyes, large ears, and a deep and glandular pouch beneath the anus.

Dental Formula:—Incisors, $\frac{6}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{5-5}{4-4} = 34$.

The false molars, three above and four below, are conical, blunt, and very large. The upper flesh-tooth (carnassière) has a small tubercle within and in front, but the lower one has none, and presents only two trenchant points. The whole of the dental and molar organisation, and indeed the whole cranial structure, appears to have been formed with a view to the bringing into the most available action the formidable natural instruments which enable the Hyænas to break the hardest bones.

Dr. Buckland gives the following account of the feats of a Cape Hyæna which he saw at Oxford in the travelling collection of Mr. Wombwell, the keeper of which confirmed in every particular the evidence given to Dr. Wollaston by the keeper of Exeter 'Change, and noticed in 'Reliquiæ Diluvianæ,' p. 20:—"I was enabled," says Dr. Buckland, "to observe the animal's mode of proceeding in the destruction of bones. The shin-bone of an ox being presented to this Hyæna, he began to bite off with his molar teeth large fragments from its upper extremity, and swallowed them whole as fast as they were broken off. On his reaching the medullary cavity the bone split into angular fragments, many of which he caught up greedily, and swallowed entire. He went on cracking it till he had extracted all the marrow, licking out the lowest portion of it with his tongue: this done, he left untouched the lower condyle, which contains no marrow, and is very hard. . . . . I gave the animal successively three shin-bones of a sheep; he snapped them asunder in a moment, dividing each in two parts only, which he swallowed entire, without the smallest mastication. On the keeper putting a spar of wood two inches in diameter into his den, he cracked it in pieces as if it had been touchwood, and in a minute the whole was reduced to a mass of splinters. The power of his jaws far exceeded any animal force of the kind I ever saw exerted, and reminded me of nothing so much as a miner's crushing-mill, or the scissors with which they cut off bars of iron and copper in the metal founderies." ('Reliquiæ Diluvianæ.')

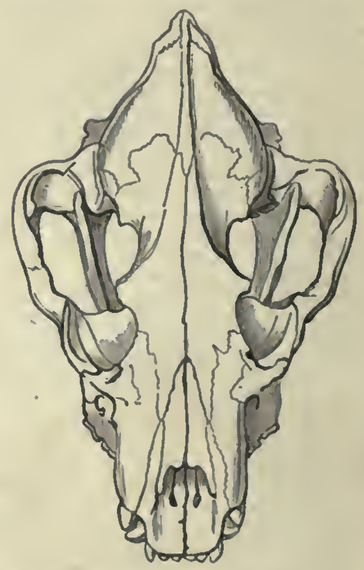


Teeth of Hyæna. (F. Cuvier.)

The accompanying figures will give the reader some idea of the area and space devoted to the attachment and development of the muscles destined to move the powerful jaws. These muscles, aided by the muscles of the neck, are so strong that it is almost impossible to drag from their vice-like grip that which the animal has once seized. Cuvier remarks that their efforts in this way sometimes produce anchylosis of the cervical vertebræ, and that this has given rise to the assertion that Hyænas have but a single bone in the neck. He also states that their name among the Arabs is the symbol of stubbornness. The tongue is rough. The feet have four toes each, like those of the suricates. The same author sums up their character by saying that they are voracious nocturnal animals, inhabiting caverns, living for the most part on carcasses, for which they ransack the tombs, and that they are the subjects of an infinity of superstitious traditions.

Skull of Spotted Hyæna: profile. (Cuvier.)

Skull of Striped Hyæna: profile. (Cuvier.)



Skull of Spotted Hyæna, seen from above.

The strength of these animals and their power of dragging away large bodies is strikingly exemplified in Colonel Denham's narrative. At Kouka he relates that the Hyænas (Dhubba), which were everywhere in legions, grew so extremely ravenous that a good large village, where he sometimes procured a draught of sour milk on his duck-shooting excursions, had been attacked the night before his last visit, the town absolutely carried by storm, notwithstanding defences nearly six feet high of branches of the prickly tulloh, and two donkeys, whose flesh these animals are, according to our author, particularly fond of, carried off, in spite of the efforts of the people. "We constantly," continues Colonel Denham, "heard them close to the walls of our own town at nights, and on a gate being left partly open, they would enter and carry off any unfortunate animal that they could find in the streets." From the same narrative it appears that it was necessary to protect the graves from the attacks of these rapacious brutes. Mr. Toole's grave had a pile of thorns and branches of the prickly tulloh, several feet high, raised over it as a protection against the flocks of hyænas which nightly infested the burying-places in that country.

Linnæus, in his last edition (12th) of the 'Systema Naturæ,' places the Hyæna under the genus *Canis*, between the Wolf and the Fox, and describes the Striped Hyæna only as *Canis Hyæna*, with sufficient accuracy. Brisson had already given the form a generic distinction under the name of *Hyæna*.

Gmelin, in his edition, adds the spotted species under the name of *Canis crocuta*, and places these hyænas between the *Canis Thous* and *C. aureus*, the latter being the Jackal; but Pennant had previously described both species in his synopsis under the title of 'Hyæna,' and as the Striped and Spotted Hyænas, arranging the form between the 'Dog' and the 'Cat,' names which he uses as generic distinctions for those carnivorous types, in the largest sense.

Cuvier makes the Hyænas the last subdivision of the Digitigrades following his Civets (*Viverra*), and immediately preceding the Cats (*Felis*). He describes the subdivision as containing the most cruel and most carnivorous animals of the class, and as comprising two genera (which he does not distinguish), adding that three species are known, namely, L'Hyène Rayée (*Canis Hyæna*, Linn.); L'Hyène Brune (*Hyæna brunnea*, Thunberg; *H. villosa*, Smith); and L'Hyène

Tachetée (*Canis crocuta*, not of Linnæus, as Cuvier quotes it, but of Gmelin).

Dr. J. E. Gray, in his method ('Annals of Philosophy,' 1825), brings the Hyænas under the family *Felidæ*, which he divides into two sections; the first consisting of those genera which have no tubercular grinders in the lower jaws; the second consisting of those which have tubercular grinders in both jaws. The first sub-family of the first section (which also includes *Felina*) is *Hyenina*, consisting of the genera *Hyæna* (Brisson) and *Proteles* (Geoffroy). [AARD-WOLF.]

M. Lesson arranges the genus *Hyæna* under his third section of the tribe of Digitigrades, which section consists of those genera which are without a small tooth behind the great molar of the lower jaw. Its situation is between *Proteles* and the Cats (*Felis*), and three species are recorded, the same as those mentioned by Cuvier, but two of them with different names; thus, the Spotted Hyæna is termed *Hyæna Capensis* (Desm.), and the Brown Hyæna, or Hyène Brune, is named *Hyæna rufa* (G. Cuv.).

The species are entirely confined to the Old World, Africa, and Asia.

Hyæna striata, the Striped Hyæna. This is the Ὕαινα and Hyæna of the ancients; the *Canis Hyæna* of Linnæus; *H. striata* of Zimmerman; *H. vulgaris* of Desmarst; and *H. antiquorum* of Temminck. *H. orientalis*, of Tiedemann, the Hooandor of Buffon, Bennett, and other writers. Ground colour uniform brownish-gray, rather darker above than beneath. Sides marked by several irregular, distant, transverse, blackish stripes or bands, which are more distinct on the lower part. Towards the shoulders and haunches these stripes become oblique, and they are continued in regular transverse lines on the outside of the legs Front of the neck, muzzle, and outsides of the ears black; the latter broad, moderately long, and nearly destitute of hairs, especially on the inside. Hairs of the body long, particularly on the back of the neck, and on the spine, where it forms a full and thick mane, which may be said to be continued even upon the tail, the latter being furnished with strong tufted hairs of considerable length. Mane and tail both marked with blackish spots or stripes, variously and irregularly placed. Individuals vary much in colour and markings. (Bennett.)

Striped Hyæna (*Hyæna striata*).

It seems uncertain whether this is the animal alluded to in the Bible. Some translate the words rendered in our copies of the Holy Scriptures 'the valley of Zeboim' (1 Sam. xiii. 18; Nehem. xi. 34) as 'the valley of Hyænas;' and the 'Seventy' render the words given by the English translators as 'a speckled bird,' and 'a bird of divers colours' (Jer. xii. 9), as 'the cave of the Hyæna,' Σπήλαιον Ὑαίνης, while others would substitute one of the Hebrew letters composing the word in Samuel for another, and make the reading 'vipers,' as if certain streaked serpents were meant. Bochart (and Scheuchzer seems to agree with him) shows that by the Tsabhua, or Tseboa, the word occurring in the ninth verse of the twelfth chapter of Jeremiah, the Hyæna was intended, and, if this opinion be correct, there can be little doubt that 'the valley of Zeboim' means 'the valley of Hyænas.' Dzuba and Dubba are, it appears, Arabic names for this species.

Whatever may be the opinions as to the Striped Hyæna being alluded to in those passages of Scripture which we have quoted, there can be no doubt that it is the Ὕαινα of Aristotle ('Hist. Anim.,' vi. 32; viii. 5) and the Greeks. The most monstrous fables were rife respecting this animal, and the extent to which they had reached may be supposed when we find Aristotle (vi. 32) taking pains to demonstrate the absurdity of the assertion that the animal was bisexual, or a true hermaphrodite. He declares that the genital parts of the male resemble those of the wolf and dog, and that the part which had been taken for the female organ is an opening with an imperforate bottom placed under the tail. This, as we have seen, is characteristic of the genus. Aristotle describes the parts with great minuteness; but notwithstanding his accuracy, we find Pliny (viii. 30, and xxviii. 8), and Ælian (i. 25, and vi. 14), stating not only that the Hyæna is bisexual, but that it changes the sex, being a male one year, and a female another. It is true that Pliny, in the passage first quoted, after stating—"Hyænis utramque esse naturam, et alternis annis mares, alternis fæminas fieri, parere sine mare, vulgus credit"—adds, "Aristoteles negat." But he leaves the subject there; and continues in such a strain, in both the books quoted, that his authority has been cited in support of these and other absurdities. Thus we are told that magicians looked on it with the greatest admiration, as possessing the magical power of alluring men.

It would be a waste of time and space to enumerate all the wonderful powers that were attributed to it; but among other accomplishments it was said to imitate the language of men, in order to draw to it shepherds whom it devoured at leisure, and to have the power of charming dogs so that they became dumb.

The animal does not seem to have made a part of the Roman shows till a comparatively late period. The third Gordian appears to have been the first who so introduced it; ten are said to have made their appearance at the games given by the emperor Philip, about A.D. 247.

The early modern naturalists repeated the fables of the ancients. Even Bélon, who was a good observer, gives "Le Portrait de la Civette, qu'on nommoit anciennement Hyæna." This figure is by no means bad for the time, and beneath in the small quarto volume 'Portraits D'Oyseaux, Animaux,' &c., &c., is the following quatrain:—

> "Voyant cecy, tu voy de la Civette
> Le vray portrait; qui rend abondamment
> Par son conduit le musc, pour excrement,
> Odeur, que plus à sentir on souhaite."

And this is the more curious when we find the same author ('Aquat.') giving a very fair cut of the Striped Hyæna (which Gesner, Aldrovandus, and Jonston copied) as the sea-wolf, an amphibious animal, satiating itself with fish, and seen on the shore of the British Ocean.

Pennant notices the propensity of this species to violate the repositories of the dead, and greedily devour the putrid contents of the grave. He also states, that it preys on the herds and flocks; but adds, on the authority of Shaw ('Travels'), that for want of other food it will eat the roots of plants, and that it will feed on the tender shoots of palms. He speaks of it as an unsociable animal, solitary, and inhabiting the chasms of the rocks, and says (also on the authority of Shaw), that the superstitious Arabs, when they kill one, carefully bury the head, least it should be applied to magical purposes; as the neck was of old by the Thessalian sorceress—

> "Viscera non Lyncis, non diræ nodus Hyænæ
> Defuit."
>
> "Nor entrails of the spotted Lynx she lacks,
> Nor bony joints from fell Hyænas' backs."—Lucan—Rowe.

After referring to the wild opinions of the ancients on this subject, he remarks, that it is no wonder that an ignorant Arab should attribute to its remains preternatural powers.

"They are," continues Pennant, "cruel, fierce, and untameable animals, with a most malevolent aspect; have a sort of obstinate courage, which will make them face stronger quadrupeds than themselves. Kæmpfer relates that he saw one which had put two lions to flight, regarding them with the utmost coolness." ('Synopsis Quadr.') This is a somewhat extraordinary translation of a passage in the second fasciculus of Kæmpfer's 'Amœnitates Exoticæ,' where he relates that he went to see a male Hyæna (Kaftaar), which a certain rich Gabr, or fire-worshipper, kept as a curiosity, the animal having been taken when a suckling. It was muzzled by means of a rope fastened round its jaws, led out, and the rope lengthened so as to enable the animal to run more freely; and Kæmpfer goes on to say, "Narrabant Gabri, sic frænatum nuper se opposuisse duobus leonibus, quos, adspectante serenissimo,* in fugam verterit." Kæmpfer gives a figure which, though rude, cannot be mistaken for any animal but a Striped Hyæna. Pennant seems to have been aware of his misconstruction, for afterwards, in his 'History of Quadrupeds,' he stops at, "put two lions to flight," omitting, "regarding them with the utmost coolness."

In the last-mentioned work Pennant remarks, that it will venture near towns; and quotes Niebuhr as authority that it will, about Gambron, in the season when the inhabitants sleep in the open air, snatch away children from the sides of their parents.

It has been the custom, among other fabulous assertions, to state that the Hyæna is not to be tamed: now, as Mr. Bennett observes, in the 'Tower Menagerie,' there is scarcely any animal that submits with greater facility to the control of man. He speaks of the docility and attachment to his keepers manifested by the Striped Hyæna, especially when allowed a certain degree of liberty, which the animal shows no disposition to abuse, though those which are carried about from fair to fair in close caravans are surly and dangerous from irritation and ill-treatment. The individual which Mr. Bennett figures was remarkably tame, and confined in the same den with one

* The king of Persia, apparently.

of the American bears. [BEAR.] Colonel Sykes ('Proc. Zool. Soc.,' 1830-31) remarks, that this species, Turrus of the Mahrattas, is numerous in Dukhun (Deccan), and susceptible of the same domestication as a dog. Other travellers speak of the Hyæna being susceptible of domestication and performing the duty of watch-dogs.

The Striped Hyæna is found in Asia, and Northern and Central Africa, the mountains of Caucasus, and the Altaic Chain, Asiatic Turkey, Syria, Persia, Barbary, and Senegal, and even as low as the Cape. There are living specimens in the Gardens of the Zoological Society at the Regent's Park.

H. maculata (Humboldt), the Spotted Hyæna. This species is the Tiger-Wolf of the colonists at the Cape; *Canis crocuta* of Erxleben and Gmelin; *Hyæna crocuta* of Zimmerman; *Hyæna Capensis* of Desmarest; *Crocuta maculata* of Gray. Gesner has a figure of this species devouring a dog; and the Spotted Zilio Hyæna of Jonston appears to owe its origin to the same animal.

Spotted Hyæna (*Hyæna maculata*).

Cuvier remarks that this and the preceding Hyæna are entirely distinct specifically, notwithstanding their generic resemblance, both externally and in the skeleton. The Spotted Hyæna has, he observes, no mane on the back, and instead of stripes has only round or black spots more or less scattered. He states that the last lower molar in the Spotted Hyæna is simply compressed and bilobated with a heel or process behind, whilst the Striped Hyæna has in addition a particular tubercle on the internal surface of its posterior lobe; there are also other osteological differences, which the reader will find pointed out in the 'Ossemens Fossiles.'

Size rather less than that of the Striped Hyæna. Muzzle short, but not so abruptly truncated. Ears short and broad, nearly quadrilateral. Colour yellowish-brown, the whole body covered with numerous spots of a deeper brown, tolerably uniform in size, but sometimes not very distinctly marked, and occasionally arranged in longitudinal rows. Hair shorter than in the Striped Hyæna; and though longer on the neck and in the central line of the back than elsewhere, it does not form so distinct and well-furnished a mane as that of the Striped Hyæna. Tail blackish-brown, covered with long bushy hair. (Bennett.)

It is found in the south of Africa, and especially the neighbourhood of the Cape of Good Hope. Lesson and others say that it is found even as high as Barbary, but this is doubtful. Ludolph, in his 'Ethiopia,' or rather the translator (i. 10), says, "The hyæna, or the *Crocuta*, near akin to the wolfe, is the most voracious of their wild beasts; for she not only by night and by stealth, but openly and in the daytime, preys upon all she meets with, men or cattle; and rather than fail, digs down the walls of houses and stables. Gregory described her to be speckled with black and white spots." To this is appended the following note:—"Begot between a Hyæna and a Lioness: familiar to Ethiopia. See 'Solinus,' l. 65, and Salmatius upon him." There is a living specimen in the Gardens of the Zoological Society, at the Regent's Park. It came from South Africa.

Numerous are the writers who have treated of the habits of this destructive animal. Le Vaillant, Sparrman, and other travellers give very interesting accounts of its manners; but we select the statement made in the first catalogue of the African Museum (where it is named *H. maculata*), which was dispersed in 1838, because we think that the statement carries internal evidence of its having proceeded from the pen of the eminent and accurate zoologist under whose zealous superintendence that collection was made. The catalogue, then, states that there are two species of Hyæna in South Africa, and that the Spotted Hyæna, or Tiger-Wolf of the colonists, is more numerous and more widely diffused than the other species, which has the name of the Strand, or Coast-Wolf, and is also more voracious and destructive, not only devouring such animals as it chances to find dead, but also carrying off the smaller ones from the pens of the farmers during the night, and often succeeding in killing or mutilating such of the larger kinds as have not been secured before dusk. Sickly animals, it appears, are less liable to suffer from the voracity of this creature than those that are in full health; the latter, by their rapid flight, inspiring their enemy with a courage of which by nature he is destitute; whereas the sickly face him, and thus intimidate him from attacks which might be successful if made. So anxious is he for the flight of the animals, as a preliminary to his

attack, that he uses all the grimace and threatening he can command to induce them to run, and never dares to attack them unless they do so. "The character of this hyæna," continues the author, "makes his destruction an object of no small importance to the farmers, whose ingenious snares for him call forth amazing cunning and dexterity on the part of the animal to render them of no avail. The more common methods employed against beasts of prey, such as spring-guns, traps, &c. do not succeed in his case. During his nocturnal wanderings he minutely examines every object that presents itself to his notice with which he is not perfectly familiar; and if he see reason to suspect that it can injure him, he will turn back and make his way in an opposite direction. Thus cords or leather thongs, which are often laid across the footpaths the hyæna is accustomed to travel upon, and which are attached to the triggers of loaded guns, with the design that his contact with the thong may cause the discharge of the gun in his direction, are very carefully examined by him, and the usual result of his examination is his deciding against trusting himself in contact with them. The farmers have so often observed this result, that they now very rarely attempt his destruction by this means, but occasionally succeed by substituting for cords the delicate stems of creeping plants, which are regarded by him without suspicion until he has actually suffered through them. Many other ingenious methods, suggested by the necessity of the case, have been adopted by the farmers for the destruction of hyænas; but a description of them, though elsewhere desirable, would here be out of place. This species seldom, if ever, moves abroad during the day, but passes that period in a state of repose, either in holes in the ground, or in retired situations densely covered with bush. Night is his favourite season for seeking his food; and towards nightfall his howlings are regularly heard, announcing to the various animals the approach of their voracious enemy, and thus enabling many of them to escape his wiles. The propensity this beast has for howling seems therefore to be disadvantageous to him; and if his almost continuous noise be not intended to put the animals upon which he preys upon their guard, its actual purpose is scarcely conceivable. Some have surmised it to be his call to creatures of his own species; but that this is not the case is certain from the fact that hyænas are heard to utter their supposed call even while separating from each other farther and farther as each cry is uttered; in addition to which it may be remarked that it is contrary to the habit of this animal to hunt in company, or even to congregate in large numbers, save when assembled by the temptation of an abundance of carrion. A still further proof that the hyæna's cry is not a friendly call to his own species, may be found in the fact that when individual hyænas have found a dead animal they cease to utter their melancholy howl, as if in fear of calling participators of their feast."

It appears from the above interesting account that the Spotted Hyæna puts in practice "all the grimace and threatening he can command" to induce the objects of his attack to run: in other words, his plan of attack is founded upon intimidation. May not his howls be intended to inspire terror and shake the nerves of the animals within hearing of the doleful nocturnal sounds?

"Till lately," adds the author in conclusion, "hyænas were in the habit of paying nightly visits to the streets of Cape Town, and were regarded as very useful in carrying away the animal refuse, which might otherwise have been disagreeable. This however no longer occurs, partly perhaps from better regulations now existing in the town, and partly from the number of these animals having very greatly decreased. Even now however individual hyænas occasionally approach the town, and their howlings are sometimes heard under Table Mountain, and in other directions, during the nights. In the countries inhabited by the Kaffirs they are very numerous and daring, generally approaching the villages during the night, and attempting, either by strength or stratagem, to pass the wattles by which the houses are defended. If they be thus far successful, they next endeavour to enter the houses, which they sometimes accomplish, in which case they not unfrequently carry off some young child of the family. Scars and marks on various parts of the body often testify to the traveller how dangerous a foe the natives have in this animal."

Mr. Steedman, in his 'Wanderings and Adventures in the Interior of Southern Africa,' gives most appalling accounts of the rapacity of the Spotted Hyæna. He states that Mr. Shepstone, in a letter from Mamboland, relates that the nightly attacks of wolves, as the Hyænas are generally called, have been very destructive amongst the children and youth; for within a few months not fewer than 40 instances came to his knowledge wherein that beast had made a most dreadful havoc. "To show clearly," says that gentleman, "the preference of the wolf (spotted hyæna) for human flesh, it will be necessary to notice that when the Mambookies build their houses, which are in form like beehives, and tolerably large, often 18 or 20 feet in diameter, the floor is raised at the higher or back part of the house, until within 3 or 4 feet of the front, where it suddenly terminates, leaving an area from thence to the wall, in which every night the calves are tied to protect them from the storms or from wild beasts. Now it would be natural to suppose, that should the wolf enter, he would seize the first object for his prey, especially as the natives always lie with the fire at their feet; but notwithstanding this, the constant practice of this animal has been in every instance to pass by the calves in the area, and even by the fire, and to take the children from under the mother's kaross, and this in such a gentle and cautious manner, that the poor parent has been unconscious of her loss until the cries of her little innocent have reached her from without when a close prisoner in the jaws of the monster." Mr. Shepstone then particularises two instances within his own knowledge, one of a boy abont ten years of age, and the other of a little girl about eight, who had been carried off by this species, and wretchedly mangled, but recovered by the attention of Mr. Shepstone and his friends. Notwithstanding this ferocity, the Spotted Hyæna has, it is stated, been domiciliated in the houses of the peasantry, "among whom," says Mr. Bennett, "he is preferred to the dog himself for attachment to his master, for general sagacity, and even, it is said, for his qualifications for the chase."

H. villosa the Strand-Wolf. In a communication to the Zoological Society of London (1833), Dr. Andrew Smith stated his belief that the Striped Hyæna does not inhabit South Africa; its place being occupied by the *H. villosa*, which bears, when young, considerable resemblance to that species. *H. villosa* was first described by Dr. Smith in the 'Transactions of the Linnæan Society.' This animal was considered by Cuvier as identical with L'Hyène Brune (*H. brunnea* of Thunberg), which is quoted by M. Lesson as Hyène Rousse, (*H. rufa*, of Cuvier). In the list of the specimens of *Mammalia* in the British Museum, this animal is regarded as a variety of *H. striata*. The following are the dimensions of a specimen in Mr. Steedman's collection:—

	Feet.	Inches.
From the nose to the root of the tail	4	4
Height at the shoulder	2	4
Height at the croup	2	0
Breadth of head between the ears	0	5½
Length of head from nose to occiput	0	10
Length of the ear	0	5
Length of the tail to the extremity of the vertebræ	0	9½
Length of the tail with hair	1	2

Strand-Wolf (*Hyæna villosa*).

The hair is described as remarkably long, coarse, and shaggy over the whole body of the animal; whilst on the head, ears, and extremities alone it is short and crisp. Its length on the back and sides is 8 or 10 inches, and it does not form a long mane on the spine, as is the case with the common Striped Hyæna. The general colour of the head, body, and extremities, is grizzled brown, from the long hairs being grayish at the roots and brown at the points, marked on the sides and hips with large but rather indistinct transverse bands of a deep vinous brown-colour. The legs, particularly those before, which as in other Hyænas, are much longer than those behind, are marked with transverse black bands much more distinct and apparent than those on the body. The upper lip is furnished with remarkably long bristly black moustaches, and the tail, which is thickly covered with long hair, and of greater length than in the common Hyæna, is uniform dark-brown. The fore-arms and thighs are darker than other parts of the animal, and a large collar of dirty yellowish-white surrounds the throat and extends up the sides of the neck, occupying the entire space between the setting on of the head and shoulders. Under each eye is a large irregular black patch; the chin is black also, and a narrow band of the same colour marks the junction of the head and neck, bordered by the dirty white collar above mentioned. The ears are large, erect, and rather pointed. The individual was aged, all the teeth being mnch worn: the two exterior incisors were much larger than the others, and had the form and size of small canines. A young one, 19 inches in length, also in Mr. Steedman's collection, exhibited all t o general characters of the aged specimen, excepting that the hair was shorter and more woolly. (Steedman.)

This animal inhabits the sea-coast throughout the whole extent of Southern Africa, but is by no means so common as the Spotted Hyæna. The young specimen mentioned above was obtained alive with two others in the neighbourhood of the Nieuveld Mountains, a considerable distance in the interior of the country, which shows, as Mr. Steedman observes, that the species is not so strictly confined to the vicinity of the sea-coast, as its name 'Straand-Wolf' would imply, or as the accounts of travellers would lead us to imagine.

The Straand-Wolf devours carrion and such dead animal substances, whales for instance, as the sea casts up: but when pressed by hunger its habits seem to resemble those of the other species, for it then commits serious depredations on the flocks and herds of the colonists, who hold its incursions in great dread. Mr. Steedman, who states this, says he saw a very fine specimen, which had been shot by a farmer residing in the vicinity of Blauwberg, and was informed that it had destroyed three large calves belonging to the farmer. He adds, that it is said to be a remarkably cunning animal, retiring to a considerable distance from the scene of its depredations to elude pursuit, and concealing itself during the day-time in the mountains, or in the thick bush, which extends in large patches throughout the sandy district in which it is usually found.

H. rufa, the Brown Hyæna. It is the *Crocuta brunnea* of Gray; *H. fusca* of Geoffroy; the *H. crocuta rufa* of Fischer, and the *H. brunnea* of Thunberg. This species is a native of South Africa, and has been taken at Natal. There is a living specimen at present in the collection of the Zoological Society in Regent's Park.

Fossil Hyænas.—Fossil Hyænas occur abundantly in the third period of the Tertiary deposits (Pliocene of Lyell), especially in the ossiferous caverns. Dr. Buckland gives the following localities for the remains of Hyænas in caves or fissures:—Kirkdale, Plymouth, Crawley Rocks, near Swansea, Paviland Caves near Swansea, district of Muggendorf, district of the Harz, Fouvent in France, Sundwick in Westphalia, and Köstritz near Leipzig. Those found in the superficial loam or gravel are stated to have occurred at Lawford near Rugby, at Herzberg, and Osterode, Canstadt near Stutgardt, Eichstadt in Bavaria, and the Val-d'Arno near Florence. The fossil species named are *H. spelæa*, Goldf.; *H. spelæa major*, Goldf.; *H. prisca* (Hyène Rayée Fossile), M. De Serres; *H. intermedia*, M. De Serres; *H. Perrierii*, Brav., Croiz., and Job.; *H. Arvernensis*, Brav., Croiz., and Job.; and *H. dubia*, Brav., Croiz., and Job. Of these the only species which has been found in the caves of great Britain is the *H. spelæa*. As the discovery of the bones principally of this animal in the caves at Kirkdale were amongst the first to attract attention among the numerous extinct *Mammalia* which formerly lived in Great Britain, we give an extract from Dr. Buckland's description of that remarkable locality.

"Both the roof and the floor for many yards from the entrance are composed of regular horizontal strata of limestone, uninterrupted by the slightest appearance of fissure, fracture, or stony rubbish of any kind; but farther in the roof and sides become irregularly arched, presenting a very rugged and grotesque appearance, being studded with pendent and roundish masses of chert and stalactite; the bottom of the cavern is visible only near the entrance, and its irregularities, though apparently not great, have been filled up throughout to a nearly level surface by the introduction of a bed of mud or loamy sediment. There is no alternation of mud with any repeated beds of stalactite, but simply a partial deposit of the latter on the floor beneath it; and it was chiefly in the lower part of the earthy sediment, and in the stalagmitic matter beneath it, that the animal remains were found: there was nowhere any black earth, or admixture of animal matter, except an infinity of extremely minute particles of undecomposed bone. In the whole extent of the cave only a very few large bones have been discovered perfect; most of them are broken into small angular fragments and chips, the greater part of which lay separately in the mud, whilst others were wholly or partially invested with stalagmite; and others again mixed with masses of still smaller fragmeuts, and cemented by stalagmite, so as to form an osseous breccia. In some few places where the mud was shallow and the heaps of teeth and bones considerable, parts of the latter were elevated some inches above the surface of the mud and its stalagmitic crust, and the upper ends of the bones thus projecting, like the legs of pigeons through a pie-crust, into the void space above, have become thinly covered with stalagmitic drippings, whilst their lower extremities have no such incrustation, and have simply the mud adhering to them in which they have been imbedded; a horizontal crust of stalagmite about an inch thick crosses the middle of these bones, and retains them firmly in the position they occupied at the bottom of the cave. A large flat plate of stalagmite, corresponding in all respects with the above description, and containing three long bones fixed so as to form almost a right angle with the plane of the stalagmite, is in the collection of the Rev. Mr. Smith of Kirby Moorside. The same gentleman has also, among many other valuable specimens, a fragment of the thigh-bone of an elephant, which is the largest I have seen from this cave. The effect of the loam and the stalagmite in preserving the bones from decomposition, by protecting them from atmospheric air, has been very remarkable; some that had lain uncovered in the cave for a long time before the introductiou of the loam were in various stages of decomposition, but even in these the further progress of decay appears to have been arrested as soon as they became covered with it, and in the greater number little or no destruction of their form, and scarcely any of their substance, has taken place. I have found on immersing fragments of these bones in acid till the phosphate and carbonate of lime were removed, that nearly the whole of their original gelatine has been preserved.

"Analogous cases of animal remains preserved from decay by the protection of similar diluvial mud occur on the coast of Essex near Walton, and at Lawford, near Rugby, in Warwickshire. Here the bones of the same species of elephant, rhinoceros, and other diluvial animals occur in a state of freshness and perfection even exceeding that of those in the cave at Kirkdale, and from a similar cause, namely, their having been guarded from the access of atmospheric air, or the percolation of water, by the argillaceous matrix in which they have been imbedded; whilst other bones that have lain the same length of time in diluvial sand or gravel, and have been subject to the constant percolation of water, have lost their compactness and strength and great part of their gelatine, and are often ready to fall to pieces on the slightest touch, and this where the beds of clay and gravel alternate in the same quarry, as at Lawford. The bottom of the cave on first removing the mud was found to be strewed all over like a dog-kennel, from one end to the other, with hundreds of teeth and bones, or rather splintered fragments of bones of all the animals above enumerated; they were found in greatest quantity near its mouth, simply because its area in this part was most capacious; those of the larger animals—elephant, rhinoceros, &c.—were found co-extensively with all the rest, even in the inmost and smallest recesses.

"Scarcely a single bone has escaped fracture, with the exception of the astragalus and other hard and solid bones of the tarsus and carpus joints, and those of the feet. On some of the bones marks may be traced which, on applying one to the other, appear exactly to fit the form of the canine teeth of the hyæna that occur in the cave. The hyænas' bones have been broken and apparently gnawed equally with those of the other animals.

"Heaps of small splinters, and highly comminuted yet angular fragments of bones, mixed with teeth of all the varieties of animals above enumerated, lay in the bottom of the den, occasionally adhering together by stalagmite, and forming, as has been before mentioned, an osseous breccia. Many insulated fragments also are wholly or partially enveloped in stalagmite, both externally and internally. Not one skull is to be found entire; and it is so rare to find a large bone of any kind that has not been more or less broken, that there is no hope of obtaining the materials for the construction of a single limb, and still less of an entire skeleton. The jaw-bones also even of the hyænas are broken to pieces like the rest; and in the case of all the animals, the number of teeth and solid bones of the tarsus and carpus is more than twenty times as great as could have been supplied by the individuals whose other bones we find mixed with them."

Dr. Buckland continues:—

"Mr. Gibson alone collected more than three hundred canine teeth of the hyæna, which at least must have belonged to seventy-five individuals, and, adding to these the canine teeth I have seen in other collections, I cannot calculate the total number of hyænas of which there is evidence at less than two or three hundred. The only remains that have been found of the tiger species are two large canine teeth and two molar teeth, exceeding in size the largest lion's or Bengal tiger's. There is one tusk only of a bear, which exactly resembles those of the extinct *Ursus spelæus* of the caves of Germany.

"In many of the most highly-preserved specimens of teeth and bones there is a curious circumstance, which before I visited Kirkdale had convinced me of the existence of the den, namely, a partial polish and wearing away to a considerable depth of one side only: many straight fragments of the larger bones have one entire side, or the fractured edges of one side, rubbed down and worn completely smooth, whilst the opposite side and ends of the same bones are sharp and untouched, in the same manner as the upper portions of pitching stones in the streets become rounded and polished, whilst their lower parts retain the exact form and angles which they possessed when first laid down. This can only be explained by referring the partial destruction of the solid bone to friction from the continual treading of the hyænas and rubbing of their skins on the side that lay uppermost at the bottom of the den."

The species of Hyæna whose remains have been found in such large numbers in the caves at Kirkdale and other parts of this country was first determined by Cuvier. It differs chiefly in its larger and more robust proportions; the scapula is narrower in proportion to its articular extremity, and the deltoid crest of the humerus is longer and stronger.

"In the numerous specimens," says Professor Owen, "of the Fossil Hyæna from British localities which I have examined and compared in public and private collections, I have not hitherto detected any characters indicative of a species distinct from the *Hyæna spelæa*; the differences observed have been those only of size and dental development, depending on diversity of sex and age. Of that fossil species which is more nearly allied to the Striped Hyæna (*Hyæna Monspessulana*, Christol) no trace has presented itself to my notice. It appears to have been confined to the middle of France, Languedoc, and Italy. Fossil remains of the Hyæna have been discovered by MM. Baker and Durand in the tertiary strata of the Sewalik Hills; and, what is more remarkable, were represented in the ancient Fauna of South America by a species which its discoverer Dr. Lund has termed *Hyæna neogæa*." (Owen, *British Fossil Mammals.*)

HYALÆIDÆ, a family of *Pteropoda*, according to the systems of Lamarck and Cuvier, but belonging to the family *Thecosomata* (order *Aporobranchiata*) of De Blainville. M. Rang, in his 'Tableau Méthodique,' follows De Férussac in making the *Hyalæidæ* a family, and enumerates the following genera as composing it:—*Cymbulia*, *Limacina*, *Hyalæa*, *Cleodora*, *Cuvieria*, *Euribia*, and *Psyche*.

The following are the characters of the family:—Animal furnished with a head, but it is not distinct, with a third natatory membrane smaller and intermediate at the ventral part; mouth situated at the bottom of a cavity formed by the union of the locomotive organs.

Shell nearly always present, and very variable in form. The shell is absent in the genus *Psyche*.

Cymbulia.—Cuvier describes the *Cymbulia* as having a cartilaginous or gelatinous envelope in the form of a boat or slipper, beset with points in longitudinal rows; and the animal itself as possessing two great wings of a vascular tissue, which are at once branchiæ and fins, and between them on the open side a third smaller lobe, which is three-pointed. The mouth with two small tentacula is placed between the wings, towards the shut side of the shell, and above two small eyes and the orifice of generation, whence issues an intromissive male organ in the form of a small proboscis (trompe). The transparency of the texture permits the observer to distinguish the heart, the brain, and the viscera through the envelopes.

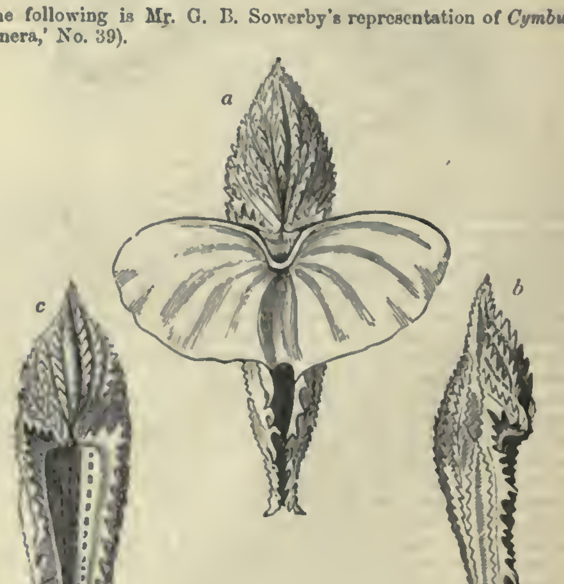
M. Rang gives the following characters of this genus:—Animal oblong, gelatinous, transparent, furnished with two eyes (?), two tentacles (?), and a mouth in the form of a proboscis (trompe)? Two lateral fins, which are large and rounded, carry the vascular net of the branchiæ; they are united at their base, on the posterior side, by an intermediate appendage in form of an elongated lobe.

Shell gelatinoso-cartilaginous, oblong, in the form of a slipper, entirely covered with a delicate and hardly visible membrane, with a superior opening, long and truncated at one of its extremities.

Cymbulia.

a, *a*, fins; *b*, the intermediate lobe; *i*, the viscera, seen through the shell; *h*, the shell.

The following is Mr. G. B. Sowerby's representation of *Cymbulia* ('Genera,' No. 39).



a, the animal in the shell, seen from above; *b*, the shell, seen edgewise; *c*, the shell, seen from above.

M. Rang further observes that this curious and very incompletely known genus only contains a single species, which is found in the Mediterranean Sea; and he adds that he only knows it by a drawing communicated to him by Cuvier, who remarks ('Règne Animal') that in the figure given by M. De Blainville ('Malacologie,' xlvi. 3) the animal is placed in the shell the wrong way ("en sens contraire du veritable"), and that his (Cuvier's) description rests on recent and repeated observations made by M. Laurillard. M. Deshayes confirms this remark as to the inverse position of the animal, and says that he has had occasion to verify it often.

M. Rang in 1829 knew but one species. M. Deshayes, in his edition of Lamarck (1836), enumerates five. The species known to M. Rang must have been *Cymbulia Peronii.*

Limacina (*Spiratella*, De Bl.).—Animal elongated anteriorly, turned into a spiral form behind; branchiæ in the form of plaits on the back; mouth furnished with two small appendages, which are united by one of their extremities to the anterior border.

Shell very delicate, fragile, vitreous, spiral, not carinated, turning rather obliquely on itself, with a circular aperture and simple borders. (Rang.)

Cuvier is of opinion that the *Limacinæ* ought, according to the description of Fabricius, to bear a strong relationship to *Pneumodermon;* but their body is terminated by a tail, which is twisted spirally ("contournée en spirale"), and is lodged in a very delicate shell, of one whorl and a half, umbilicated on one side and flattened on the other. Cuvier adds that the animal uses its shell as a boat and its wings as oars when it would swim on the surface of the sea. The same author remarks, that the only species, *Clio helicina* of Phipps and Gmelin, is scarcely less abundant in the icy sea than *Clio borealis* [CLIO], and is considered as one of the principal aliments of the whale. He observes that he does not know whether the animal figured by Mr. Scoresby, of which M. De Blainville ('Malacologie,' pl. xlviii. bis, f. 5) makes his genus *Spiratella*, is in reality, as M. De Blainville believes, the same animal with that of Phipps and Fabricius. M. Rang considers *Spiratella* of M. De Blainville as synonymous with *Limacina*, of which M. Rang states that but one species is known, and says that it would be interesting to have new accounts of it. He speaks of its inhabiting the North Sea, its prodigious abundance, and the possibility of its serving as food for the whales. Phipps mentions it as being found in innumerable quantities in the arctic seas, and describes its body as of the size of a pea, rolled up into a spire like a helix, and its ovate, obtuse, expanded wings as being greater than the body. The following cut is taken from the figure of M. De Blainville, who founds his genus (which he places under his family of *Pteropoda*, between *Atlanta* and *Argonauta*) on the materials furnished by the Rev. Dr. Scoresby, and considers his *Spiratella* as synonymous with Cuvier's *Limacina.*

Spiratella Limacina of De Blainville.

Mr. G. B. Sowerby gives a figure of a *Limacina* ('Genera of Recent and Fossil Shells,' in the same number as that which contains *Cymbulia*) from Messina. He describes it as a thin, fragile, spiral, discoid shell, umbilicated on both sides, and carinated on the back and below, with a membranaceous lamellar keel, and he says that it has externally much the appearance of a very diminutive umbilicated *Nautilus.*

M. Deshayes, in his edition of Lamarck, remarks that the *Limacinæ*, of which M. De Blainville formed his genus *Spiratella*, have in fact much analogy with the *Cleodoræ;* and that they are *Cleodoræ* whose shell is spiral, and not swimming Gastropods, like the *Carinariæ* and *Atlantæ.* M. Deshayes goes on to state that he has many individuals preserved in spirit, which he owes to the generosity of Dr. Fleming, that he has examined them with attention, and that they have not the projecting foot of *Atlanta*, nor a fin-like foot, but two lateral fins of the form of those of the *Cleodoræ.* He adds that they have no tentacles, and no eyes, but a mouth in the shape of a triangular slit at the summit of the angle which forms the fins. The shell is not closed by an operculum as that of *Atlanta* is. The anus and the organs of generation have their issue from the right side, below the fin and at its base. M. Deshayes is of opinion that the genus ought to remain among the Pteropods, where it was placed by Cuvier and Lamarck.

Spiralis.—Shell thin, transparent, of several spiral whorls, coiled to the left, spire elevated or depressed, surface smooth or reticulated, mouth angulated below or canaliculated, sometimes prolonged into a spine-like curved beak. Animal elongated, spiral; head not distinct; two fin-like expansions united at their base by an intermediate lobe bearing an operculum; branchiæ in a cavity formed by the mantle. Operculum vitreous, very thin and transparent, of few whorls.

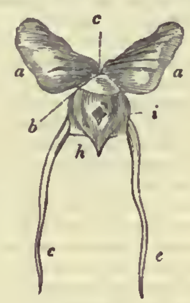
This genus was constituted by the naturalists attached to the exploring ship Bonite, for some very small Pteropods they met with during their voyage. They are distributed through all seas, and are equally present in the Atlantic, the Indian, and Pacific Oceans. Three species of this genus have been recorded as British, *S. Flemingii*, *S. MacAndrei*, and *S. Jeffreysii.* They are all very rare.

Hyalæa.—Animal globular or oblong, furnished with two lateral expansions more or less elongated backwards; the intermediate lobe of a demi-circular form; two very short tentacles, hardly distinct, contained in a cylindrical sheath; the aperture of the mouth provided with two labial appendages; orifice of the anus at the right side of the mantle; that of the male organ in front and within the right tentacle; that of the female organ on the same side, at the point of separation of the two parts of the body; branchiæ pectinated on each side in a particular cavity.

Shell horny or vitreous, transparent and fragile, in form of a slipper, straight or recurved, with an anterior opening, and split laterally, tricuspidated backwards. (Rang.)

M. Rang remarks that this beautiful and interesting genus, the anatomy of which has been made known by M. Cuvier and M. De Blainville, is perfectly distinct from those which approach it. He speaks of the *Hyalææ* as very small animals, spread over all the seas of the torrid zone and a great part of those of the temperate zones, and of the occurrence of the same species on the most opposite points of the globe. He adds that the discovery which he had made of many species, one in a fossil state, had caused him to divide the *Hyalææ* into the two following groups: 1. *Globulosæ.*—Shell subglobular, having the lateral slits nearly as long as itself, and the appendages placed very much backward. *H. uncinata*, &c. This group, he says, is the most numerous. 2. *Elongatæ.*—Shell elongated, having the lateral slits short and the appendages advanced. *H. trispinosa*, &c.

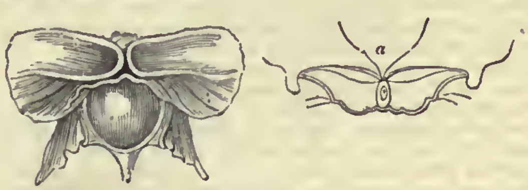
He states that at the time he wrote five species completed the group, and gives the following figure of a *Hyalæa.*



Hyalæa.

a, fins; *b*, intermediate lobe; *c*, mouth; *e*, lateral expansions of the mantle; *i*, viscera, seen through the shell; *h*, the shell.

Cuvier describes *Hyalæa* as having two great wings, no tentacles, a mantle slit at the sides, lodging the branchiæ in the bottom of the fissures, and covered by a shell equally slit at the sides, the ventral surface of which is very convex, the dorsal flat and longer than the other, and the transversal line which unites them behind furnished with three pointed dentilations. In the living state, the animal projects by the lateral slits of the shell filaments more or less long, which are productions of the mantle. Cuvier concludes by observing that the species most known (*Anomia tridentata*, Forskahl; *Cavolina natans*, Abildgaardt; *Hyalæa cornea* (*tridentata*), Lamarck) has a small yellowish demi-transparent shell, which is found in the Mediterranean Sea and in the ocean.



Hyalæa tridentata.

a, the anterior border, showing the mouth.

M. De Blainville, who has published a monograph of this genus in the 'Journal de Physique' and in the 'Dictionnaire des Sciences Naturelles,' states that it contained at that time (1825) from five to six species, all of which appear to be the inhabitants of warm climates. He considers the genus *Glandiolus* of De Montfort as belonging to the *Hyalææ*, and quotes the observation of M. Defrance to that effect with approbation.

M. Deshayes in his edition of Lamarck (1836) observes, that in the comparison which the latter makes of the *Hyalææ* with the Conchifers, he had remarked that they approached so closely that he had found it proper to place the *Hyalææ* at the head of the Mollusks. Lamarck had suffered himself to be seduced by an analogy rather apparent than real. It is not with the Lamellibranchiate Conchifers, continues M. Deshayes, that the *Hyalææ* should be compared, but with the Brachiopods, an inferior class of animals [BRACHIOPODA]; for the *Hyalææ* and the Brachiopods are placed in the shell in the same way. We find, he observes, in the *Hyalææ* the two valves of the *Terebratula* soldered together; and, in becoming free, the animal has closed the umbo of the great valve, and the shell has left a passage always open for the ciliated appendages, changed into locomotive organs. This comparison, says M. Deshayes, would appear sufficiently just, and yet it is not. Upon the examination of the two groups we are soon convinced of their dissemblance in all the essential parts of their organisation. To this we beg to add, that it will be probably difficult to establish any essential difference in the organisation of the two groups except upon the higher development of the nervous system, and the presence of a head in *Hyalæa*. M. Deshayes enumerates sixteen recent species exclusive of *Hyalæa cuspidata*, which, he says, is not a true *Hyalæa*, as Bosc, De Roissy, and Lamarck believed, but a *Cleodora*. Messrs. Rang, D'Orbigny, Lesueur, and Quoy and Gaimard, have principally contributed to the number of species.

H. tridentata is the *Anomia tridentata* of Forskahl, Gmelin, and Dillwyn; *Hyalæa papilionacea* of Bory de St. Vincent; *H. cornea* of De Roissy. M. Deshayes keeps Lamarck's synonym with a query—*Monoculus telemus* (?), Linnæus. It is a native of the Mediterranean and the seas of warm climates. The size scarcely reaches that of a small hazel-nut.

In the 'History of British Mollusca,' *H. trispinosa* is admitted, a specimen having been taken by Mr. Robert Ball at Youghal in Ireland.

Cleodora.—Cuvier remarks that the *Cleodoræ*, for which Brown originally founded the genus *Clio*, appear analogous to the *Hyalææ*, in the simplicity of their wings and the absence of tentacles between them: their conic or pyramidal shell, he adds, is not slit on the sides; and he quotes M. Rang's genera and sub-genera.

M. Deshayes, in his edition of Lamarck, states that the *Cleodoræ* are much more allied to the *Hyalææ* than the *Clios*, approaching the former not only in having a shell, but also in the form of the animal, which bears a great resemblance to that of *Hyalæa*. It is not astonishing, proceeds M. Deshayes, to see Lamarck, who had approximated the *Cleodoræ* to the *Cliones*, indicate not very natural relations to the former; for when he wrote but a very small number of species were known, and he could hardly foresee that the assiduous researches of Messrs. Quoy and Gaimard, Rang and D'Orbigny, should have contributed to throw so much light on the Pteropods in general, and the *Hyalææ* and *Cleodoræ* in particular. If we have before us a sufficient number of species belonging to the two last-named genera, we shall see them blend into each other so as to make it impossible to draw the line between them. It is thus, continues M. Deshayes, that we proceed by insensible degrees from the globular to the lanceolate species. A globular *Hyalæa* seems formed of two unequal valves soldered together, leaving between them a principal anterior slit, and also lateral slits, sometimes without communication with the aperture, and sometimes forming the prolongation of this part. The posterior extremity is prolonged into a spine, which is ordinarily short, sometimes straight, and sometimes curved. Taking these species of *Hyalæa* as the commencement of the genus, M. Deshayes points out the following alterations of their characters in the rest of the series. At first the posterior extremity is seen to be elongated, and in this case the two parts of the shell are flattened, become nearly equal, and, if in some of the species there remains the trace of posterior lateral slits, for the most part these slits rise sufficiently to be in continuation of the aperture. This aperture is always transverse and narrow, as in the *Hyalææ* properly so called. When the shells are thus elongated, some have their posterior extremity curved; others have it straight, as in the *Cleodoræ*. These last are elongated more and more, and in proportion as this elongation exists the aperture is enlarged, and the lateral slits progressively diminish, are reduced to simple inflexions, and at last entirely disappear. These changes in the form of these shells are not, M. Deshayes observes, more extraordinary than those to which he has drawn attention in other groups, and principally in the Acephalous Mollusks. If, continues the same author, the animals coincide with these modifications in their external form, their internal organisation offers but little alteration; and he cites the authority of Messrs. Quoy and Gaimard, who assert positively that the lanceolate *Cleodoræ* differ in nothing essentially from the *Hyalææ* properly so called. This M. Deshayes considers as the more important to him, inasmuch as he is thereby confirmed in the opinion which he had long entertained as to the analogy of the *Hyalææ* and *Cleodoræ*.

The following is M. Rang's definition of *Cleodora*:—Animal of an oblong or elongated form, furnished with an intermediate demicircular lobe, but having no lateral expansions; mantle open in front; branchiæ and organs of generation incompletely known.

Shell fragile, vitreous, in form of a sheath or case (gaine ou cornet), more or less pointed posteriorly; aperture very large, nearly always without a slit, and without lateral appendages.

The same zoologist having, as he states, obtained many new species, and studied their organisation, divides the genus into the following sub-genera:—

1. *Cleodoræ* properly so called.—Animal of an oblong form, having the mantle very much dilated and advanced on each side.

Shell pyramidal, angular, very much dilated anteriorly, with a very large aperture, canaliculated on each side, and rarely slit.

M. Rang makes this sub-genus comprise (1829) five species only, two of which he considers as very doubtful.

C. lanceolata. Shell compressed, elongated, lanceolate; aperture dilated.

It inhabits the seas of warm climates.

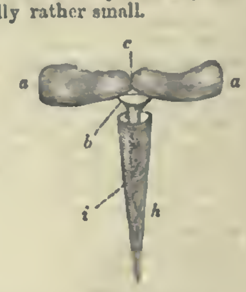
The following figure will convey a general idea of the form of the animal and shell.

Cleodora pyramidata.

a, animal and shell; *b*, shell, seen edgewise; *c*, shell, seen from above.

M. Deshayes, in his edition of Lamarck, records 13 species, besides *Hyalæa cuspidata*.

2. *Cresis* (Rang).—Animal very slender; the mantle not dilated on its sides, fins generally rather small.



Cresis.

a, fins; *b*, intermediate lobe; *c*, mouth; *i*, viscera, seen through the shell; *h*, the shell.

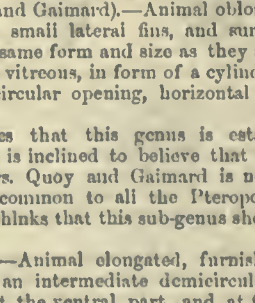
Shell very slender, fragile, and diaphanous, in the form of a straight or curved case (cornet), with an aperture almost always as large as the shell itself, and generally without a canal; no lateral appendages. M. Rang, who gives this description, says, that he formed this subgenus for some very small new mollusks, which he frequently met with in the middle of the ocean, and to which he unites, by analogy, the genera *Vaginella* of Daudin, and the *Gadus* of Moutagu, known in the fossil state; and M. Rang reckons 9 species.

3. *Tripter* (Quoy and Gaimard).—Animal oblong, fleshy, contractile, furnished with two small lateral fins, and surmounted by a membranous veil of the same form and size as they are.

Shell diaphanous, vitreous, in form of a cylindrical sheath, rounded posteriorly, with a circular opening, horizontal and dentilated on its borders.

M. Rang observes that this genus is established on a single species, and that he is inclined to believe that the membranous veil described by Messrs. Quoy and Gaimard is nothing more than the intermediate lobe common to all the Pteropods of the family of *Hyalæidæ*, and he thinks that this sub-genus should be united to the preceding.

Cuvieria (Rang).—Animal elongated, furnished with two rather large fins and with an intermediate demicircular lobe; the exterior branchiæ situated at the ventral part, and at the base of the intermediate lobe; organ of generation incompletely known; the mouth furnished with dentiform pieces proper for mastication.



Cuvieria.

a, fins; *b*, intermediate lobe; *c*, mouth; *e*, gills; *i*, viscera, seen through the shell; *f*, ovaries; *g*, heart; *h*, shell; *d*, posterior cavity of the shell.

Shell in form of a cylindrical case, rather flattened near its aperture, which is heart-shaped with sharp edges; the side opposite to the aperture shut by a diaphragm which is convex externally but not terminal, being surpassed by the walls of the cylinder.

M. Rang remarks that he established this curious genus on a species equally common in the Indian Sea, the ocean, and the South Sea.

Euribia (Rang).—Animal furnished with two horizontal fins, at the base of which is the mouth; the intermediate lobe is very small and of a triangular form; body globular, short; gills and organs of generation unknown.

Shell cartilagino-membranous, delicate, transparent, regular, and in form of a reversed cap (calotte).

M. Rang states that there is only a single species which he has not been able to observe sufficiently, but which presented well-defined generic characters.

Psyche (Rang).—Shell absent. Animal enveloped in a membranous mantle, furnished with two rather long fins, but which do not appear united on the ventral side by an intermediate lobe; branchiæ overspreading the fins.

M. Rang established this genus on a species from the seas of Newfoundland (Terre-Neuve); he adds that Mr. Reynaud brought back from his Indian voyage some drawings of Pteropods which appear to be referrible to it.

M. Deshayes says that he is led to reject many genera proposed some years since by M. Rang, in the 'Annales des Sciences Naturelles,' as well as in his 'Mannel,' under the name of *Cresis* and *Cuvieria*. M. Deshayes observes that M. Rang has comprehended under his subgenus *Cresis* a living shell named *Gadus* by Montagu, and some other fossils placed by Lamarck in the genus *Dentalium*. [DENTALIUM.] Although M. Deshayes is as yet uncertain as to these species, he adopts the opinion of Lamarck as preferable, because, he says, M. Rang has contested it only on the supposition that they had been defined after the mutilation of their posterior extremity, which, being naturally short, only presented itself as open by accident. This view taken by M. Rang, he continues, is not founded on any good observation, and he says that he has seen a sufficiently large number of individuals perfectly preserved, to be able to affirm that their posterior extremity was open when the animal was alive. These shells then, he states in conclusion, do not belong to the Pteropods, and are more probably *Dentalia*. This opinion is a very strong one, and, coming from the quarter it does, is deserving of all respect: but as M. Rang has justly the reputation of a good observer in this department of natural history, we have thought it right to lay before the reader the descriptions and figures given by him.

Fossil Hyalæidæ.

M. Rang, as we have seen, mentions one fossil species of *Hyalæa*, and Mr. G. B. Sowerby states that the genus occurs in a fossil state in Sicily. M. Rang notices the fossil analogue of *Cleodora* from Piedmont; if *Vaginella* and *Gadus* are to be considered as belonging to this family, they must be added. The last-mentioned author says that he has detected a fossil species of *Cuvieria* in the shell sand of Piedmont, where it had been collected by the elder De Luc. M. Deshayes, in his tables, enumerates two fossil (tertiary) of *Hyalæa* and three of *Cleodora*,* tertiary also; of the latter he records *Cleodora lanceolata* as a species found both living and fossil (tertiary).

HYALITE, a Mineral, a variety of Opal. [SILICA.]

HYALOSIDERITE, a synonym of the Mineral Chrysolite. [CHRYSOLITE.]

HYAS, a genus of Brachyurous Crustaceans belonging to the *Maia* family. [MAIADÆ.]

HY'BODUS, a genus of Fossil Fishes placed in the order of Placoidians by M. Agassiz ('Recherches sur les Poissons Fossiles,' vol. iii., tab. 8, 9, 10). The information which M. Agassiz has collected concerning this extinct group of fishes appears to be considerable, yet only in a few instances (from the Lias of Lyme Regis and Bristol) has he been able to reconstruct the whole skeleton. In consequence, the spinous rays and the teeth of one species may be, and probably are, described under different specific names. The species of *Hybodus* are supposed to amount to 22, and extend from the New Red-Sandstone (Grès Bigarré) to the Chalk inclusive. They present analogies to the genus *Squalus* of Linnæus, in the teeth and spinous rays; it appears that there were two dorsal fins, each having spinous rays, not differing more than in recent species of fishes with two spinous dorsal fins.

HYBRID. This term is generally applied in natural history to the produce of two organic beings supposed to belong to different species. It is not in all cases that animals or plants of different species will breed together, and where offspring occurs it is generally regarded as indicative of a closer relationship or affinity between the species. One peculiarity of all hybrids is their inability to continue the characters of both parents. Although they are known amongst birds and higher animals to produce fertile offspring, yet in the course of time the tendency to the character of the original species of one or other of the first parents is so strong, that the hybrid character is lost. Amongst plants the same law holds good. The knowledge of the fact that the pollen-cells of one species of plant will produce embryoes with the ovules of another is often used in horticulture for the purpose of producing new forms of plants. [HYBRIDISATION, in ARTS AND SC. DIV.; REPRODUCTION IN PLANTS; REPRODUCTION IN ANIMALS.]

* Including, probably, *Cresis* and *Vaginula*.

HYBRID PLANTS. [SEXES OF PLANTS.]

HYDA'TICA, a genus of Fossil Plants (probably aquatic) from the Coal Formation. (Artis.)

HYDATIDS. [ENTOZOA.]

HYDNOCARPUS. [FLACOURTIACEÆ.]

HYDNO'PORA (Fischer), a genus of *Polypiaria*, nearly synonymous with *Monticularia* of Lamarck. Goldfuss ranks some of the species under his somewhat indefinite group of *Astræa*.

HYDNORA. [CYTINACEÆ.]

HYDRA (Linnæus), a genus of Polypiferous Animals, including the Fresh-Water *Hydra*, or Polype. It has the following technical definition:—Polypes locomotive, single, naked, gelatinous, subcylindrical, but very contractile and mutable in form; the mouth encircled with a single series of granulous filiform tentacula.

As of all the forms of polypiferous animals the *Hydra* is the most interesting, we give an abstract of their history, from Dr. Johnston's 'British Zoophytes:'—

Leeuwenhoek discovered the *Hydra* in 1703, and the uncommon way its young are produced; and an anonymous correspondent of the Royal Society made the same discovery in England about the same time; but it excited no particular notice until Trembley made known its wonderful properties about the year 1744. These were so contrary to established experience, and so foreign to every preconceived notion of animal life, that by many they were regarded as impossible fancies. Leading men of our learned societies were daily experimenting on the creature, and transporting it by careful posts from one to another, while even ambassadors were forwarding to their respective courts early intelligence of the engrossing theme. The *Hydræ* are found in fresh waters only. They prefer slowly-running or almost still water, and adhere to the leaves and stalks of submerged plants. The body is exceedingly contractile, and hence liable to many changes of form; when contracted it is like a tubercle, a minute top, or button, and when extended it becomes a narrow cylinder, being ten or twelve times longer at one period than another, the tentacula changing in size and form with the body. On the point opposite the base, and in the centre of the tentacula, we observe an aperture, or mouth, which leads into a wider cavity, excavated as it were in the middle of its body, and from which a narrow canal is continued down to the sucker. When contracted, and also when fully extended, the surface appears smooth and even; but in 'its middle degree of extension' the sides seem to be minutely crenulated, an effect probably of a wrinkling of the skin. The tentacula encircle the mouth and radiate in a star-like fashion; but they seem to originate a little under the lip, for the mouth is often protruded like a kind of small snout; they are cylindrical, linear, or very slightly tapered, hollow, and roughened, at short and regular intervals, with whorls of tubercles, which under the microscope form a very beautiful and interesting object.

Each tentaculum forms a slender membranaceous tube, filled with an albuminous nearly fluid substance, intermixed with some oleaginous particles; and at certain definite places this substance swells out into tubercles or denser wartlike nodules, which are arranged in a spiral line. Every nodule is furnished with several spinigerous vesicles, used as organs of touch, and with a very singularly constructed organ for catching the prey. The organ of touch consists of a fine sac, inclosing another with thicker parietes, and within this there is a small cavity. From the point where the two sacs coalesce above there projects a long cilium, or capillary spine, which is non-retractile and apparently immovable. Surrounded by these cilia, and in the centre of the nodule, is placed the captor organ, called the 'hasta;' this consists of an obovate transparent sac, immersed in the nodule, with a small aperture even with the surface. At the bottom of the sac, and within it, there is a saucer-like vesicle, on whose upper depressed surface is seated a solid ovate corpuscle, that gives origin to, and terminates in, a calcareous sharp sagitta, or arrow, that can be pushed out at pleasure, or withdrawn, till its point is brought within the sac. When the *Hydra* wishes to seize an animal, the sagittæ are protruded, by which means the surface of the tentacula is roughened, and the prey more easily retained; and Corda believes that a poison is at the same time injected—a conjecture offered to explain the remarkable fact of the almost instant death of the prey. The nodules of the tentacula are connected together by means of four muscular fibres, or bands, which run up, forming lozenge-shaped spaces by their intersections. These are the extensor muscles of the tentaculum. They are again joined together by transverse fibres, which Corda believes to be adductor muscles, and to have also the power of shortening the tentacula. But it may be doubted whether this muscular apparatus is of itself sufficient to effect the wonderful extensibility of these organs —from a line, or, as in *H. fusca*, to upwards of eight inches; and to produce this degree of elongation, it seems necessary to have superadded the propulsive agency of a fluid. Water flows, let us say by suction, into the stomach through the oral aperture, whence it is forced by the vis-a-tergo, or drawn by capillary attraction, into the canals of the tentacula, and its current outwards is sufficient to push before it the soft yielding material of which they are composed, until at last the resistance of the living parts suffices to arrest the tiny flood, or the tube has become too fine in its bore for the admission of water attenuated to its smallest possible stream—how inconceivably slender may indeed be imagined, but there is no thread fine enough to equal it, seeing that the tentacula of *H. fusca*, in tension, can be compared to nothing grosser than the scarce visible filaments of the gossamer's web.

The *Hydra*, though usually found attached, can nevertheless move from place to place, which it does either by gliding with imperceptible slowness on the base, or by stretching out the body and tentacula to the utmost, fixing the latter, and then contracting the body towards the point of fixture, loosening at the same time its hold with the base; and by reversing these actions it can retrograde. Its ordinary position seems to be pendant, or nearly horizontal, hanging from some floating leaf or weed, or stretching from its sides. In a glass of water the creature will crawl up the sides of the vessel to the surface and hang from it, sometimes with the base and sometimes with the tentacula downwards; and again it will lay itself horizontally. Its locomotion is very slow, and the disposition of the zoophite is evidently sedentary; but the contractions and mutations of the body are very vivacious, while in seizing and mastering its prey it is surprisingly nimble, seizing a worm with as much eagerness as a cat catches a mouse. It enjoys light, and expands more freely under its influence; hence we generally find the *Hydra* near the surface and in shallow water. The *Hydræ* are very voracious, feeding only on living animals. In confinement however Trembley found they might be fed on minced veal, fish, or beef and mutton. They will sustain long fasts with no other change than a paler colour indicates. Small worms, crustaceans, and insects seem to form a favourite food. Sometimes two polyps will seize upon the same worm, and most amusing is it then to witness the struggle that ensues, sometimes resulting in the swallowing of the weaker polyp by the stronger, which however is soon disgorged with no other loss than his dinner. This is the more curious when contrasted with the fate of the worms on which they feed. No sooner are they seized than they evince every symptom of painful suffering, but their contortions are merely momentary, and a certain death suddenly follows their capture. How this effect is produced is still a matter of conjecture. Worms are in ordinary circumstances most tenacious of life, and hence one is inclined to suppose that there must be something poisonous in the *Hydra's* grasp. To the *Entomostraca* the touch is not equally fatal, their shell evidently protecting them from the poisonous secretion. The *Hydra* is chiefly celebrated on account of its manner of propagation. It is like zoophytes in general, monœcious, and every individual possesses the power of continuing and multiplying its race, principally however by the process of subdivision. During the summer season a large tubercle arises on the surface, which lengthening and enlarging every hour, in a day or two develops in regular succession and in successive pairs a series of tentacula, and becomes in all respects except in size similar to its parent. It remains attached for some time, and grows and feeds, and contracts and expands after the fashion of its parent, until it is at length thrown off by a process of exfoliation or sloughing. They develop with great rapidity in warm weather, and sometimes the young ones themselves breed others, and they again a third or fourth generation before they become separated from the original parent. Trembley found that an individual of *H. grisea* produced 45 young ones in two months. In autumn the *Hydra* generates by internal oviform gemmules, which extrude from the body, and lie during the winter in a quiescent state, and are stimulated to evolution only by the returning warmth of the spring. Few observations have been made on these ova, so that their structure, source, manner of escape, and condition are scarcely known.

These are the modes in which the *Hydra* naturally multiplies its kind, but it can be increased by artificial sections of the body in the same manner that a perennial plant can by shoots or slips. If the body be halved in any direction each half in a short time grows to a perfect *Hydra;* if it is cut into four or eight or even minced into forty pieces, each continues alive, and develops a new animal which is itself capable of being multiplied in the same extraordinary manner. If the section is made lengthwise so as to divide the body into two or more slips connected merely by the tail, they are speedily reunited into a perfect whole, or if the pieces are kept asunder each will become a perfect polyp. If the tentacula are cut away, new ones are quickly produced, and the lopt-off parts are not long without a new body. When a piece is cut out of the body the wound speedily heals, and as if excited by the stimulus of the knife, young polyps sprout from the wound more abundantly; when a polyp is introduced by the tail into another body, the two unite and form one individual, and when a head is lopt off, it may safely be ingrafted on the body of any other which may chance to want one. And the creature suffers nothing itself by all these apparently cruel operations; for before the lapse of many minutes the upper half of a cross section will expand its tentacula and catch prey as usual, and the two portions of a longitudinal division will after an hour or two take food and retain it. A polyp cut transversely in three parts requires four or five days in summer and longer in cold weather for the middle piece to produce a head and a tail, and the tail part to get a body and head, which they do in pretty much the same time. And what is still more extraordinary, polyps produced in this manner grow much larger and are far more prolific in the way of their natural increase than those which were never cut. When such things were first announced, when to a little worm the attributes of angelic beings were assigned, and the wild fictions of antiquity realised, it is not wonderful that the vulgar disbelieved, when naturalists, familiar with all the miracles of the insect world, were amazed and wist not what to do.

The following are British species of this genus:—

H. viridis (Polypes Verds of Trembley), is of a grass-green colour. The body cylindrical or insensibly narrowed downwards; tentacula 6 to 10, shorter than the body. It is commonly found in ponds and still waters. The polyps of this species differ from the following, not only in colour, but likewise in their arms, which are much shorter in proportion to their bodies, capable of but little extension, and narrower at the root than the extremity, which is contrary to the other species. Their arms were so short they could not clasp round a very small and slender worm, but seemed to pinch it fast till they could master and devour it, which they did with as much greediness as any. It was first observed in England in the spring of 1743 by a Mr. Ducane of Essex. It appears to be a hardy animal, and is easily kept for a length of time in a phial of water.

H. vulgaris is of an orange-brown or yellowish colour, body cylindrical, tentacula 7 to 12, as long or longer than the body. It is found in weedy ponds and slowly-running waters. This does not exceed *H. viridis* in size, which it resembles also in its habits and form. It is always of an orange-brown or red colour, the intensity of the tint depending on the nature of the food, or the state of the creature's repletion. Every part of the body is generative of young, which may frequently be seen hanging from the parent at the same time in different stages of their growth.

H. attenuata is of a light oil-green colour, the body attenuated below, with pale tentacula longer than itself. It is found in ponds, and in Yetholm Lough, Roxburghshire. This is a larger animal than *H. vulgaris*, and comparatively rare, less sensible to external impressions, and of a more graceful form. Its colour is a pale olive-green, with paler tentacula, which are considerably longer than the body, and hang like silken threads in the water, waving to and fro without assuming that regular circular disposition which they commonly do in *H. viridis*. Dr. Johnston says he has not observed more than one young at a time, which pullulated from near the middle of the body, and after this has attained a certain growth the polyp has the appearance of being dichotomously divided.

H. oligactis (Polypes à Long Bras of Trembley) is brown or griseous; inferior half of the body suddenly attenuated; tentacula several times longer than the body. It is found in still waters in England, rare. In a pond at Hackney; and in a pond at Cranmore, near Belfast, September 1812. The tails of these are long, slender, and transparent, and when placed under the microscope a long straight canal may be seen passing from the body or stomach to an opening at the end thereof; these are rather lighter coloured than *H. vulgaris*, and have seldom more than 6 or 8 arms, but those capable of great extension. It may be worth while to call attention to the remarkable resemblance of the *Hydra fusca* to the *Cucullanus cirratus* of Müller, which is an intestinal worm.

(Johnston, *History of British Zoophytes;* Landsborough, *Popular History of British Zoophytes;* Trembley, *Mémoires pour servir à l'Histoire d'un Genre de Polypes d'Eau douce*, the Hague, 1743; Baker *Natural History of the Polype.*)

HYDRACHNA. [TRACHEARIA.]

HYDRACTINIA. [HYDROIDA.]

HYDRALES. [ENDOGENS.]

HYDRANGEA. [HYDRANGEACEÆ.]

HYDRANGEACEÆ, *Hydrangeads*, a natural order of Exogenous Plants consisting of shrubs, with perfectly opposite simple leaves, smooth or downy, with simple hairs, destitute of stipules, sometimes creeping and rooting like ivy. Flowers usually in cymes; those in the centre male, the marginal often sterile, and furnished with larger petals than the others. Calyx adhering more or less to the ovary, 4- or 6-toothed. Petals 4 or 6, inserted within the edge of the calyx, deciduous. Stamens 8 or 12, in two rows, inserted in the orifice of the calyx, distinct, deciduous. Anthers oblong or roundish, pollen with three longitudinal furrows. Ovary more or less adherent to the calyx, consisting of from 2 to 5 carpels, adhering by their sides, and forming an incompletely 2- or 5-celled cavity; placentæ distinct from each other, but touching with many anatropal ascending or horizontal ovules; styles as many as the carpels, perfectly distinct, diverging, with simple reniform stigmas. Fruit a capsule crowned by the permanent diverging styles, 2- or 5-celled, with a number of minute seeds, sometimes indefinite, sometimes few, in consequence of the abortion of a part of the ovules. Testa thin, membranous, netted, occasionally expanded into a wing. Embryo orthotropal in the axis of a small quantity of fleshy albumen. The relationship between Hydrangeads and Saxifrages is admitted by all systematists, who have in general united them in the same order. Lindley places this order between *Saxifragaceæ* and *Cunoniaceæ*, and near *Philadelphaceæ* and *Caprifoliaceæ.* It differs from *Hensloviaceæ* mainly in its indefinite seeds, small quantity of albumen, and constant tendency to produce a superior ovary. Out of the species hitherto discovered, all of which inhabit the temperate parts of Asia and America, two only belong to the southern hemisphere, and twenty-three or about one-half to China and Japan. The species are found naturally in moist shady places. None of them appear to be of much use to man.

Hydrangea is a well-known genus of hardy shrubs, of which one species is commonly cultivated for the sake of its beautiful flowers. This plant is a native of China and Japan: it was originally observed in the gardens of Canton by Loureiro, who took it for a primrose, and called it *Primula mutabilis.* It was next met with by Commerson, a French traveller, who named it *Hortensia,* in compliment to Madame Hortense Lépeaute. Thunberg referred it to the genus *Viburnum,* and Smith called it by its present name, coupling with it the name *Hortensia* of Commerson, converted however into *Hortensis.* When this plant is hardy enough to survive the winter, it grows to a considerable size, and when covered by a multitude of its very large round heads of rosy flowers, becomes a magnificent object. But as it is rather tender, we more commonly see it grown in pots, by which its beauty is much diminished. To have it in perfection it should be planted in the open ground in rich soil; during winter it should be covered with a mat well stuffed with straw. As soon as it begins to move its buds in spring, it should be unpacked, and during summer it should be most abundantly supplied with water. We have known a large plant receive as much as 100 gallons of water daily. If thus treated, the *Hydrangea* is without a rival in the shrubberies of this country. The blue colour which the flowers of this plant now assume does not indicate a distinct variety, but is only owing to the soil in which the plant is made to grow containing a greater quantity of iron than usual. Other species are *H. arborescens* and *H. quercifolia.*

The leaves of *H. Thunbergii* are dried in Japan and used as a kind of tea, which for its excellence they call Ama-tsja, or Tea of Heaven. There are 9 genera and 45 species of this order.

HYDRARGYRUM. [MERCURY.]

HYDRASTIS. [WARNERA; RANUNCULACEÆ.]

HYDRIDÆ, a family of Snakes belonging to the Colubrine suborder of Dr. J. E. Gray's arrangement, and the first section of this sub-order, which includes the *Hydridæ* and *Boidæ.* [BOIDÆ.] It is thus characterised:—Belly covered with narrow elongate shields or scales, nearly resembling those of the back.

The following is a synopsis of the genera, and a list of the species, compiled from the Catalogue of the specimens of Snakes in the British Museum:—

Hydridæ.—The ventral shields narrow, hexagonal or band-like; the hinder limbs not developed; the eyes and nostrils superior, vertical, the latter valvular, generally placed in the middle of a shield, with a slit or groove to its outer edge; fangs moderate, intermixed with the maxillary teeth; pupil small, round; tail compressed or conical. They live in the sea or salt-water lakes, or in fresh water.

Synopsis of the Genera.

I. Tail compressed (except in *Acrochordus*). Belly keeled, with two rows of small scale-like shields, often united together into a single, rather broad, 6-sided shield.

A. Head shielded to the nape. Nasal shields very large, with a large, operculated, superior nostril in their hinder edge; the frontal shields two pairs, small; loreal shield none; labial shields high, large. *Hydrina.*

These are the true Sea-Snakes. They coil themselves up on the shore, and appear to live on sea-weed, and lay their eggs on the shore. They are often found asleep on the surface of the sea, where they are easily caught, for they cannot descend into the sea without throwing themselves on to their backs. This arises apparently from the necessity of expelling the air from their large lungs. They are often thrown ashore in the surf, and are occasionally carried up rivers by the tide, but they cannot live in fresh water. Their bite is venomous, and they are held in great dread by fishermen wherever they occur, on this account. In spite of their venomous properties, one species at least, the *Hydrus* (*Pelamis*) *bicolor* is said by Cuvier to be eaten at Taheite.

a. Scales square or 6-sided, placed side by side.

* Head elongate, depressed.

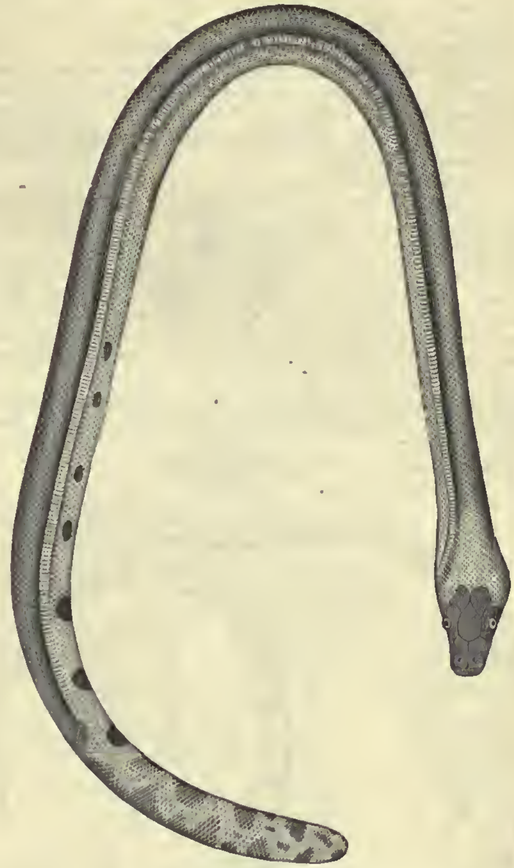
1. *Pelamis.*
P. bicolor. Pacific Ocean.
P. ornata. Borneo.

** Head moderate, rather compressed; gape moderate.

2. *Lapemis.*—Head moderate, short, rounded in front; dorsal scales square; ventral shield broad, 6-sided.
L. curtus. Madras.
L. Hardwickii. Borneo.

3. *Aturia.*—Head moderate, short, rounded in front; dorsal scales 6-sided; ventral shield 6-sided.
A. ornata. Indian Seas.
A. Belcheri. New Guinea.

4. *Microcephalophis.*—Head small; scales 6-sided; ventral scales keeled.
M. gracilis, the Kadel Nagam. Madras.



Pelamis bicolor (*Hydrus bicolor,* Schn.).

b Scales ovate, 6-sided, imbricate, keeled, or with the keel reduced to a tubercle on the centre of the scales; head and gape moderate.

* Labial shields occupying the greater part of the lips; the eyes over the fourth, or rarely over the third, or the fourth or fifth shield; ventral shield united.

5. *Enhydrina.*—Rostral plates narrow, erect; lower linear, sunken; nasal narrowed in front; ventral shield flat; head moderate, short; eyes moderate.
E. Bengalensis. Madras.
E. Valakadyen. Madras.

6. *Hydrophis.*—Rostral broad, transverse; lower triangular; nasal truncated or notched in front; ventral shield flat; head short; eyes small.
H. obscura, the Shootur Sun. Madras.
H. Lindsayii. China.
H. fasciata. Indian Ocean.
H. nigrocincta, the Kerril. Bengal.
H. doliata, the Black-Headed Kerril. Australia.
H. subcincta, Shaw's Chittul. Indian Ocean.
H. sublævis, the Chittul. China and Indian Ocean.
H. mentalis, the Pale Chittul. Indian Ocean.
H. ocellata, the Eyed Chittul. Australian Seas.
H. spiralis, the Shiddil. Indian Ocean.
H. subannulata, the Ringed Sea-Snake. India.
H. aspera, the Rough Sea-Snake. Singapore.
H. cærulescens, the Bluish Sea-Snake. Bengal.

7. *Chitulia.*—Rostral broad, transverse; lower triangular; nasal truncated or notched in front; ventral shields flat; head elongate, depressed; eyes large.
C. inornata. Indian Ocean.
C. fasciata. Indian Ocean.

8. *Kerilia.*—Rostral broad, transverse; lower triangular; nasal truncated in front; ventral shield broad, convex, forming a slight keeled ridge; the hinder ones with a keel on each side; head short, shelving; scales very large, broad, 6-sided; eyes rather large, over third and fourth labial shields.
K. Jerdonii, the Kerilia. Madras.

** Labial shield occupying the front half of the lip; eyes over the fifth or sixth shield; hinder part of the face covered with small scales; ventral scales generally 2-rowed, forming a keeled ridge, some united in pairs into 6-sided shields.

9. *Hydrus.*
H. major, the Sea-Snake. India; Australia.
H. annulatus, the Ringed Sea-Snake. Singapore.

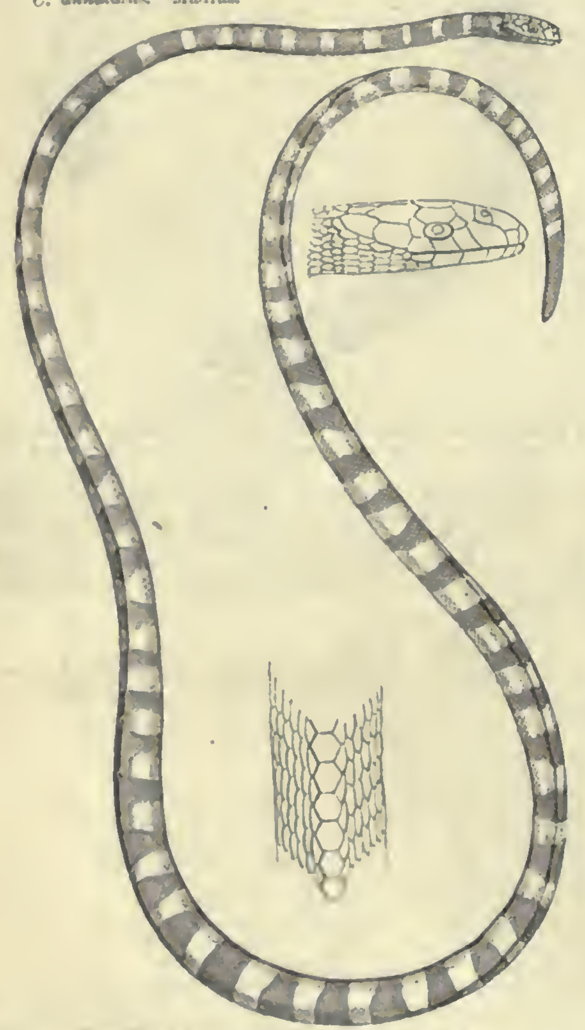
c. Body covered with smooth polished imbricate scales; head as large as the body; ventral shields rather large, transverse, smooth, folded together and keeled.

10. *Tomogaster.*—Head with regular shields; superciliary shields simple; ventral shields entire.
T. Eydourii. Indian Ocean.

11. *Stephanohydra.*—Head shields numerous; superciliary shields 3 or 4; ventral shields nicked behind.
S. fusca, Jukes's Hypotrophis. Darnley Islands.

B. Head covered with scales, like the body; nostrils surrounded by a small, continuous ring; eyes surrounded by a series of small scales; labial shields small, with a larger series above them; pupil round; ventral shields very small, scale-like, separated on each side of a keeled ridge. The species are all inhabitants of rivers. *Acrochordina.*

12. *Chersydrus.*—Tail compressed, sword-shaped, prehensile; body fusiform, covered with small rhombic scales, with a central tubercular keel.
C. granulatus, the Chersydrus. Madras.
C. annulatus. Madras.



Chersydrus granulatus (*Acrochordus fasciatus*, Shaw).

13. *Acrochordus.*—Tail conical, tapering, moderate; body fusiform, covered with tricuspid scales.
A. Javanicus. Java.

II. Tail conical, tapering. Belly rounded beneath, with more or less broad band-like shields. Rivers or ponds.

A. Head shielded; tail scaly beneath; abdominal shields flat, small, 6-sided, with a keel on each side, as if formed of two united scales; nostrils in a ring of small scales; scales keeled. *Erpetonina.*

14. *Erpeton.*
E. tentaculus, the Erpeton. [ERPETON.]

B. Head shielded; tail with two series of shields beneath; nostrils between two shields; abdominal shields broad, keeled on each side; scales smooth. *Bitiana.*

15. *Bitia.*—Head small.
B. hydroides.

C. Head shielded; scales striated, and keeled or smooth; tail conical, tapering, with two series of shields beneath; nostrils in centre of a large nasal shield, with a groove to the outer side; ventral shields rounded (or rarely slightly keeled on the sides); frontal shields 3, rarely 2 or 4, all small. *Cerberina.*

a. Crown scaly; occipital rudimentary; frontals 4; anterior pair very small.

16. *Cerberus.*—Scales keeled, striated; hinder labial shield low.
C. cinereus, the Karoo Bokadam. India.
C. acutus. Borneo.
C. unicolor. Philippines.
C. australis. Australia.

b. Crown shielded; occipital moderate.

* Head distinct, depressed; frontals 4; anterior pair small; rostral rounded.

17. *Ferania.*—Scales smooth; seventh upper labial low, with a large shield over it.
F. Sieboldii. Bengal.

** Head distinct, depressed; frontals 3; anterior transverse; rostral rounded.

† Fourth and fifth hinder labial shields small or divided.

18. *Homalopsis.*—Scales keeled.
H. buccata. Java.
H. Hardwickii. India.

19. *Phytolopsis.*—Scales smooth.
P. punctata. India.

†† Hinder labial large, like others; scales keeled; rostral rounded.

20. *Uranops.*—Scales truncated, strongly keeled, striated; eye over fourth shield.
U. angulatus. Tropical America.

21. *Tachynectes.*—Scales truncated, strongly keeled.
T. Leopardina.

22. *Tropidophis.*—Scales ovate, keeled, striated; eye over fourth and fifth shield.
T. Schistosus, the Chittee. Ceylon.

23. *Myron.*—Scales ovate, slightly keeled, smooth.
M. Richardsonii. Australia.
M. trivittatus. India.

24. *Helicops.*—Scales ovate, polished; of back and tail keeled.
H. carinacaudus. North America.

††† Hinder labials large, like others; scales smooth; rostral rounded.

25. *Hypsirhina.*—Seventh labial large; eye over fourth and fifth labial; loreal distinct.
H. plumbea. Borneo.
H. Hardwickii. Penang.
H. Aer, the Ular Aer. Borneo.
H. bilineata. China.
H. Chinensis. China.
H. Bennettii. China.

26. *Farancia.*—The seventh labial large; eye over the third and fourth labial.
F. fasciata, the Wampum-Snake. New Orleans.

27. *Hydrops.*—The seventh labial large: eyes over the fourth labial; ventral shield broad; body thick; loreal none.
H. Martii. Brazil.

28. *Hygina.*—The seventh labial large; eyes over the fourth labial; ventral shield narrow; body slender; loreal none.
H. fasciata. Demerara.

29. *Dimades.*—The seventh labial short, small; eye over third and fourth labial; loreal none.
D. plicatilis. New Orleans; North America.

*** Head moderate, depressed; frontal 3; anterior elongate, erect, between the nasals; seventh smooth; rostral rounded.

30. *Fordonia.*—Scales broad, rhombic; ventral shield rounded; loreal none; eye over third labial.
F. leucobalia. Timor.
F. unicolor. Borneo.

31. *Gerarda.*—Scales broad, rhombic; ventral shields rounded; eye over fourth shield; loreal square.
G. bicolor, the Gerard. West Indies.

32. *Hipistes.*—Scales narrow, flattened; ventral shields keeled at each end; loreal square.
H. fasicatus. West Indies.

**** Head indistinct; frontal 4; anterior 4-sided, rather smaller; scales smooth; body cylindrical.

33. *Abastor.*—Body cylindrical; loreal shield none; anterior frontal 4-sided; posterior ocular 2.
A. erythrogrammus, the Striped-Wampum. North America.

34. *Raclitia.*—Head small, conical; body subcylindrical; anterior frontal very small, triangular; loreal distinct; posterior ocular.
R. Indica. India.

35. *Miralia.*—Head small, conical; body compressed; frontal plates 2 pairs; loreal none; posterior ocular 2.
M. alternans. Java.

***** Head moderate, depressed; frontal shields, 2, small, lateral; rostral shield angular, high, erect, between frontals and nasal.

36. *Ficinia.*—Head small; rostral plate large, produced between the frontal, angular and recurved in front.
F. olivacea. Mexico.

****** Head small; frontal shields 2, transverse, band-like; rostral triangular, subangular.

37. *Prosymna.*
P. meleagris. Guinea.

D. Head covered with small scales; tail with one row of shields beneath; abdominal shield broad, rounded, smooth; nostril in a shield, anterior, sublateral; scales granular, with rows of keeled scales. *Xenodermina.*

38. *Xenodermus.*
X. Javanicus, the Gonionote. Java.

Dr. Gray says, "The separation of the specimens of this family into species and genera is attended with great difficulty; the form and number of the shields of the head, lips, temple, and chin are liable to great variation, not only in the different specimens, but often in the two sides of the same individual. The two ventral series of scales are, in the same specimen, sometimes separate, and at other times united into a shield; and many specimens have a series of small triangular shields on the edge of the lips, between the sutures of the lip-shield, not found in other individuals of the same species.

"The distribution of the colours on the body appears to be one of the most permanent characters of the species; but this becomes less distinct in the older specimens, and is often lost in the specimens that have been carelessly or long preserved in a museum."

The existence of this family of Water-Snakes has undoubtedly given rise to the notion that a large Ophidian, which meets the popular view of a Great Sea-Serpent, exists. In all cases however the reports of the existence of such a creature have been traced to the capture or sight of some other animal, or to the exaggerated representations of some other natural object. The *Hydridæ* amongst the *Ophidia* are of comparatively small size, seldom equalling the *Boidæ* in this respect, and falling far short of the enormous dimensions popularly attributed to the Great Sea-Serpent. [BOIDÆ; OPHIDIA.]

HYDRILLA. [HYDROCHARIDACEÆ.]

HYDRO'BATA, Vieillot's name for the Water-Blackbirds, *Cinclus.* [MERULIDÆ.]

HYDRO'BATES, Temminck's name for the Sea-Ducks. [DUCKS.]

HYDROBORACITE, a Mineral, occurring in small needle crystals, which appear to be flat six-sided prisms. Its colour is white, with spots of red from silicated peroxide of iron. Hardness similar to that of gypsum. It is translucent. The specific gravity is 1·9. Found in a collection of Caucasian minerals. The following is an analysis by Hess:—

Boracic Acid	49·22
Lime	13·74
Magnesia	10·71
Water	26·33
	100

HYDROCANTHERA, a tribe of Insects belonging to the Pentamerous family of the *Coleoptera.* They are all aquatic in their habits. The principal sections are the *Dytiscidæ* and *Gyrinidæ.* [DYTISCIDÆ; GYRINIDÆ.]

HYDROCHARIDA'CEÆ, *Hydrocharads*, a small natural order of Endogenous Plants inhabiting ditches, lakes, and rivers in various parts of the world. They have tripetaloideous flowers, often separate sexes, and an inferior ovary. The latter character cuts them off from *Alismaceæ* and *Butomaceæ*, to which they bear some resemblance in habit. *Vallisneria spiralis*, a plant of this order, is remarkable for its spiral flower-stalk, which enables it to accommodate itself to the depth of the stream in which it floats, so as always to keep its flowers above water when it is necessary. [VALLISNERIA.] It is in the leaves of this plant that a peculiar movement in the interior of the cell called *Cyclosis* [CYCLOSIS] was originally observed. The same movement is also seen in the cells of *Hydrocharis Morsus Ranæ* and *Anacharis alsinastrum*, and is probably present in the whole of the order. The species are natives of fresh-water in Europe, North America, and the East Indies. One species is found in Egypt (*Damosonium Indicum*), and two Vallisnerias in Australia. Nothing is known of their uses unless that the fruit of *Enhalus* is eatable, and its fibres capable of being woven. According to Agardh, *Ottilia* and *Boottia* are eaten in India as pot-herbs.

Hydrocharis Morsus Ranæ.

1, a portion of the plant, with flowers, leaves, and stem; 2, a male flower; 3, a female flower; 4, a section of the ripe fruit; 5, a seed, with a part of the testa stripped off to show the embryo.

The Janji of Hindustan, the *Vallisneria alternifolia* of Roxburgh *Hydrilla* of Hamilton, is one of the plants used in India for supplying water mechanically to sugar in the process of refining it, "as clay is used in the West Indies to permit the slow percolation of water." Lindley places this order near *Naiadaceæ*, *Pistiaceæ*, and *Bromeliaceæ.* It has 12 genera and 20 species.

HYDROCHARIS. [HYDROCHARACEÆ.]

HYDROCHŒRUS. [HYSTRICIDÆ.]

HYDROCOTYLE (from ὕδωρ, water, and κοτύλη, a cavity), a genus of Plants belonging to the natural order *Umbelliferæ* and to the sub-order *Orthospermeæ.* The calyx obsolete; the petals ovate, entire, acute, with a straight apex; the fruit flatly compressed from the sides; the carpels without vittæ; the five ribs or nerves nearly filiform, the carinal and lateral ones usually obsolete, and the two intermediate ones joined. The species of this genus are generally bog-herbs; but few of them are under-shrubs. The umbel is single, surrounded by a few-leaved involucrum; the flowers sessile or pedicillate, white.

Upwards of ninety species of plants have been referred to this genus. It is not however improbable that a more attentive study of them will lead to the distinction of other genera amongst them.

H. vulgaris, Pennywort, has peltate orbiculate double crenate leaves; umbels capitate, of 5 flowers, often proliferous; fruit emarginate below. This plant is a native of Great Britain, and throughout nearly the whole of Europe, in marshy boggy places, and on the margins of rivulets on a peat soil. This plant is commonly called Pennywort, on account of its leaves lying flat on the ground and having the size and form of a piece of money. It is also known by the names of Water-Pennywort, Sheep-Killing Pennygrass, White-Rot, Fluke-Wort, and Sheep's-Bane. These latter names it has obtained on account of its being supposed to produce the rot and other diseases in animals that feed on it. This is however an error, as this plant will not produce disease in animals; but it occurs in damp moist situations, where animals that feed are likely to be attacked with rot and other diseases. It is in this way that other marsh-plants, as the species of *Drosera* and *Pinguicula*, have been supposed to cause disease in sheep and oxen.

Of the large number of species of this genus few if any are used in the arts or medicine, and none of them are sufficiently ornamental to lead to their cultivation. *H. Asiatica* is said to be used in India as a diuretic, and occasionally as a culinary vegetable. *H. umbellata* is recommended by Martius as a remedy in hypochondriasis, but on what grounds is not stated. The fresh juice acts as an emetic. It is said to possess an aromatic odour and an agreeable taste. The species of *Hydrocotyle* are easily cultivated; they must all be kept moist. The stove-greenhouse and frame kinds should be grown in pots placed in pans of water.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines*; Babington, *Manual of British Botany*.)

HYDROCYON, a genus of Fishes belonging to the *Malacopterygii Abdominales*. The species are very numerous. They have the point of the muzzle formed by the intermaxillaries, the maxillaries nearer, before the eyes, and completing the aperture; the tongue and vomer smooth, the jaws with conical teeth, and the large suborbital covers the cheek like an operculum.

A large number of species inhabit Brazil. They are also found in the Nile.

HYDRODICTYON. [ALGÆ.]

HYDROIDA, a name given to a section of the order *Polypifera*, embracing forms resembling the fresh-water *Hydra* in the simplicity of their organisation. The following is Dr. Johnston's arrangement of the families of British Zoophytes referred to the *Hydroida*:—

* Ovisacs or bulbules naked, bud-like, pullulating from the bases of the tentacula.

Tubularina, Ehrenberg (*Tubularia*, Linnæus; *Tubulariadæ*, Johnston; Les Tubulaires, Van Beneden).

Family I.—Polyps naked, or with only a rudimentary polypidom. *Corynidæ*.

† Polyps naked.

The tentacula scattered. *Clava*.
The tentacula in one row. *Hydractinia*.

†† Polyps with a horny cuticle.

The tentacula with globose tips. *Coryne*.
The tentacula filiform. *Cordylophora*.

Family II.—Polypidom fistular; the tentacula whorled. *Tubulariadæ*.

† The tentacula in a single whorl. *Eudendrium*.

†† The tentacula in a double whorl.

Polypidom rooted. *Tubularia*.
Polypidom unrooted and deciduous. *Corymorpha*.

** Ovisacs in the form of horny capsules or vesicles scattered on the polypidoms, and deciduous.

Sertularina, Ehrenberg (*Sertularia*, Linnæus).

Family III.—Cells of the polyp sessile. *Sertulariadæ*.

† Cells biserial.

Cells alternate, tubular. *Halecium*.
Cells vasiform, everted. *Sertularia*.
Cells conico-tubular, appressed. *Thuiaria*.

†† Cells uniserial.

The branchlets plumose or pectinate. *Plumularia*.
The branchlets whorled. *Antennularia*.

Family IV.—Polype-cells on ringed stalks. *Campanulariadæ*.

Cells alternate, campanulate. *Laomedea*.
Cells irregular, or whorled. *Campanularia*.

*** Polyps propagating by buds and ova, which develop themselves on and in the body of the parent.

Hydrina, Ehrenberg (*Hydra*, Linnæus; *Hydraidæ*, Johnston). One genus only. *Hydra*. [HYDRA; POLYPIFERA.]

HYDROLEA'CEÆ, a very small and unimportant natural order of Monopetalous Exogenous Plants, which are by most authors united with *Hydrophyllaceæ*. [HYDROPHYLLACEÆ.] They are weeds inhabiting the East Indies, with alternate glandular or stinging leaves, monopetalous regular flowers, with a gyrate inflorescence, definite stamens, a superior polyspermous 2- or 3-celled fruit, and seeds with the embryo lying in the midst of fleshy albumen. In their gyrate inflorescence they correspond with *Boraginaceæ*.

HYDROLITE. [GMELINITE.]

HYDROMAGNESITE. [MAGNESITE.]

HYDROMETRIDÆ, a family of Insects belonging to the order *Hemiptera*. This family was established by Dr. Leach, and is thus characterised:—Rostrum with 2 or 3 distinct joints; labrum very short; eyes moderate; feet very long, formed for walking on the water, with the claws minute, inserted laterally into a fissure on the extremity of the terminal joint of the tarsus.

The genera *Hydrometra*, *Gerris*, and *Velia* of Latreille belong to this family. Those species which have setaceous antennæ, the head prolonged into a snout and receiving the rostrum beneath, belong to the first of these three genera, of which the *Hydrometra stagnorum* will serve as an illustration. This insect is about 3-8ths of an inch in length, and not broader than an ordinary sized pin, of a black or brown colour, with pale brown legs, and is very common on ponds and ditches, generally near the margin. Like the other species of the

Hydrolea spinosa.

1, a flower, seen from beneath; 2, a stamen; 3, a ripe seed-vessel; 4, a section of a seed, showing the embryo.

family *Hydrometridæ*, it possesses the power of walking upon the surface of the water: it differs however from those of the two remaining genera, inasmuch as its movements are comparatively slow.

In the genus *Velia* the antennæ are filiform, 4-jointed, the first joint the longest, the remaining joints long, about equal to each other, and bent at an angle with the first; rostrum 2-jointed; legs moderate, and nearly equidistant.

V. rivulorum (Latreille) is a very common insect in this country, frequenting running streams, and running on the surface of the water with great rapidity. It is about 1-4th of an inch in length, and 1-12th of an inch in breadth; of a black colour, the body red, spotted with black, the thorax brown, with two white spots, and the elytra each with four white spots.

The principal characters of the genus *Gerris* are—Antennæ filiform, 4-jointed, the basal joint nearly as long as the remaining three; rostrum 3-jointed, legs long, the second pair the longest, and inserted far from the first.

G. Paludum is about 5-8ths of an inch in length, and 1-12th of an inch in breadth, of a brownish-black colour above, and silvery-white beneath. This insect is very abundant, and its peculiar habits of darting about on the surface of the water must have attracted the attention of all persons. Its food appears to consist chiefly of such insects as are blown or accidentally fall into the water, which it seizes with its fore legs.

HYDROPELTIDEÆ, *Watershields*, a natural order of Exogenous Plants (*Cabombaceæ* of Torrey, Gray, and Lindley). The species are aquatic plants, with floating peltate leaves. Flowers axillary, solitary, yellow, or purple. Sepals 3 or 4, coloured inside. Petals 3 or 4, alternate with the sepals. Stamens definite or indefinite, hypogynous, arising from an obscure torus. Anthers linear, turned inwards, continuous with the filaments. Carpels 2 or more, terminated by a short style. Ovules orthotropal, pendulous. Fruit indehiscent, tipped by the hardened style. Seeds definite, pendulous. Embryo minute, 2-lobed, inclosed in the fleshy sac of the amnios, at the apex of the nucleus, and external to an abundant fleshy albumen. There can be no doubt of the near relationship of these plants to the Water-Lilies. They are American water-plants, found from Guyana to New Jersey, and also on the coast of Australia beyond the tropics.

Hydropeltis purpurea is said to be nutritious, but slightly astringent. The leaves are employed as a remedy for phthisis and dysentery.

(Lindley, *Vegetable Kingdom*.)

HYDROPELTIS. [HYDROPELTIDEÆ.]

HYDROPHANE. [SILICA.]

HYDROPHI'LIDÆ, a family of Coleopterous Insects established by Leach. The insects of this family are included by Latreille in his section *Palpicornes*. They have generally nine joints to the antennæ, but sometimes only 6; the terminal joints always form a perfoliated knob; the maxillary palpi are very long and slender; the body is usually oval or rounded, convex above and flat beneath, or nearly so: the tarsi are 5-jointed, and the mandibles bidentate.

The principal genera of the family *Hydrophilidæ* may be thus characterised:—

Genus *Hydroüs*.—Antennæ with the terminal joint acuminated; sternum produced into an acute spine, which reaches considerably beyond the insertion of the posterior pair of legs; scutellum large; labrum entire; tarsi of the four posterior legs compressed, and furnished with bifid claws. The male sex has the anterior tarsus dilated.

Hydroüs piceus (*Hydrophilus piceus* of the older authors) is one of the largest beetles of this country, measuring about one inch and a half in length. It is of a glossy black colour and oval form, convex above and flat beneath, and has the elytra somewhat pointed at the apex. This insect is not very uncommon in stagnant waters in certain parts of England. It lives near the bottom of the water, and may be said to walk rather than swim in that element. The female insect deposits her eggs in a little nest composed of a gummy substance, which is ejected from the abdomen, and in this nest the eggs float until they are hatebed. The larvæ, which are of a lengthened form and brownish colonr, live in the water.

Genns *Hydrophilus* (Leach).—Labrum emarginated; mandibles internally ciliated; antennæ with the terminal joint somewhat obtnse and obliqnely truncated; sternum terminating in a slightly acute spine, which scarcely reaches beyond the insertion of the posterior legs; claws dentated at the base; the anterior tarsi simple in both sexes.

Hydrophilus caraboides (Linnæus), a common insect in some parts of England, and like the species which is given as an illustration of the preceding genus, lives in stagnant waters. Its form is oval, convex above, and flattened beneatb; and the elytra are rounded posteriorly. It is of a glossy black colour, sometimes with a bluish or violet hne, and about tbree-quarters of an inch in length.

The genus *Spercheus* (Fabricius) is chicfly distinguished by the antennæ, which apparently are only 6-jointed; the clypeus emarginate; the maxilla with the external lobe palpiform: tibia smooth. The body is very convex.

Spercheus emarginatus (Fabricius) is about a quarter of an inch in length, and of a brownish colour above and blackish beneath. It lives in stagnant waters, and has been found adhering to the roots of plants. As yet this has always been considered a very uncommon insect in England.

Genus *Berosus* (Germar).—Eyes prominent; clypeus entire; apparently 8-jointed, the terminal joint large and somewhat globular; thorax very convex; the elytra broader than the thorax, and also very convex; posterior tarsi ciliated.

Berosus luridus (Stephens) is less than a quarter of an inch in length, of an oval form, and grayish-yellow colour. The head is of a brassy green colour, and there is a spot of the same hue on the thorax. The elytra are striated. This species is common in ponds, &c. in various parts of England.

Genus *Hydrobius* (Leach).—Antennæ 9-jointed, the terminal joint somewhat compressed and acuminated; clypeus entire; scutellum small; sternum simple; eyes small and not prominent; claws simple.

The species of this genus are usually of small size, of an oval or rounded form, and always very convex. Like those of the preceding genera, they live in ponds and ditehes, and appear to prefer stagnant waters. Mr. Stephens, in his 'Illustrations of British Entomology,' enumerates 25 species.

HYDROPHIS. [HYDRIDÆ.]

HYDROPHITE, a Mineral, a variety of Green Serpentine containing vanadium. It occurs amorpbous. Its fracture is irregular. The colour is mountain green. Soft. Specific gravity 2·65. It is found at Taberg in Smaland. Tho following is its analysis:—

Silica	36·195
Oxide of Iron	22·729
Oxide of Manganese	1·66
Magnesia	21·082
Vanadic Acid	0·115
Water	16·080
	——97·861

HYDROPHYLLACEÆ, *Hydrophyls*, a natural order of Exogenous Plants, consisting of small trecs, bushes, or herbaceous plants, often hispid. The leaves are often lobed, alternate, or the lower ones opposite. The flowers arranged in gyrate racemes or unilateral spikes, or occasionally solitary and stalked in the axils of the leaves. Calyx inferior, persistent, deeply 5-cleft, the recesses usually augmented with reflexed appendages. Corolla monopetalous, hypogynous, regular, shortly 5-cleft, between campanulate and rotate, rarely fnnnel-shaped. Stamens 5, epipetalous, alternate with the segments of the corolla, inflected in æstivation; anthers versatile, 2-celled, tho cells parallel, dehiscing longitudinally. Ovary superior, simple, 1- or 2-celled, styles 2, long; stigmas 2, terminal; placentæ 2, free at their back, or nnited to the shell of the ovary, with two or many amphitropal ovules on their inner face. Fruit capsular, 2-valved, sometimes 1-celled, with a large placenta filling the capsule, sometimes somewhat 2-celled, with the dissepiments incomplete. Seeds reticulated; albumen abundant, cartilaginous; embryo conical, with its radicle next the hilum. For many years it has been considered that *Hydroleaceæ* was a distinct order from *Hydrophyllaceæ*, but recent botanists recognise so little distinction between them, that they are now both included in the above definition. Dr. Lindley places

Hydrophyllum virginicum.

1, an entire flower; 2, the ovary; 3, a ripe seed-vessel; 4, a section of a mature seed.

Hydrophyllaceæ near *Primulaceæ*, *Plumbaginaceæ*, and *Boraginaceæ*. Some of the species are cultivated in gardens for the sake of their gay flowers, but none appear to possess useful qualities of any importance. They are mostly found either in tbe north or south provinces of America, and are not known much beyond that continent. *Nama* and *Hydrolea* are found in the East Indies. In the United States a decoction of *Hydrophyllum Canadense* is one of the many remedies for snake bites. *Hydrolea* is bitter, and the leaves are applied as a poultice in India.

Many of tbe species, especially those of the genera *Nemophila* and *Eutoca*, are beautiful objects, and are extensively cultivated in our gardens. There are 16 genera and 75 species.

HYDROPHYLLUM. [HYDROPHYLLACEÆ.]

HYDROPIPER. [ELATINACEÆ.]

HYDROSAURUS. [IGUANIDÆ.]

HYDROSTATICA. [ACALEPHÆ.]

HYDROTALCITE, a Mineral, occurring massive, investing Steatite in foliated masses. The colour is white. Streak the same, with a pearly lustre. Transparent. It is flexible, with a soapy fcel. Hardness 2. It is found at Snarum. The following is its analysis:—

Magnesia	36·30
Alumina	12·00
Peroxide of Iron	6·90
Carbonic Acid	10·54
Water	32.66
Insoluble residue	1·20
	—— 99·60

HYDRUS. [HYDRIDÆ.]

HYLA. [AMPHIBIA.]

HYLACTES, a genus of Birds established by Captain Philip Parker King, R.N., for a form allied to *Megapodius*, with the following characters:—Bill sub-elongated, rather thin, with a sub-emarginate apex; nostrils basal, longitudinal, the membrane subtumescent, and covered with hairs down the middle. Wings very short, rounded; fiftb quill longest. Tail sub-elongated, graduated. Feet strong; tarsi rather elongated, scutellated in front; toes aud claws elongated, the latter rather strong and sub-compressed; hallux very strong, incumbent.

Ex. *Hylactyes Tarnii.* It inhabits the Island of Chiloe and Port Otway, in the Bay of Peñas. ('Zool. Proc.,' 1830-31.)

HYLÆOSAURUS, Dr. Mantell's name for an extinct Saurian discovered by him in the forest of Tilgate, and thence termed the Forest-Lizard. The remains upon which this genus was characterised were embedded in a block of stone 4½ feet by 2½ feet, and consisted principally of bones of the trunk. A chain of five cervical and five dorsal vertebræ with corresponding ribs, and four detached vertebræ, were visible; as were the coracoids and omoplates of both sides. There was a peculiarity in the structure of the last-mentioned parts which, in the opinion of Dr. Mantell, warranted the separation of this Saurian from all recent and fossil genera; for the *Hylæosaurus* had the omoplates of a crocodile with the coracoids of a lizard. There was also a still more extraordinary osteological structure, consisting of a series of spinous bony apophyses, which varied from 3 to 17 inches in length, and from 1¼ to 7 inches in width. These maintained a certain parallelism with the vertebral column, as if they had occupied a line along the back. Dr. Mantell suggested that these processes might be the remains of a dermal fringe or serration, with which, as in some recent species of Saurians, the back of the Forest-Lizard might have been armed; but he at the same time noticed many anatomical peculiarities which led him to hesitate in determining positively that these parts had formed such appendages. He next entered upon a careful examination of the reasons why they could not be processes of the vertebræ. Dr. Mantell also discovered many dermal bones, which served to support the large scales, in the stone: he finally proposed the genus as depending for its characters on the peculiarity of the sternal apparatus and the spinous processes. The paper in which the remains of this large extinct Saurian were described was read before the Geological Society of London in December, 1832.

Dr. Buckland ('Bridgewater Treatise') is of opinion that this extinct Saurian was probably about 25 feet long, and speaks of its most peculiar character as consisting of the remains of the series of long flat and pointed bones, which, Dr. Buckland thinks, seem to have formed an enormous dermal fringe like the horny spines on the back of the modern Iguana. (Dr. Mantell, 'Geology of the South-East of England,' 8vo, London, 1833.)

The remains of several specimens of this extinct reptile are now, with the rest of Dr. Mantell's collection, in the British Museum. The original species described by Dr. Mantell has been named *H. Oweni.* (Mantell, 'Petrifactions and their Teachings.')

HYLO'BATES (from ὑλοβάτης, wood-walker, or one that goes through woods), Illiger's name for the Long-Armed Apes, or Gibbons. The general characters of these Apes as to dentition and form agree with those of the Orangs; but there is some modification of the dental system in the Gibbons, which have also longer anterior extremities and have posterior callosities, though they have no tail. The vermiform appendix of the cœcum is also shorter.

Dental formula:—Incisors, $\frac{4}{4}$; canines, $\frac{2}{2}$; molars, $\frac{10}{10} = 32$.

In the upper jaw the first incisor is large, terminated by a straight line, worn obliquely within, and cut transversely by the impression of the lower incisor; the second is smaller than the first, and worn obliquely on the side of the canine, which is wider than it is thick, trenchant on its posterior border, and presents two longitudinal furrows on its internal surface, separated from each other by a projecting rib,* the posterior furrow being larger and deeper than the anterior one. The two next teeth are false molars, and the second is rather larger than the first; but both are composed of blunt tubercles, one on the external and the other, smaller, on the internal border. The three next molars, which increase gradually in size from the first to the last, have the same form; they are composed of four tubercles, two of equal size on the external and two on the internal border, the posterior tubercle being smaller than that which precedes it: these tubercles are formed by furrows, which divide the tooth unequally.

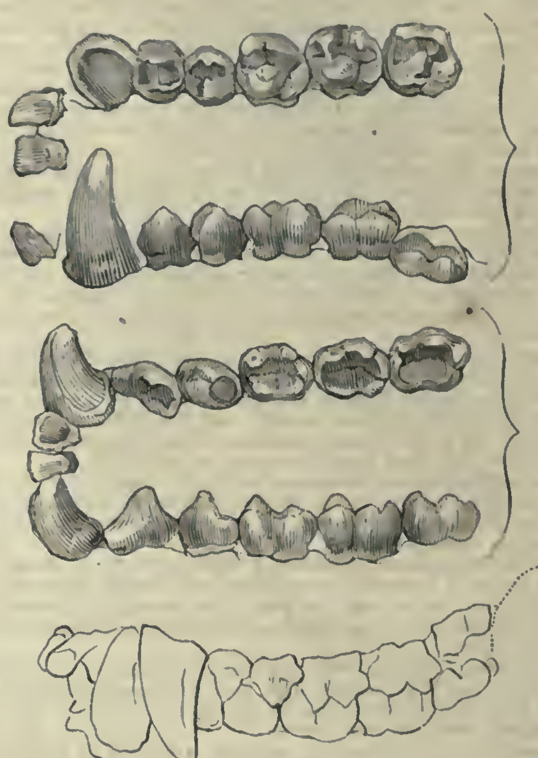
In the lower jaw the first incisor is small, and terminated by a straight line; the second is rounded on its external surface, terminated in a point, and strengthened on its internal surface by a longitudinal rib, which thickens it in the middle. The canine is more equal in its dimensions than that of the other jaw, and is terminated posteriorly by a process or heel; but its internal surface presents also the two furrows and the rib which are found in the other. The first false molar, which is placed obliquely, has only a single point; the second has two, one internal and the other external, situated nearer to the anterior than to the posterior border. Three molars succeed, which progressively increase in size, and resemble each other. They present five tubercles, two of which are anterior, and three, disposed in a triangle, posterior.

F. Cuvier takes this type of dentition from the Siamang, and says that it is also found in the Wow-Wow and Onko.

The height of the Gibbons rarely exceeds four feet, and when they are placed in an erect posture their upper extremities reach the ground.

The species are found all over India and its islands. The forests are the haunts of these creatures, and they are rarely seen at a distance from them. Gregarious, but shy and timid, they keep up a howling concert, resembling in this respect in some degree the Howling Monkeys of America, and having some of them guttural sacs like that tribe. In the forest the activity of certain species is great, and they make way on the trees with their long arms and lengthened feet most rapidly; but when surprised on open plain ground they are altogether as helpless. Other species (the Siamang, for instance) appear to be more sluggish; but these make good use of their acute eyes and ears, and are generally off before the enemy approaches near enough for a capture.

* In *Hylobates Hoolock* the canines are remarkably long.



Teeth of *Hylobates*, increased 1-6th. F. Cuvier.

In confinement they are gentle, and seem capable of great attachment to those who are attentive to them. Dr. Burrough gives a most interesting account of three individuals of the species called Hoolock (*Hylobates Hoolock*), which he had an opportunity of observing in that state. One of them, a male, showed a most amiable and docile disposition; and a young female, which died early, was equally gentle and pacific. The Siamang kept by Sir Stamford Raffles was, according to Dr. Horsfield, very tame and tractable, and was never happy unless it was in the company of some person. Mr. George Bennet gives

Wow-Wow (*Hylobates agilis*), male.

a lively description of the affectionate manners of another of these apes towards those who made its captivity light by their kindness.

H. agilis, the Wow-Wow, or Active Gibbon, may be taken as an example of the genus. It has the forehead very low; orbitary arches very projecting; face blackish-blue in the male, and brown in the female; in the former a white band over the eyes, which unites with the whitish whiskers. Hair of the body fine, except about the neck, where it is longer and inclined to be woolly and curled; upper part chocolate-brown; back and fore part of the thighs yellowish-brown, but the colour varies a good deal according to the sex and age, the young being paler than the adults and aged, and the very young uniform yellowish-white. Height about 2 feet 7 or 8 inches. No guttural sac.

Wow-Wow (*Hylobates agilis*), female and young.

It is very agile in its habits. As soon as they reach the forest they set pursuit at defiance, swinging, leaping, and throwing themselves from tree to tree with great rapidity. Notwithstanding the want of the guttural sac they howl in a manner very nearly resembling the Siamang, which has one.

In captivity they are not very lively, as might be expected, from the impossibility of their exerting that freedom of motion on which their vivacity in a state of nature so much depends; but though timid they are soon re-assured, take pleasure in being caressed, and become familiar and even playful.

This species is found in the forests of Sumatra, where the species is named Ungapnti.

The Siamang of the Malays, *Simia syndactyla* of Sir Stamford Raffles's 'Catalogue of a Zoological Collection made in Sumatra' ('Linn. Trans.,' xiii. 241), *Pithecus syndactylus* of Desmarest, *Hylobates syndactylus* of F. Cuvier, has a peculiar formation of the hands or feet of the lower extremities, the index and middle fingers being united as far as the middle of the second phalanx. This peculiarity would seem to indicate a generic distinction, notwithstanding the similarity of the teeth and skull to those of the rest of this tribe. These Sumatran Apes, sluggish and timid as they are, exhibit strong maternal affection; for though, if any of the troop are wounded, the rest abscond and leave them to their fate, the mother will remain with her little one if it is hurt, and will suffer herself to be captured rather than abandon it. The females are also generally very attentive to their offspring, according to the accounts given by Messrs. Diard and Duvaucel.

The following species are given in the 'British Museum Catalogue':—

Hylobates Hoolock, the Hoolock. It is the Simia Hoolock, Harlan; *H. Seyrites* and *H. Coromandus*, Ogilby; *H. Houloch*, Lesson. Asam (?).

H. agilis, the Oungha; *Pithecus agilis*, Desmarest; *H. variegatus*, Müller; *H. Rafflesii*, Geoffroy; *H. Lar*, F. Cuvier. Black specimens are marked from the Himalaya, and brown from Malacca.

H. Lar, the Gibbon; *Homo Lar*, Linnæus; *Simia longimana*, Schreber; *S. albimana*, Vigors and Horsfield; Le Grand Gibbon of Buffon. It is a native of Malacca.

H. leuciscus, the Silvery Gibbon, or Wow-Wow. *Simia leucisca*, Schreber, Moloch, Audeb. Malacca.

HYLOBIUS. [CURCULIO.]

HYMENÆA (from 'Hymen,' in reference to its twin leaflets), a genus of Plants belonging to the natural order *Leguminosæ*. It has a calyx furnished with two bracts at the base; the tube turbinate, coriaceous; the limb 4-5 parted, deciduous, with two lobes sometimes united into one; 5 petals nearly equal, glandular; 10 stamens, distinct, inflated in the middle; the style filiform; the legume woody, oblong, many-seeded, containing fecula; the embryo straight. The species are trees, with bifoliate leaves, and corymbs of white or yellow flowers.

H. Courbaril, Locust-Tree, or Gum-Anime Tree, has oblong ovate leaflets, unequal-sided, and unequal at the base, ending in a long point; with the legume oblong, compressed, yellowish, shining. It is a fine lofty spreading tree, and grows in the tropical parts of America and in Jamaica. The seeds are enveloped in a cellular mealy substance, which is sweet like honey, and is eaten by the Indians with great avidity. When fresh it is slightly purgative, but by keeping it loses this property. A decoction of this substance, when allowed to ferment, forms an intoxicating drink resembling beer. From between the principal roots of this tree there exudes a fine transparent resin, of a red or yellowish-red colour, and which is collected in large lumps and sold under the name of Gum Anime, or Gum Animi. This resin resembles amber, is very hard, and sometimes contains leaves, insects, or other objects imbedded in it, which remain in a perfect state of preservation. It burns readily, emitting a very fragrant smell. Dissolved in rectified spirits of wine it makes one of the finest kinds of varnish. According to Lindley this resin is called Jataby, Jatchy, or Copal, and, in Minas Geraës, Jatoba. Courbaril is the name of the tree in some parts of South America. In countries where this tree grows the resin is used medicinally, and has also been employed in that way in Europe. It acts as a stimulant when taken internally, and as an irritant when applied externally. In fumigation it has been employed for persons labouring under asthma and dyspnœa. Dissolved in spirits of wine or oil it is used as an embrocation in rheumatism. Internally it has been recommended as a substitute for guaiacum, in venereal disease, and chronic rheumatism. The inner bark, either in the form of tincture or decoction, is administered as a vermifuge. The curadores have a method of mixing it with sugar and rum, so as to make a very agreeable emulsion or syrup. The wild bees are fond of building their nests in the trunk of this tree. The timber of the old trees is very hard and tough, and is in great request for wheelwork, particularly for cogs. The wood is so heavy that a cubic foot is said to weigh a hundred pounds: it takes a fine polish.

Several other species of *Hymenæa* are described, but of these comparatively little is known. The Copal of Madagascar, and probably of the East Indies generally, is furnished by *H. verrucosa*. The Locust-Trees of the West have long been celebrated for their gigantic stature, and other species are the Colossi of South American forests. Some of them are, according to Martius, 84 feet in circumference at the bottom, and 60 feet where the boles become cylindrical.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

HYMENO'CERA, Latreille's name for a genus of Macrurous Crustaceans belonging to the tribe of Alpheans, in the family of the Salicoques, or Shrimps, according to the system of M. Milne-Edwards, who places it between *Atya* and *Alpheus*.

HYMENODICTYON. [CINCHONACEÆ.]

HYMENOMYCE'TES, the first sub-order of the *Fungi*, a natural order of Plants. [FUNGI.] They are characterised by their reproductive organs, called the hymenium, being naked. This sub-order is divided by Fries into four tribes [FUNGI]; by Berkeley into six tribes. Those of the latter are—*Pileati, Clavati, Mitrati, Cupulati, Tremellini*, and *Sclerotiacei*.

The tribe *Pileati* contains the following British genera:—

Agaricus, in which the hymenium consists of plates radiating from a common centre, with shorter ones in the interstices, composed of a double closely-connected membrane, more or less distinct from the pileus: the veil is various or absent. [AGARICUS.]

Cantharellus has the pileus furnished below with dichotomous, radiating, branched, subparallel folds, not separable from the flesh, sometimes anastomosing or obsolete.

Merulius has the hymenium veiny, or sinuoso-plicate; the folds not distinct from the flesh of the pileus, forming unequal angular or flexuous pores. [MERULIUS.]

Schizophyllum has the gills radiating from the base, composed of a folded membrane, which is ruptured along their edge; the two portions of the fold being revolute, bearing asci only on the outer surface.

Dædalea has the hymenium composed of anastomosing gills, or flexuous elongated pores formed out of the corky substance of the pileus.

Polyporus has the hymenium concrete, with the substance of the pileus consisting of subrotund pores with their simple dissepiments.

Boletus has the hymenium distinct from the substance of the pileus, consisting of cylindrical separable tubes, with oblong sporidia. [BOLETUS.]

Fistulina has the hymenium formed of a distinct substance but concrete with the fibres of the pileus; the tubes at first wart-like, somewhat remote, closed, radiate-fimbriate, at length approximated, elongated, open.

Hydnum has the hymenium of the same substance as the pileus, composed of free spine-like processes.

Sistotrema has the hymenium somewhat distinct from the pileus, composed of irregularly-disposed curved and gyrose lamellate teeth.

Irpex has the hymenium concrete with the substance of the pileus, torn into distinct spines, disposed in rows or in a reticulate manner, their bases connected together by lamellate, sinuous, or porous folds; the asci slender, situated only on the toothed processes.

Radulum has the hymenium tuberculated; the tubercles shapeless, resembling papillæ or rude somewhat angular spines, more or less obtuse, distant, distinct or irregularly fasciculate, the inner substance homogeneous with the receptacle; the asci occupying indifferently all parts of the hymenium.

Phlebia has the hymenium homogeneous and concrete, with the pileus smooth, venoso-rugose, wrinkles interrupted, disposed irregularly, straight or flexuous, bearing asci all over.

Thelephora has the hymenium homogeneous and concrete with the pileus, even or papillate, the whole surface bearing asci.

Of these genera *Agaricus* contains by far the greatest number of species. On this account it has been found necessary to class the species under various sub-genera. The following table contains the sub-genera of Fries arranged in seven series:—

Agaricus.—Lamellæ simple, unequal, juiceless, persistent, discrete from the pileus.	*Leucosporus.* Lamellæ unchangeable; veil variable or none; sporidia white.	*Amanita.* *Lepiota.* *Limacium.* *Tricholoma.* *Clitocybe.* *Omphalia.* *Collybia.* *Mycena.* *Omphalia.* *Pleurotus.*
	Hyporhodius. Lamellæ changeable in hue; veil none; sporidia rose-coloured.	*Clitopilus.* *Eccilia.* *Leptonia.* *Nolanea.*
	Inocybe. Lamellæ changeable; veil springing longitudinally from the innate fibres of the pileus; sporidia tawny brown.	*Inocybe.*
	Derminus. Lamellæ discoloured; veil floccose; sporidia subferruginous.	*Pholiota.* *Hebeloma.* *Flammula.* *Naucoria.* *Galera.* *Tapinia.* *Crepidotus.*
	Phæotus. Lamellæ changeable, nebulous; veil various; sporidia dark brown.	*Pratellarius.*
	Pratellus. Lamellæ changeable, lax, nebulous; veil floccose; sporidia brownish purple.	*Volvaria.* *Psalliota.* *Gomphus.* *Hypholoma.* *Psilocybe.* *Psathyra.*
	Coprinarius. Veil partial; lamellæ lax; nebulous; sporidia black.	*Coprinarius.*

Most of the species included under the series *Leucosporus* are eatable, and contain those species which are mentioned as edible in the article AGARICUS. It also contains the various species of *Amanita*, which are among the largest and most remarkable forms of the fungi. *A. Cæsarea* is remarkable for its beauty, but not so much so as for the traditional belief that it was in a dish of these mushrooms, which were regarded by the Romans as one of the greatest luxuries of the table, that Agrippina administered poison to her husband Claudius Cæsar, in order to hasten her son's accession to the imperial power. *A. muscaria* possesses an intoxicating or narcotic property. It is used by the inhabitants of the north-eastern parts of Asia in the same manner as wine, brandy, arrack, spruce, &c. are by other nations. One large or two small fungi is a common dose to produce a pleasing intoxication for the whole of the day. [FUNGI.]

Upwards of 700 species of the genus *Agaricus* have been described; of these 333 are natives of the British Islands.

Eight species of the genus *Cantharellus* inhabit Great Britain. The *C. aurantiacus* is said to be a poisonous plant. It is common in fir-woods and pastures. It has a beautiful orange colour and a strong smell. *C. cibarius*, the Common Chanterelle, is common in woods in the summer and autumn. The pileus is of a pale yellow colour, and the whole plant has an agreeable smell like that of apricots. On the continent of Europe this fungus is eaten, but is not often used in Great Britain. It is however dangerous when eaten raw, and should always be cooked. They form a delicious ingredient in rich gravies.

One of the species of *Merulius* has been supposed to be the cause of dry-rot. [DRY-ROT; MERULIUS.] Berkeley describes five species of this genus as natives of Great Britain.

Of *Schizophyllum* but one species has been found in Great Britain, the *S. commune*. It is a very beautiful fungus, and has been found in almost every part of the world.

The genus *Dædalea* has been so named from the remarkable sinuosities and sculpture-like pores of its hymenium. *D. quercina* is found commonly on oak-trees or stumps and roots of that wood. It is an astringent, and has been applied to wounds to arrest hæmorrhage. It is commonly called "the lungs of the oak," and was formerly on this account used as a remedy in phthisis. It is at the present day sold in Covent Garden market for that purpose. There are several other species of this genus which are indigenous in Great Britain. *D. suaveolens* is a northern plant. It yields an agreeable perfume.

Upwards of forty species of the genus *Polyporus* are found in Great Britain, and many more European species have been described. Many of the species are used in arts and medicine. *P. igniarius* has long been famed as a styptic. Amadou, or German Tinder, is made from this plant by separating the porous hymenium from the harder parts, and steeping it in a solution of nitre after it has been beaten into a soft spongy state. Many other species of *Polyporus* may be used for the same purpose. The Laplanders also use them for applying the actual cautery in the same way as the Japanese and Chinese use the moxa. When they suffer from pain in the limbs, they pull the fungus in pieces, and placing it on the skin, set fire to it and allow it to burn away till it blisters the skin, when it acts as a counter-irritant. *P. officinalis* is a cathartic. *P. sauveolens* has a pleasant smell. Some of the species secrete acids, and boletic, fungic, and oxalic acids have been obtained from them. *P. squamosus* is one of the largest of British fungi, weighing sometimes as much as 30 lbs. *P. destructor* is one of the fungi found on decaying timber when it is attacked with what is called dry-rot.

Many of the plants formerly included under the genus *Boletus* are now referred to *Polyporus*. Berkeley enumerates sixteen species of the genus *Boletus* as natives of Great Britain. [BOLETUS.]

The genus *Hydnum*, although named after ὕδνον, the truffle, includes a different series of plants. The hymenium is formed of spinous bodies which give to the species of this genus a very formidable appearance. Hence they are called in the country spine-stools, prickle-stools, &c. Several species are natives of Great Britain. Some are eatable, but caution should be used in their selection. De Candolle says that those which have a dark colour are dangerous.

The genus *Fistulina* has one representative in Great Britain, *F. hepatica*, the Pipe-Stool. It grows upon the trunks of old oaks and other trees. It is eaten in France. When cut into it is beautifully marbled with red and white streaks resembling a fine piece of beef. It is called in France Foie de Bœuf, Langue de Bœuf, Glue de Chêne, &c. It has an acid taste, but is rather tough. It has been known sometimes to attain the weight of 30 lbs.

The genera *Sistotrema*, *Irpex*, *Radulum*, and *Phlebia* are small genera, and not used as food, or in any other way. *Thelephora* is an extensive genus, and forty-two species are indigenous in Great Britain. They are common on decaying branches of trees, &c., and exhibit a variety of colours.

The tribe *Clavati*, which are distinguished by a single or branched vertical receptacle, embrace the following British genera:—*Clavaria*, *Calocera*, *Geoglossum*, *Spathularia*, *Mitrula*, *Typhula*, and *Pistillaria*. These plants, in their branched and club-shaped forms, resemble the corals, and were actually placed by the older naturalists in the same class. Some of the species of the *Clavati* are edible. All the *Clavaria* are esteemed as food. *C. rugosa* has an agreeable flavour like that of the common mushroom. *C. flava* and *C. pyxidata* are prized on account of their taste. *C. cinerea* is the species most commonly eaten on the Continent.

The *Mitrati* have a bullate, filiform, margined receptacle. They embrace five British genera:—*Morchella*, *Helvella*, *Veapa*, *Leotia*, and *Vibrissea*.

The genus *Morchella* yields the esculent fungus morel. [MOREL.] Three species are found in Great Britain. There are also three British species of *Helvella* as that genus is at present defined. The species of *Helvella* are edible. *H. crispa* is considered the best species for eating, but none of the species, foreign or British, are poisonous.

The tribe *Cupulati*, which has a patelliform margined receptacle with a superior hymenium, contains the following British genera:—*Peziza*, *Patellaria*, *Ascobolus*, *Bulgaria*, *Ditiola*, *Tympanis*, *Cenangium*, *Stictis*, *Cryptomyces*, *Cyphelia*. Of these *Peziza* is the most extensive genus, containing upwards of 300 species, of which 106 are natives of Great Britain. Some of these plants are very remarkable from the regular cup-like form and the deep colours they present. *P. coccinea* is perhaps the most elegant plant belonging to the natural order of *Fungi*. The outer surface of the cup which it forms is white and downy, whilst the inside is of the richest carmine. It frequently grows on sticks covered with moss, the green colour of which forms a beautiful contrast with the white and crimson of the *Peziza*. *P. æruginosa* has a deep green colour, and possesses the property of staining wood on which it grows of the same colour as itself. The *Pezizæ* are not generally eaten, but none of them are poisonous.

The fifth and sixth tribes of the *Hymenomycetes* are the *Tremellini* and *Sclerotiacei*. The *Tremellini* embrace six British genera. [TREMELLINI.] The British genera included under *Sclerotiacei* are *Pyrenium*, *Acrospermum*, *Sclerotina*, *Periola*, and *Spermoedia*. These are among the lowest forms of the Hymenomycetous *Fungi*, and include species which are found attacking the various *Cerealia*, producing the disease called ergot. [ERGOT; SPERMOEDIA.] An account of the remaining forms of the *Fungi* is given under GASTEROMYCETES.

(Burnett, *Outlines of Botany;* Berkeley, *English Flora,* vol. v.; Fries, *Systema Mycologicum.*)

HYMENOPHYLLEÆ, a family of Ferns including the British genera *Hymenophyllum* and *Trichomanes.* The fronds consist of branched veins, each accompanied throughout by a membranous wing or margin; a cluster of capsules, nearly spherical, is seated on one of these veins which projects beyond the edge of the leaf, the cluster being inclosed in a kind of cup-like involucre.

I. *Trichomanes* has thecæ on an elongated filiform receptacle within a cup-shaped involucre of the same texture with the frond.

T. radicans, Babington, the Bristle-Fern (*T. speciosum,* Wildenow), has fronds three or four times pinnatifid, glabrous; segments uniform, linear; involucres solitary, in the axils of the upper segments; setæ at first included, ultimately very prominent. The frond in fact consists of hard wiry branched ribs, each furnished throughout with a rather membranous wing. Rhizome black, downy, very long. Fronds rather triangular, very much divided, from 4 to 8 inches long. Involucres scarcely winged.

This is a very interesting fern, on account of its beauty, its rarity, its susceptibility to injury from exposure when in cultivation, and its entire absence from all European countries or islands, with the single exception of Ireland. In texture as well as in scent it resembles some of the marine *Algæ,* and it has been observed to assume a life-like appearance on being immersed in water after being kept perfectly dry for years. At the present time this plant is to be found nowhere but in Ireland, though formerly it is said to have grown at Bell Bank, in Yorkshire. It has been lately supposed by some botanists that there are two Irish species of *Trichomanes,* the Killarney and the Glouin Caragh plants. Mr. Newman however believes the latter to be merely a variety of *T. speciosum,* and calls it *T. s. Andrewsii.* It differs from the former in having lanceolate fronds and winged involucres. It is found in very damp shady places. No other fern will thrive well in a case with the *Trichomanes,* the treatment required for one being destructive to the other. The *Trichomanes* will live or even grow lazily in a glass with other ferns, but will never attain a vigorous state of growth.

II. *Hymenophyllum* has the thecæ on a narrow subclavate receptacle within a 2-valved involucre of the same texture with the frond.

H. Tunbridgense, the Tunbridge Filmy Fern, has pinnate fronds, pinnæ distichous; segments linear, undivided, or bifid, spinosely serrate; involucre compressed, spinosely serrate; rachis broadly winged. It is slender and delicate, the rhizome very long and thread-shaped. Pinnæ, rachis, aud involucres in the same place. Valves of the involucre adpressed throughout the greater part of their length, slightly gibbous at the base. It is found amongst moss and in shady places, on the surface of rocks and stones, in many places in England, Wales, and Ireland. This plant is the *Trichomanes Tunbridgense* of Linnæus, Hudson, and many of our earlier authors.

H. Wilsoni, Wilson's Filmy Fern, has pinnate fronds, pinnæ recurved; segments linear, undivided, or bifid, spinosely serrate; involucre inflated, entire, rachis slightly bordered. It resembles the preceding species, but the pinnæ curve backward and the involucres forward. The valves of the involucre are convex or gibbous throughout, touching only by their edges, which are quite entire. The range of this species seems to be much more extensive than that of *H. Tunbridgense;* it also appears to be a more northern species, and generally to prefer a greater elevation; still the two plants are often intermixed, particularly about the waterfalls in the vicinity of Killarney, and it is frequently very difficult to distinguish the one from the other. (Newman, *British Ferns.*)

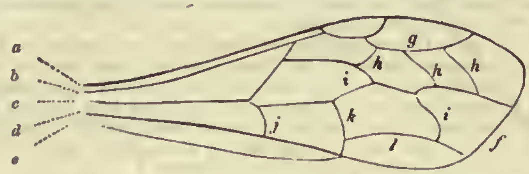
HYMENO'PTERA, one of the orders into which Insects are divided. Hymenopterous Insects possess four membranous wings, of which the anterior pair are the larger; they have all the usual parts of the mouth well-developed, that is to say, they possess labrum, labium, mandibles, maxillæ, and two pairs of palpi; besides the ordinary compound eyes, they are furnished with three ocelli, or simple eyes, which are usually situated on the vertex of the head. Their tarsi are 5-jointed. The females are provided with an ovipositor, consisting chiefly of three elongated slender processes, of which two serve as a sheath to the third. This ovipositor, in many species, is so organised that it can not only perform its ordinary function, but serve as a weapon of defence, and is the part which in bees and wasps is called the sting: in these insects it is barbed at the apex. The antennæ are generally filiform or setaceous. The mesothorax and metathorax are well-developed; the prothorax is narrow.

Insects of the order *Hymenoptera* undergo what is termed complete metamorphosis, that is, the larva is unlike the perfect insect, and the pupa does not possess the power of locomotion. The larvæ of some of these insects very much resemble those of the order *Lepidoptera* (Butterflies and Moths), but differ in the number of their legs, &c.: these feed upon plants. [SECURIFERA.] The larvæ however generally speaking are destitute of legs, and do not possess a distinct head; and these are for the most part fed by the parent insect, or, as in the case of bees and wasps, by the neuters. In the pupæ, all the parts of the perfect insect are visible, since they are inclosed only in a delicate semi-transparent membrane.

In the imago or perfect state most Hymenopterous Insects live upon flowers, or at least often frequent them, some for the purpose of gathering honey, and others find them a convenient resort wherein they may prey upon the less powerful species of their own class.

The comparatively simple neuration of the wings will serve to distinguish insects of the present order from those of the order *Neuroptera,* where the wing is divided by minute nervures into an infinite number of little cells resembling network; whereas, in the species of the order *Hymenoptera,* the basal portion of the wings is furnished with longitudinal nervures only, and the apical portion is divided into comparatively few cells, and these nervures and cells are so uniform in species nearly related to each other by affinity, that the absence of some, or even a slight difference in their form, has afforded good characters for the definition of groups. It is to Jurine that we are indebted for this discovery and a very successful application of it. We may remark that the modifications of the marginal and cubital cells and their nervures are those which have been chiefly employed by this author in characterising the various groups. The following figures from Mr. Schuckard's work on 'Fossorial Hymenoptera,' represent one of the anterior wings of a Hymenopterous Insect, in which all the nervures and cells are present.

1, stigma; 2, radial or marginal cell; 3, first cubital cell; 4, second cubital cell; 5, third cubital cell; 6, fourth cubital cell; 7, first discoidal cell; 8, second discoidal cell; 9, third discoidal cell; 10, first apical cell; 11, second apical cell; 12, costal cell; 13, externo-medial cell; 14, interno-medial cell; 15, anal cell.



a, costal nervure; *b,* post-costal nervure; *c,* externo-medial nervure; *d,* anal; *e,* posterior margin; *f,* apical; *g,* radial; *h, h, h,* transverso-cubital; *i, i,* recurrent; *j,* transverso-medial; *k,* discoidal; *l,* subdiscoidal.

The order *Hymenoptera* is divided by Latreille into two great sections, to which he applies the name of *Terebrantia* and *Aculeata.* In the species belonging to the first of these sections the female sex possesses a distinct ovipositor, whereas in the second the ovipositor is replaced by a sting. Many of the ants however form an exception, since they do not possess a sting, and defend themselves by ejecting an acid liquid. In the *Aculeata* the antennæ are always simple, and composed of 13 joints in the males and 12 joints in the females. The palpi are generally filiform; the maxillary, often the larger, have 6 joints, and the labial are 4-jointed. The abdomen is composed of 7 joints in the males, and 6 joints in the females. These two great sections, of which the principal characters have just been given, are again subdivided, the *Terebrantia* into two sub-sections, and the *Aculeata* into four.

The first sub-section of the *Terebrantia,* to which Latreille applies the name of *Securifera,* is thus characterised by that author:—Abdomen sessile, that is, it is closely joined to the thorax, of which it appears to form a continuation, and does not possess free motion. The females are provided with an ovipositor, which is most commonly serrated, and not only used to deposit their eggs, but to prepare a place for their reception. The larvæ have always six horny legs, and often others which are fleshy. This sub-section contains two families, the *Tenthredinidæ* and *Urocerata.*

The second sub-section, or the *Pupivora* [PUPIVORA], have the abdomen attached to the thorax by a slender stalk, which is often very long, and admits of free motion. The larvæ are always destitute of feet, and for the most part parasitical and carnivorous. This group is divided into six families: *Evaniales, Ichneumonides* [ICHNEUMON], *Gallicolæ* [GALLICOLÆ], *Chalcidites, Oxyuri,* and *Chrysides* [CHRYSIDIDÆ].

We now come to the sub-divisions of the second great section, the *Aculeata.* These are four in number, the *Heterogyna, Fossores, Diploptera,* and *Anthophiia.*

In the *Heterogyna* the species are many of them composed of three kinds of individuals (as in the Hive-Bee), males, females, and neuters. They have the antennæ geniculated, and the ligula is small. Some live in society, and these possess the three kinds of individuals, of which the males and females are provided with wings, aud the neuters are apterous. The Ants (*Formica,* Linn.) belong to this section.

[ANT; FORMICIDÆ.] The remaining *Heterogyna* are solitary, and there are but two kinds of individuals; the males are winged and the females apterous. The antennæ are either filiform or setaceous. This section is composed chiefly of the Linnæan genus *Mutilla*.

The *Fossores* comprise those species, possessing a sting, of which all the individuals are furnished with wings; they do not live in society, and consequently there are but males and females; the legs are formed for running, and in very many for burrowing, and hence the name which has been applied to them. The tongue is always more or less widened at the extremity, and not slender and elongated. They are divided into eight families:—1. *Scoliadæ* [SCOLIADÆ]. 2. *Sapygidæ* [SAPYGIDÆ]. 3. *Pompilidæ* [POMPILIDÆ]. 4. *Sphecidæ* [SPHECIDÆ]. 5. *Bembicidæ* [BEMBEX], containing those species in which the prothorax is transverse and narrow, elongated laterally, and extending to the base of the anterior wings; legs moderate or short; head, when viewed from above, broader than long, the eyes extending to the posterior margin; abdomen conical; labrum distinct. Of this family three genera are characterised by Latreille: — *Bembex*, *Monedula*, and *Stizus*. 6. *Larridæ* [LARRIDÆ]. 7. *Nyssonidæ* [NYSSONIDÆ]. 8. *Crabronidæ* [CRABRONIDÆ]. In the insects of this last family the head is generally very large, nearly square when viewed from above; the antennæ are often thick near or at the apex, and the abdomen is oval. It contains the following genera:—*Trypoxylon*, *Gorytes*, *Crabro*, *Stigmus*, *Celia*, *Diodontus*, *Ceratophorus*, *Passalœcus*, *Pemphredon*, *Cemonus*, *Mellinus*, *Alysson*, *Psen*, *Arpactus*, *Mimesa*, *Cerceris*, and *Philanthus*.

The *Diploptera* contains those species which have the superior wings folded longitudinally when at rest. The antennæ are usually geniculated in this group, and thickened at the extremity. The eyes are emarginated, and the prothorax is prolonged posteriorly on each side to the origin of the wings. The anterior wings possess two or three closed cubital cells, of which the second receives two recurrent nervures. The body is smooth, or nearly so, and almost always varied with black and yellow colours. Many of the species live in society, and have three kinds of individuals.

Latreille divides this tribe into two families, the *Masarides* and the *Vesparia*. The Wasp and Hornet are familiar examples of the section *Diploptera*. [VESPIDÆ.]

The last tribe, the *Anthophila*, or the Bees, are distinguished by the greatly elongated maxillæ and labium, which form the proboscis used in collecting honey. They have the two posterior legs generally formed for collecting and conveying pollen. The first joint of the tarsi of these legs is very large and much compressed. The larvæ live upon honey and pollen collected by the parent insect. The perfect insect feeds upon honey. [BEE; MELISSA.]

HYMENOSO'MA, Dr. Leach's name for a genus of Brachyurous Crustaceans. [PINNOTHERIANS.]

HYODON, a genus of Fishes belonging to the family *Clupeidæ*. The species resemble the Herring. They are found in the fresh waters of North America.

HYOSCY'AMUS, a genus of Plants belonging to the natural order *Solanaceæ*, among which it is distinguished by having an irregular corolla slit on one side, a 5-toothed permanent calyx, and a capsule opening by a transverse lid.

H. niger, Henbane, is a biennial, hairy, clammy, branched, fetid plant, from one to two feet high, growing in waste and uncultivated places. It has oblong stem-clasping coarsely-lacerated leaves, dull yellow flowers traversed with livid purple veins, and a large spiny calyx. When in fruit, the whole of the upper part of the plant is occupied by the large spreading spiny calyxes arranged in 1-sided leafy spikes. It is wild in England in calcareous soils. The leaves and seeds are officinal. The leaves should be collected when the plant is flowering. The lower leaves are large and have short petioles; the upper are smaller and sessile: they are more or less deeply sinuate, pinnatifid, or toothed, soft to the touch, hairy, slightly viscid, and of a grayish-green colour. Odour disagreeable, stupifying; taste herbaceous, nauseous, somewhat acrid. Both odour and taste are much diminished by drying, which should be quickly performed, and the leaves preserved in well-closed vessels, in a cool dry place; 100 parts of fresh leaves dry into 14, and 10 lbs. of fresh herb yield by careful management 9 ounces of inspissated juice, or extract, which is extremely apt to spoil and lose all its virtues; yet with proper attention it may be so prepared as to keep for several years with its qualities unimpaired. An insect, *Cimex Hyoscyamia* (Linn.) is apt to attack the leaves, and render them useless. The virtues are dependent on the presence of *Hyoscyamia*, which however is more easily obtained from the seeds. The seeds are small, flattened, kidney-shaped, with minute dots and indentations on the surface; of a yellowish-gray colour. When bruised they evolve an odour of henbane. Taste oily, bitter. By expression they yield a fat oil, and also furnish a very powerful extract, as well as *Hyoscyamia*. This alkaloid crystallises in stellated acicular crystals, with a silky lustre; but it more generally occurs in a colourless transparent soft viscid mass. When properly dried it is devoid of odour, but when moist, and particularly in an impure and coloured condition, the odour is highly disagreeable, stupifying, and tobacco-like. Its action, even in very small quantity, is extremely narcotic and fatal, like nicotine. It kills more slowly than conia, and scarcely causes convulsions. Applied externally to the eye, even in very minute quantity, it causes great and enduring dilatation of the pupil. Cats to which it has been given have been observed to gnash the teeth and foam at the mouth.

Hyoscyamus, when taken by a person in health, produces disorder of the nervous system, inducing symptoms greatly resembling hysteria, if the dose be moderate; but if large, it causes all the phenomena of narcotic poisoning, such as result from other solanaceous plants, particularly congestion of the vessels of the brain with coma. Administered in medicinal doses to persons with disturbance of the nervous system, it lessens the irritability, quiets the circulation, and when morbid wakefulness exists, disposes to sleep. It possesses a superiority over opium in many instances, as it does not constipate the bowels, but rather acts as a mild laxative. This circumstance often renders it a valuable agent in allaying pains and other distressing symptoms incident to females in particular states of their system. Tincture or a well prepared extract is a good form of exhibition; but probably some of the salts of *Hyoscyamia* will be found the most eligible mode of administration, or a tincture of the seeds may be used.

In case of accidental poisoning, the stomach-pump should be used, or an emetic of sulphate of zinc be given; if the brain should appear much oppressed, venesection may also be resorted to.

In some parts of the Greek continent the stalks of *H. albus* are used against the toothache. They are dried and employed instead of tobacco for smoking.

HYPANTHO'CRINUS, a genus of fossil *Crinoidea*, from the Silurian Strata.

HYPERICA'CEÆ, *Tutsans*, a natural order of Polypetalous Exogenous Plants, with an imbricated calyx, polyadelphous stamens, and a many-celled many-seeded ovary, with several styles, which are usually quite distinct. The leaves are often marked with pellucid dots, and there is in many species, in addition, a number of black dots which occupy some part, usually the margin, of both leaves and flowers. In all cases the latter belong exclusively to the xanthic series of colour.

The species inhabit various parts of the world, both within and without the tropics; they are especially common in the southern States of the North American Union. They are found on mountains and in valleys, marshes and dry places, meadows, and heaths. Many are objects of ornament, but they are little cultivated because they have frequently a disagreeable hircine odour. They are generally astringent, and in some cases, as in the genus *Vismia*, yield a substance so much resembling gamboge as to have acquired in commerce the name of American Gamboge.

In the United States a stomachic is prepared from *Elodea virginea*. *Cratoxylon Hornschuchia* is slightly astringent and diuretic. The position of the order is between *Clusiaceæ* and *Reaumuriaceæ*. It is also allied to *Saxifragaceæ*. There are 13 genera and 276 species.

HYPE'RICUM, a genus of Plants belonging to the natural order *Hypericaceæ*. The calyx is 5-parted, or it has 5 sepals; 5 petals; 3 styles, and a 3-celled capsule. The flowers of the species are mostly yellow. There are 13 British species of this genus, and 172 are enumerated by Don as growing in various parts of the world. St. John's Wort is the common name of all the species.

H. maculatum has an erect quadrangular stem, elliptical ovate obtuse leaves with a few pellucid dots, reflexed ovate lanceolate sepals having pellucid streaks, obtuse petals with purple streaks and dots beneath. It is the *H. quadrangulum* of Fries; and is found in moist places by ditches and rivers.

H. perforatum has an erect 2-edged stem, ovate or elliptical leaves with numerous pellucid dots, anthers with black dots, the styles as long as the capsule. It is found in large quantities in Britain and throughout Europe; also in the north of Asia and Africa. The flowers are of a bright-yellow colour, dotted and streaked with purple; when rubbed they emit a powerful lemon-like scent, and stain the fingers with dark purple. The whole of the plant contains a powerful volatile oil, which is aromatic and possibly astringent, though as yet it has been but little used in medicine. Its sensible qualities however, and the few instances in which it has proved beneficial, entitle its virtues to a further trial. When boiled with alum this plant yields a yellow dye, which is used for colouring wool. The common people of Germany and France gather this species of St. John's Wort with great ceremony on St. John's day, and hang it in the windows and about their houses as a charm against evil spirits, storms, thunder, and all other calamities, mistaking the meaning of some medical writers who fancifully called the plant *Fuga Dæmonum*, from a notion that it was a remedy in maniacal disorders. At one time the people of Scotland used to carry it about their persons as a protection against witchcraft and enchantment, and they fancy it prevents ropy milk by milking upon the fresh herb. Cows and goats will eat the plant, but horses and sheep refuse it. It is the Ἄσκυρον of Dioscorides (iii. 162). It is found at the present day on the high hills of Attica.

H. laxiusculum has a smooth herbaceous stem, rather distant obtuse leaves full of pellucid dots; the lower leaves narrow and lanceolate, segments of the calyx equal, nearly linear and acute. It is a native of Brazil, in the provinces of St. Paul and Minas Geraës, where a decoction of the leaves is used as a remedy against the bites of serpents.

H. crispum has a round branched stem, sessile lanceolate leaves, sinuately waved at the base, full of dots, small blunt sepals. It is native in the regions of the Mediterranean, and is the 'Υπέρικον of Hippocrates ('Morb. Mul.' i. 610); also of Dioscorides (iii. 161), and the Hypericon "quod alii chamaepityn, alii corion appellant" of Pliny (xxvi. 8; xxvii. 4, 5). At the present day it grows near the sea in Attica.

H. perfoliatum, the 'Ανδρόσαιμον of Dioscorides (iii. 163). It has a 2-edged stem; ovate clasping dotted leaves; fringed and dotted sepals and petals, and sessile flowers. It is a native of Italy.

H. Coris has a shrubby erect round stem, linear leaves in whorls, with revolute margins, and a bluntish linear calyx. It is the Κόρις of Dioscorides (iii. 174), and the Coris of Pliny (xxvi. 3). This species is a pretty little shrub, native of the Levant, and in dry places in the south of Europe.

H. organifolium is distinguished by its ascending downy stem, ovate blunt and pubescent leaves full of pellucid dots, numerous stamens, and many black dots in the corolla. It is a native of the East, about Constantinople, Thrace, and Armenia, and is frequently found on high mountains in company with *H. perfoliatum*. It is probably the 'Αγήρατον of Dioscorides (iv. 5), and undoubtedly the Ageratum of Pliny (xxvii. 4).

H. Olympicum has elliptical lanceolate leaves full of pellucid dots; a round stem, and withering corolla and stamens. It is a native of Mount Olympus and of China. Fraas thinks it probable that this is the Πολεμώνιον of Dioscorides (iv. 8).

Most of the species of *Hypericum* are showy, and deserve cultivation. The hardy herbaceous kinds will thrive in any common garden soil, and are easily propagated by dividing the roots or by seeds. Those that require the greenhouse or frame will thrive best in a mixture of loam and peat, and strike root readily in sand under a bell-glass.

(Don, *Dichlamydeous Plants*; Babington, *Manual Brit. Bot.*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

HYPEROODON. [CETACEA.]

HYPERSTHENE. [AUGITE.]

HYPERSTHENE ROCK. This is among the rarer varieties of those igneous aggregates which by many geologists are grouped together under the title of Trap. Dr. M'Culloch, who first noticed Hypersthene Rocks in Skye and Ardnamurchan, describes three varieties:—

Hypersthene with Compact Felspar.
Hypersthene with Common Felspar.
Hypersthene with Glassy Felspar.

In largeness of grain it varies from large-grained granite to ordinary greenstone, or is even as fine as basalt; the Felspar is of various colours. It passes to common greenstone.

In Skye it forms the Cuchullin Mountains; part of the mountain of Carrock Fell in Cumberland is also formed of it; a dyke of Hypersthenic Trap was noticed in Radnorshire; it occurs also in Cornwall. In the Valteline M. Necker has pointed out the passage from Hypersthenic Sienite to Granite.

HYPHÆNE. [PALMACEÆ.]

HYPNEA, a genus of Plants belonging to the natural order *Ceramiaceæ*, or Rose Tangles. In the Greek Archipelago medicinal qualities as a vermifuge are attributed to *H. musciformis*.

Several species furnish Iodine, which gives them their peculiar odour.

HYPNUM. [MUSCALES.]

HYPO'CHŒRIS, a genus of Plants belonging to the natural order *Compositæ*, to the sub-order *Cichoraceæ*, and to the section *Hypochœrideæ*, which has a scaly receptacle and a feathery pappus. The heads are many-flowered, the involucre is oblong and imbricated, the fruit glabrous, muricated, and beaked; the pappus in two rows, the outer short and setaceous, the inner long and feathery. There are two British species of this genus—*H. glabra*, with oblong dentate-sinuate leaves, and *H. radicata*, with runcinate obtuse leaves. They are found on dry and gravelly places and waste places. (Babington, *Manual of British Botany*.)

HY'POGENE, a term in Geology, implying 'nether-formed' (from ὑπὸ, below, and γεν, the root of γίγνομαι, which signifies 'birth,' or 'formation'), proposed by Sir Charles Lyell as a substitute for the word Primary. He affirms that "the popular nomenclature of geology, in reference to the rocks called Primary is not only imperfect, but in a great degree founded on a false theory; inasmuch as some granites and granitic schists are of origin posterior to many Secondary rocks. In other words, some primary formations can already be shown to be newer than many secondary groups—a manifest contradiction in terms."

As far as Granite is concerned, this remark is entirely true: its origin is proved to be independent of any particular epoch, and it has been long thrown out of the modern catalogue of primary rocks. As applied to granite, Mr. Lyell's emendation is exactly equivalent to the term Plutonic used in Brongniart's classification; but when the term Hypogene is used to include the primary stratified rocks, a particular hypothesis of their origin is tacitly assumed, which many geologists think not sufficiently established.

It is assumed in this hypothesis that the primary strata have acquired their present mineral aspect, not through any circumstances peculiar to their original formation, and supposed to be characteristic of the physical agencies exerted in the earlier eras of the world, but through the subsequent agency of heat and chemical forces in those regions, and under those circumstances where the Plutonic rocks are generated. The term Primary implies only that the rocks so named are the earliest we can trace in the crust of our planet; and as geological classification is mainly founded on succession of time, and the relative antiquity of strata can be determined as a fact, it seems unlikely that the well-known designations of Primary, Secondary, and Tertiary Strata will be abandoned, though, as expressing the subterranean origin of certain properties and conditions of mineral masses, the word Hypogene appears very suitable.

(Lyell, *Principles of Geology*.)

HYPOPITYS. [MONOTROPA.]

HYPOXIDACEÆ, *Hypoxids*, a natural order of Endogenous Herbaceous Plants, with a tuberous or fibrous perennial root. Leaves always growing from the root and crown, nowhere else, linear entire, plaited, of a dry texture. Scapes simple or branched, occasionally very short. Flowers complete, hermaphrodite. Perianth petaloid, adherent to the ovary, 6-parted, with the sepals coarser than the petals. Stamens 6, inserted into the base of the segments of the perianth; filaments distinct; anthers turned inwards, 2-celled, erect, opening lengthwise. The number of the plants of this order is very inconsiderable. Those that are known inhabit the Cape of Good Hope, Australia, the East Indies, the tropics of America, and the warmer parts of the United States.

The roots of *Curculigo orchioides* are somewhat bitter and aromatic, and are employed medicinally in India. The tubes of *C. stans* are eaten in the Marianne Islands; those of *Hypoxis erecta* are employed by the aborigines of North America in healing ulcers and against intermittents.

(Lindley, *Vegetable Kingdom*.)

HYPSIPETES. [LANIADÆ.]

HYPSIPRYMNUS. [KANGAROO.]

HYPUDÆUS, the more correct mode of writing *Hipudæus*; but the latter form is generally used by the French zoologists.

HYRAX, a genus of *Mammalia* of small size, but of great interest, in consequence of the peculiarity of their organisation, which has led modern zoologists to assign them a place among the *Pachydermata*, though their external appearance, when cursorily examined, would seem to point out their relationship to the *Rodentia*, among which they have been erroneously classed.

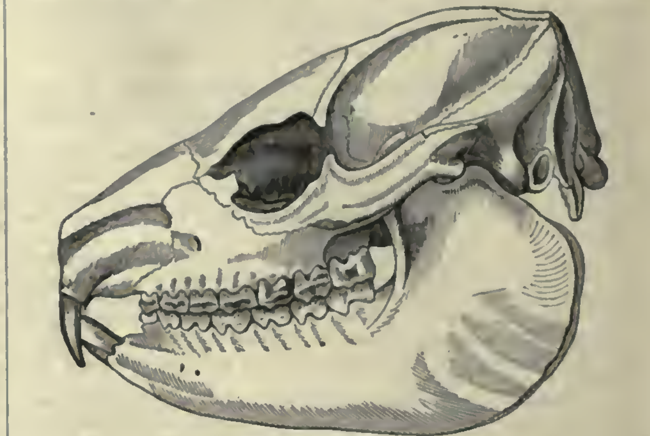
Dental Formula.—Incisors, $\frac{2}{4}$; canines, 0; molars, $\frac{7-7}{7-7} = 34$.

Teeth of *Hyrax*. F. Cuvier.

Cuvier observes that there is no species of *Mammalia* which proves more completely than *Hyrax* the necessity of having recourse to anatomy for the determination of the true relations of animals. To that great zoologist we are indebted for the fact that the quadruped under consideration is a true Pachyderm, and, notwithstanding the smallness of its proportions, must be regarded as intermediate between the Rhinoceros and the Tapir. The resemblances which the *Hyrax* bears to the former of these may be traced, according to Cuvier, as far as the osseous structure is concerned, in the general form of the trunk, in the first place. The *Hyrax* has 21 ribs on each side, a number superior to that possessed by any other quadruped, the Unau excepted, which has 23; and those which, after *Hyrax*, have the the most, belong precisely to the order of Pachyderms, in which Cuvier would arrange it. Thus the Elephant and the Tapir have each 20; the Rhinoceros has 19; the Solipeds have 18. The greater part of the Rodents, on the contrary, have only 12 or 13; and the Beaver, which has the most, has only 15. As regards the lumbar vertebræ, the resemblance begins to be more distant, for the Rhinoceros has only 3, followed by 4 sacral and 21 or 22 caudal; while *Hyrax* has 8 lumbar, 7 sacral, and 5 coccygeal. The difference becomes more marked in the form of the pelvis; for the ossa ilii are very wide in the Rhinoceros, and sufficiently narrow in the *Hyrax*; but the analogy reappears in the femora, which exhibit a very marked commencement of a third trochanter, and is continued in many respects in the formation of the feet. But it is in the bony structure of the head that the *Hyrax* departs from the conformation of the Rodents, and approaches the Pachyderms, particularly the Rhinoceros. It is true that as the nose of the *Hyrax* has no horn to support, the nasal bones have not received, as in the Rhinoceros, the thickness necessary for carrying that defensive organ; but the maxillary bones differ at once from those of the Rodents by the smallness of their extent, and the inferior size of the suborbital hole, which is generally very large in that order. In the number of the upper incisor teeth (2) the *Hyrax* resembles both the Rodents and *Rhinoceros unicornis*; but the number of lower incisors is four. The upper incisors of *Hyrax* are not formed, like those of the Rodents, in the shape of a quadrangular prism, or in that of a cylinder curved and terminated by a truncation or a corner edge. They are triangular and terminate in a point, recalling to the observer the canines of the Hippopotamus. The lower incisors are laid forward like those of the Hog; they are flat and dentilated in youth, but soon become worn by attrition against the upper incisors. The molars represent those of the Rhinoceros, both in number and form, so that, were it not for the size, they might be mistaken for each other.

Molar tooth of *Hyrax*, magnified. Cuvier.

The condyle of the lower jaw is very different from anything observable among the Rodents, in which it is compressed longitudinally. In the *Hyrax* it is compressed transversely, as in the Pachyderms, and in all the other *Herbivora* which are not Rodents, being applied besides to a plane surface of the temporal bone, whereby a motion, more or less horizontal, from right to left, and from left to right, is permitted; and it is this that eminently distinguishes the articulation from that of all the *Carnivora*, where the condyle, although in truth transversal, enters into a deep hollow of the temporal bones, and permits of no other motion to the jaw than upwards



Skull of *Hyrax*. Cuvier.

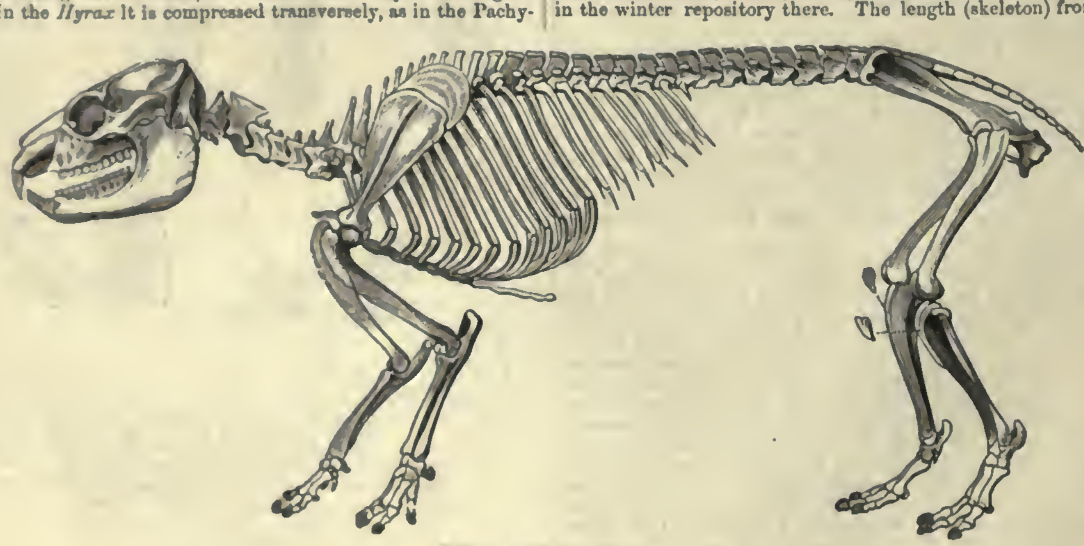
and downwards. After alluding to the form of the condyle and the dentition in the Kangaroos and *Phascolomys*, Cuvier goes on to remark that one of the most constant characters among the Rodents is the not having, at a certain age, more than a single parietal bone without suture, with two frontal bones, directly contrary to what occurs in man. In *Hyrax*, as in the Pachyderms and *Carnivora*, there are two frontal and two parietal bones. The zygomatic arch is constructed differently from that of the Rodents, and more conformably with that of Rhinoceros. In the molar teeth the construction and direction is rather that of the Pachyderms than of the Rodents.

In *Hyrax* the number of toes (four before and three behind) is precisely the same as in the Tapir. It is true, Cuvier observes, that some Rodents, and particularly the *Capybara* [HYSTRICIDÆ], have the same number, and that the last phalanges of the latter approach the flattened form of those of the Pachyderms; but their more elongated and free toes announce the family to which they belong. The *Hyrax* has the toes united by the skin down to the nail, as in the Elephant and Rhinoceros, and even more than in the Tapir and Hippopotamus.

Such are only a few of the leading points of agreement and disagreement in the bony structure of *Hyrax*, as considered relatively to the Rodents and Pachyderms.

In 1832 Professor Owen read to a meeting of the Zoological Society of London an account of the anatomical structure of *Hyrax Capensis*, which, while it was confirmatory of the anatomical description of Pallas generally, gave some additional facts, which will be readily appreciated by those who will compare his observations with the original description of *Cavia Capensis*, in the 'Spicilegia' and 'Miscellanea Zoologica' of Pallas.

The specimen, which was a full-grown male, had lived in the Gardens of the Society through the greater part of the summer, and died in the winter repository there. The length (skeleton) from the anterior surface of the upper incisors to the vent was 1 foot 5½ inches. The duodenum was not so loosely connected with the back part of the abdomen as in most of the Rodents; but it had throughout its course one entire investment of peritoneum. At its commencement it was not dilated, as in many Rodents. The cœcum seemed at first sight



Skeleton of *Hyrax*. Cuvier.

to have a great analogy to that of the Hare and other Rodents, being sacculated, and distended with a blackish pultaceous matter; but in form one would compare it rather with that of the Tapir, its magnitude arising more from its breadth than its length. The dilated part of the colon was bent in a sigmoid form, and the remainder was convoluted on a broad mesocolon, and at a distance of two feet from the dilated part (when unravelled) terminated between two conical cœca in a second dilated intestine. These singular cœca are minutely described by Professor Owen, who then makes the following observations:—"In looking through the vertebrata for an analogous formation of the intestinal canal, we shall find the *Hyrax* standing almost alone in this respect: among the *Mammalia* it is only in a few of the edentate species that the double cœcum is to be met with, as, for example, *Myrmecophaga didactyla*, Linn., and *Dasypus 6-cinctus*, Linn.; whilst in birds, although the double cœcum more generally prevails, yet an additional single cœcum, anterior to these, has only been found in a few species. This structure however completes the analogy, quoad the number of cœca; but, with respect to function, the cases are widely different: the single anterior cœcum of *Hyrax* evidently performs an important part in digestion; while in the bird it exhibits merely a trace of a structure peculiar to embryonic life. I should consider however the double cœcum of *Hyrax* as indicating an affinity to the group (*Edentata*) which intervenes, in the system of Cuvier, between the order it was originally placed in, and the one to which that great naturalist has transferred it. And it is interesting to find that while the facies of *Hyrax* so far simulates that of a Rodent as to have deceived the older naturalists, and to have concealed from them those unerring indications of its alliance with the *Pachydermata* which the osseous system exhibits; yet that nature, as if in confirmation of her abhorrence to the saltus, had left in the internal structure of this singular animal an impression borrowed from the type of the *Edentata*."

Professor Owen further remarks that although the stomach of some of the Rodents, as the Common Rat, and of the *Edentata*, as the *Manis*, exhibits a particular cuticular lining, yet it is among the Pachyderms that this structure is most prevalent. In *Hyrax* two-thirds of the stomach, on the cardiac side, are lined with a thick white and wrinkled cuticle.

The liver had the same form and number of lobes as described by Pallas. The middle lobe had the usual two notches, into the left of which the coronary ligament entered; but the right contained no gall-bladder, which in *Hyrax*, as in some of the Rodents and many of the Pachyderms, is deficient. Professor Owen observed that a compensation for this deficiency was however in some measure apparent in this animal; for the hepatic ducts, immediately on leaving the lobes of the liver, dilated into three globular receptacles, the united capacities of which would have equalled a moderate-sized gall-bladder. Professor Owen also observed that, in Pallas's 'Spicilegia Zoologica,' the peculiar insertion of the ureters is described with a note of admiration, and he stated that he was not aware that a parallel structure has since been discovered in any mammiferous animal possessing a urinary bladder. It is not however, he added, precisely in the fundus or summit of the bladder that the ureters open: they enter between the muscular fibres at the back part of the fundus, at the angles, analogous to the situation at which the Fallopian tubes enter the human uterus; but they run obliquely downwards and inwards for two lines before they terminate, leaving however a full inch of space between them and the orifice of the urethra. For what purpose this structure is designed in *Hyrax*, or whether the urine undergoes any change in consequence of it, is uncertain. "The chief peculiarity observed in the muscular system was a modification of the digastric muscle of the lower jaw, which arose, as in the Armadilloes, from the upper part of the sternum instead of the occiput or temporal bone; and was inserted into the whole ramus and angle of the lower jaw: it was of remarkable strength, being as large as the sterno-cleido-mastoideus in man. It is this muscle which occasions the peculiar fulness of the neck in the *Hyrax*." (Owen.)

In 1835 Mr. Martin dissected a second specimen of *Hyrax Capensis*, presented to the Society by Mr. Rudston Read. The total length of the animal, which was a young male, was 1 foot 4 inches, that of the head being 3½ inches. ('Poceedings of the Zoological Society' for 1835.)

Kolbe appears to be the first modern author who has noticed the *Hyrax* of the Cape; and he mentions it as a Marmot, a name adopted by Vosmaer and Buffon, the latter of whom also applies to it the term Daman, of which we shall presently have to speak. Blumenbach left it among the Rodents; and Pallas, who first gave a methodical and anatomical description of it, placed it under the genus *Cavia*, observing however that it differed remarkably from the congeners with which he arranged it. Linnæus gave the form the same place in his system under the name of *Cavia Capensis*. Pennant does not mention the animal in his 'Synopsis,' but in his 'History of Quadrupeds' he figures it as the Bristly Cavy, with the synonyms of *Agnus Filiorum Israel*, 'Prosp. Alp. Ægypt.;' Daman Israel, Buff.; Ashkoko, Bruce; *Hyrax Syriacus*, Gmel. and Schreb. Hermann however was the first who established the genus, and gave it the name of *Hyrax*. Pennant also notices the form under the appellation of Cape Cavy (*Cavia Capensis*, Pallas). Gmelin makes *Hyrax* the last genus of the *Glires*, and records two species, namely, *Hyrax Capensis* and *H. Syriacus*. We have seen the place assigned to it by Cuvier. Dr. Fischer arranges *Hyrax* under the order *Belluæ*, between *Elasmotherium*, an extinct genus, and *Dicotyles;* he gives three species, *Hyrax Capensis, H. Syriacus*, and *H. Hudsonius*, Schreb. (*Lipura Hudsonia* of Illiger). The latter is not a *Hyrax*. Dr. Gray places the genus in his sub-family *Rhinocerina*, belonging to the family *Elephantidæ*, the third family of his order *Ungulata*, observing that *Hyrax* is allied to *Caviina*, and giving the form a position between *Rhinoceros* and *Lipura* and *Elasmotherium*. M. Lesson arranges *Hyrax* under the order Pachyderms or *Belluæ* of Linnæus, between *Elasmotherium* and *Dicotyles*. Mr. Swainson ('Classification of Quadrupeds,' 1835) places *Hyrax Syriacus*, the Rock-Rabbit, next to *Rhinoceros*; and, after quoting Cuvier, remarks that "there is an obvious relation of some sort between this singular genus, of which three species are now known, and the *Glires;* but whether of analogy or affinity it is impossible to determine: for the present we place it as the gliriform type of the Pachyderms upon the sole authority of what M. Cuvier has said of its feet." In the next paragraph Mr. Swainson treats of *Megalonyx*. In the arrangement according to natural affinities, at the end of the volume, *Hyrax* is the last of the Pachyderms, the first 'tribe' of the order *Ungulata*. The next tribe is 'Anoplotheres,' and the first genus of that tribe *Sus*.

The generic characters of *Hyrax* are as follows:—Conformation of molar teeth like those of Rhinoceros. Two strong incisors without recurved roots in the upper jaw (and two small canines in youth). Body covered with thick hair, and beset here and there with erinaceous bristles. A simple tubercle in lieu of a tail. Six teats, two pectoral and four ventral. Four toes on each foot before, and three behind. Dental formula given in col. 174.

H. Syriacus, the Daman, the Hyrax of Syria, is brownish-gray above, and has the lower parts white; a yellowish tint intervenes between the two colours: the head and feet are more gray than the body. The separate hairs are ringed with yellowish, black, and white. The skin, where it is exposed, is of a blackish violet. Length about 1 foot; height about 11 inches.

This species has been supposed to be identical with the Ashkoko, or Askoko, of Bruce, who says that it is found in Ethiopia, in the caverns of the rocks, or under the great stones in the Mountain of the Sun, behind the queen's palace at Koscam. It is also frequent, he says, in the deep caverns in the rocks in many other places in Abyssinia; and he remarks that it does not burrow nor make holes, like the rat and the rabbit, nature having interdicted this practice by furnishing the animal with feet the toes of which are perfectly round, soft, and pulpy, the fleshy parts projecting beyond the nails, "which are rather broad than sharp, much similar to a man's nails ill grown; and these appear to be given him rather for the defence of his soft toes than for any active use in digging, to which they are by no means adapted."

Hyrax.

Bruce states that, "in place of holes, the animal seems to delight in less close or more airy places, in the mouths of caves or clefts in the rock, or where one projecting, and being open before, affords a long retreat under it, without fear that this can ever be removed by the strength or operations of man." He describes it as gregarious, and says that frequently several dozens of them sit upon the great stones at the mouth of caves warming themselves in the sun, and coming out to enjoy the freshness of a summer evening. "They do not," he continues, "stand upright upon their feet, but seem to steal along as in fear, their belly being nearly close to the ground, advancing a few steps at a time, and then pausing. They have something very mild, feeble like, and timid in their deportment; are gentle, and easily tamed, though when roughly handled at first they bite very severely." The same author says that these quadrupeds are found plentifully on

Mount Libanus, and that he has also seen them among the rocks at the Pharan Promontorium, or Cape Mahommed, which divides the Elanitic from the Heroopolitic Gulf, or Gulf of Suez. They seemed to him to be the same in all places; but, if there was any difference, those of the Mountain of the Sun were superior in size and fatness. He kept one some time, and gives an interesting account of its habits in confinement. This species is called *H. Abyssinicus* in the 'British Museum Catalogue.'

The captive specimen noticed by F. Cuvier had the appearance and somewhat of the habits of the Rodents, resembling the *Spermophili*. It was quick, lively, active, inquisitive, and tried to get into narrow openings or holes for concealment. It delighted in heat, exposing alternately different parts of its body to the sun. In cold weather it wrapped itself up in its hay or litter.

H. Capensis, the Klipdas. The following account of the habits of this animal is given by W. H. Rudston Read, Esq.:—It is found at the Cape of Good Hope, inhabiting the hollows and crevices of rocks, both on the summits and sides of hills, as well as near the sea-shore, even a little above high-water mark. It appears to live in families, and is remarkably shy in its wild state. In winter it is fond of coming out of its hole and sunning itself on the lea-side of a rock, and in summer of enjoying the breeze on the top; but in both instances, as well as when it feeds, a sentinel is on the look-out (generally an old male), which gives notice, usually by a shrill prolonged cry, of the approach of danger, or even the least movement of any suspicious object. It lives on the young shoots of shrubs, the tops of flowers, herbs and grass, particularly of all those which are aromatic; which occasions the necessity of paunching the animal as soon as killed, in order to make it fit for eating. The stomachs of those shot by Mr. Hennah were always much distended with food scarcely masticated. "A friend of mine," continues Mr. Read, "kept two young ones alive for some time, which became very tame; they would find him out when lying on the sofa or in bed (for they were suffered to run about the house), and, climbing up, shelter themselves on his breast within his waistcoat, or creep under the bed-clothes at his back, and, lying quiet, enjoy the warmth. The one brought home by Mr. Hennah, when allowed to run unconfined about the room, was inclined to be sociable, but was restless and inquisitive, climbing up and examining every person or thing in the cabin, and startling at any noise, which caused it instantly to run and hide itself. But from confinement it became savage and snarling, and tried to bite when anything was put near its cage. Both wild and in restraint it is remarkably clean in its habits, always frequenting and depositing its dung in one place. From its faintly crying in its sleep we may conclude that it dreams. I have also heard it chewing its food by night, when everything has been quiet, and after going into its sleeping apartment. In its food it was pleased with variety, eating first a few leaves of one plant and then of another, and greedily licking salt when given to it. In its passage home its food was Indian corn bruised, bread, raw potato, and onion, with a small quantity of water, which in drinking it partly lapped and partly sucked up. It was very sensible of cold; for when a candle was placed near the bars of its cage it readily acknowledged the little warmth given out by turning its side, and sitting still to receive the full benefit of the rays of heat. I am inclined to think that the female does not produce more than two young ones at a time, from having observed in several instances but two following the old ones. Its name at the Cape is the Dasse, which is I believe the Dutch for a badger." In Mr. Steedman's 'Wanderings,' the Dasse, or *Hyrax*, is stated to be an extremely quick and active little animal, skipping along the shelving ledges of the overhanging cliffs, and darting with incredible swiftness into the holes and crevices of the rocks, by which it frequently eludes the grasp of its pursuers. It is said to be preyed upon by the lions, hyænas, and some of the birds of prey of Africa. The 'Catalogue of the African Museum' states that *Aquila vulturina* resorts exclusively to high rugged mountains, where it preys upon *Hyrax Capensis*, the Dasse of the Cape colonists.

Mr. Read says that the flesh of the Cape Hyrax is very like that of a rabbit in flavour. Hemprich states that both the natives of Arabia and the boors of the Cape regard the urine of the *Hyrax* as medicinal.

The term שפן (Shaphan or Saphan) is to be found in the following parts of the Bible:—Levit. xi. 5.; Deut. xiv. 7; Psalm civ. 18; Prov. xxx. 26. In our English translation now in use this word is rendered 'coney,' and 'conies' in all the passages quoted; and so it is in Robert Barker's Bible (1615). In the Tigurine version, as given by Scheuchzer, Schaphan is translated (Levit. xi. 5) 'cuniculus,' and in the Vulgate, as given by the same author, 'choerogyllus.' In Psalms civ. 18, the Tigurine version given is "celsos montes ibicibus, et petras (dedit) confugium *Alpinis muribus*" (Alpine mice). In the vulgate is given—"montes excelsi cervis: petra refugium *herinaceis*" (Hedgehogs). In Prov. xxx. 26, the Tigurine version is printed "Cuniculi, gens minimè potens, attamen in petra domicilium suum collocant," with the following note to Cuniculi: "Quidem murem montanum esse putant, et videtur hic quadrare." The vulgate is printed "*Lepusculus*, plebs invalida, qui collocat in petra cubile suum."

We have seen that the *Hyrax* has been termed Daman by the French zoologists. Dr. Shaw speaks of the Daman Israel as "an animal of Mount Libanus, though common in other places of this country" (Palestine). "It is a harmless creature, of the same size and quality with the rabbit, and with the like incurvating posture and disposition of the fore teeth; but it is of a browner colour, with smaller eyes and a head more pointed. The fore feet likewise are short, and the hinder are nearly as long in proportion as those of the jerboa. Though this animal is known to burrow sometimes in the ground, yet, as its usual residence and refuge is in the holes and clefts of the rocks, we have so far a more presumptive proof that this creature may be the Saphan of the Scriptures than the jerboa. I could not learn why it was called Damau Israel, that is Israel's Lamb, as those words are interpreted." Though there is error in this description such as might be easily made by a casual observer, there can be no doubt that Dr. Shaw, in the passage quoted, alluded to the *Hyrax*: the words Daman Israel are probably mistaken for Ganam or Gannim Israel, as we shall presently have occasion to notice; "animal quoddam humile, cuniculo non dissimile quod *agnum filiorum Israel* nuncupant." ('Prosp. Alp. Ægypt.')

Dr. Harris states that Jerome, cited by Bochart, says that the שפנים are a kind of animal not larger than a hedgehog, resembling a mouse and a bear (the latter, Dr. Harris supposes, in the clumsiness of its feet), whence in Palestine it is called Αρκτομυς, the Bear-Mouse; that there is a great abundance of this genus in those countries, and that they are wont to dwell in the caverns of the rocks and the caves of the earth.

The 'Seventy' translate 'Saphan' by 'χοιρογρύλλιοι' in all the places quoted. This term, compounded of χοῖρος, a hog, and γρύλλη, a grunting, points curiously enough to a pachydermatous form. Bruce, in his travels, describes the Syrian Hyrax, as we have seen. He adds:—"In Amhara this animal is called Ashkoko, which, I apprehend, is derived from the singularity of those long herinaceous hairs, which, like small thorns, grow about his back, and which in Amhara are called Ashok. In Arabia and Syria he is called Israel's Sheep, or Gannim Israel; for what reason I know not, unless it be chiefly from his frequenting the rocks of Horeb and Sinai, where the children of Israel made their forty years' peregrination: perhaps this name obtains only among the Arabians. I apprehend he is known by that of Saphan in the Hebrew, and is the animal erroneously called by our translators Cuniculus, the rabbit or coney." Of this opinion are Pennant, Cuvier, and others among the zoologists; and though M. Lesson, in the introduction to his 'Manuel,' speaks of the rabbit (lapin), "which is supposed to be the Schaphan of the Hebrews, although it is more probable that it was the Rat of Pharoah (Rat de Pharaon)"—on what grounds he does not state—as a prohibited animal (Levit.; Deut.), there can be little doubt that the Shaphan, the "feeble folk" that "yet made their houses in the rock," belonged to the genus *Hyrax*.

In the Gardens of the Zoological Society there are three species, named *H. Capensis*, *H. Syriacus*, and *H. arboreus*. The last is from Western Africa.

HYSSOP. [LAMIACEÆ.]

HYSTATITE. [ILMENITE.]

HYSTRICIDÆ, a family of Animals belonging to the order *Rodentia*. According to Mr. Waterhouse ('Natural History of Mammalia') it has the following characters:—Molar teeth $\frac{4-4}{4-4}$; the muffle, or terminal portion of the muzzle clothed with small hairs; the skull with a large antorbital opening, through which a portion of the masseter muscle passes, as well as the infraorbital nerve; the lower jaw with the angular portion joined to the outer (not the under) surface of the bony covering of the inferior incisor; tibia and fibula distinct. The family is essentially a South American group; it may be divided into six minor sections, or sub-families, namely, *Hystricina*, *Dasyproctina*, *Echimyina*, *Octodontina*, *Chinchillina*, and *Caviina*; of those, the most highly-organised division which includes the Porcupines (*Hystrix* of Linnæus) has a wide geographical range, having representatives in the four quarters of the globe. With the exception of two species, the whole of the species forming the remaining five sub-families are exclusively found in the New World, being chiefly confined to South America: two or three species in the West Indian Islands, and about the same number in Central America form the exceptions.

The members of the sub-families *Hystricina*, *Dasyproctina*, and *Echimyina* increase in number towards the tropical portions of South America; whilst in the southern parts of that continent, the less highly-organised species only are found, these being members of the remaining three sub-families.

On the western side of the Southern Andes, but one of the sub-sections alluded to has representatives—the *Octodontina*.

The relations of the sub-families of the *Hystricidæ* may be expressed by arranging them as follows:—

Hystricina.

Dasyproctina . . . . . with rooted molar teeth.

Echimyina.

Caviina . . . . . *Octodontina* . with rootless molar teeth.

Chinchillina.

"By this mode of placing the groups," says Mr. Waterhouse, "we wish to express that the Agoutis (*Dasyproctina*) in their characters, partake of those of the three groups to which they are approximated; that certain members of the section *Echimyina* lead off to the *Hystricina*, whilst others approach more nearly to the *Chinchillina*; and lastly, that the Octodons are nearly related on the one hand to the *Echimyina*, and on the other to the *Chinchillina*: they bear the same kind of relationship to the Echimys group as do the *Arvicolæ* to the True Rats."

The following is the character of the sub-family *Caviina*:—Molar teeth rootless, divided by folds of enamel so as to form lobes having acute angles; the series of molars on opposite sides of the upper jaw converging, and nearly meeting in front; incisor teeth comparatively short, those of the lower jaw not being extended backwards as far as the springing of the angular portion, or descending ramus; four toes to the fore feet, and three to the hind; tail wanting, or rudimentary; upper lip entire; a strongly-developed horizontal ridge on the outer surface of the lower jaw; the angular portion of this jaw produced much beyond the condyloid portion, descending below the level of the dental portion, and with a curved lower margin; clavicles wanting.

The Cavies have almost invariably been associated with the Agoutis (*Dasyprocta* and *Cœlogenys*), and frequently the animals of both divisions have been linked together under the sectional name *Subungulata*, by the more recent writers, who thus adopt Illiger's name for the section and his views regarding it.

The nature of the affinity which exists between these two groups is by no means so near as is generally supposed.

Both groups belong to the same great family; and besides the characters which are peculiar to this family, the species of the genus *Dasyprocta* may be said to approach the Cavies, from the circumstance of their having the same number of toes to their feet, and being almost (or entirely) destitute of a tail; but this is weak evidence in favour of the supposition that there exists a very near affinity between the genera associated under the name *Caviina* and those arranged under the head *Dasyproctina*, such an affinity, in fact, as is indicated by the arrangement of these two groups in a section apart. A certain degree of importance must be given to the characters thus referred to, when we find them combined with numerous other peculiarities exhibited in the structure of the teeth, skull, and skeleton, as in the *Caviina*, but evidence of a distinct minor type, in the structure of these parts will be educed when we treat of the *Dasyproctina*.

Dolichotis, Desmarest; *Mara*, Lesson.—The limbs are long, the ears fully half as long as the head, pointed, broad at the base, and deeply emarginated behind; tail very short, and recurved; metatarsus with the anterior half clothed with hairs on the under surface; the hinder half as well as the heel, naked; molar teeth small, compared with the bulk of the skull; the three foremost of the upper jaw and the three hindermost of the lower, divided by folds of enamel, each into two equal lobes; the last molar of the upper jaw three-lobed as well as the foremost of the lower jaw.

D. Patachonica, the Patagonian Cavy; *Cavia Patachonica*, Shaw; *Dasyprocta Patachonica*, Desmarest; *Chloromys Patagonicus*, Lesson; *Mara Magellanica*, Lesson; *Dolichotis Patagonica*, Wagner. Fur dense and crisp; on the upper parts of the head and body gray, on the sides of a yellow rust-colour; chin, throat, and abdomen, white; rump black, but with a broadish white transverse band crossing immediately above the tail; limbs for the most part rusty yellow, but grayish in front. It inhabits Patagonia, ranging from about 48° 30′ to 37° 30′ S. lat., on the east coast, and extending into La Plata as far north as Mendoza.

"The Patagonian Cavy," Mr. Darwin observes, "is found only where the country has a desert character. It is a common feature in the landscape of Patagonia to see in the distance two or three of these Cavies hopping one after the other in a straight line over the gravelly plains, thinly clothed by a few thorny bushes and a withered herbage.

"Near the coast of the Atlantic the northern limit of the species is formed by the Sierra Tapalguen, in 37° 30′ S. lat., where the plains rather suddenly become greener, and more humid. The limit certainly depends upon this change, since near Mendoza (33° 30′) four degrees farther northward, where the country is very sterile, the animal again occurs.

"Its southern limit is between Ports Desire and St. Julian about 48° 30′ S. lat. From the same source we learn the following particulars relating to this Hare-like Cavy. It is a burrowing animal, but when found in the same districts with the Viscacha it will avail itself of the excavations of this latter animal for a retreat. The Patagonian Cavies wander at times to great distances from their homes, and usually two or three are seen together on these occasions. The animal in its mode of running more nearly resembles the Rabbit than the Hare, and though its limbs are long it does not run very fast; it seldom squats after the manner of the Hare, is very shy and watchful, and feeds by day; and in connection with this circumstance I may mention that the eyes, like those of the Kangaroos, are defended from the direct rays of the sun, by well-developed eye-lashes, which is not the case with ordinary Cavies.

"It generally produces two young at a birth, and brings forth in its burrow: its flesh is white when cooked, but rather dry and tasteless. The long legs and rather long erect ears, combined with the general form of the head, and the short recurved tail, have caused this animal to be very generally mistaken for the Hare, by casual observers; and we have pointed out certain other characters in which the resemblance is further carried out; it nevertheless is a Cavy in all the more essential details of structure.

"For size it greatly surpasses the common Hare, full-grown individuals weighing from twenty to thirty pounds, and indeed the Patagonian Cavy must rank amongst the largest of the Rodent tribe, though far surpassed by its aquatic congener, the *Capybara*."

Cavia, Klein; *Anœma*, F. Cuvier; Les Cobayes, Cuvier.—The limbs short and the ears likewise short; feet naked beneath; molar teeth nearly of equal size, each molar with two principal lobes.

C. rupestris, Rock-Cavy; *Kerodon Moco*, F. Cuvier; *K. cinereus*, Geoffroy; *Cerodon rupestris*, Wagner. Nails of the toes short, obtusely pointed, and scarcely projecting beyond the large fleshy pads with which the toes are terminated; fur soft, its general hue gray, tinted with rufous on the hinder part of the back; throat white, chest whitish; abdomen white suffused with pale orchreous yellow; sides of the face tinted with rufous; hinder part of the posterior limbs suffused with chestnut red; fore legs and tarsi whitish, tinted with rufous. The Rock-Cavy inhabits Brazil in rocky situations.

According to Prince Maximilian it inhabits the interior of Brazil, and is confined to rocky districts, where it seeks its retreat in holes amongst the fragments of the rocks. It is frequently met with at Belmonte, Rio Pardo, and Rio de St. Francisco (all nearly under the 16th parallel of south latitude), being found near the rivers, but always in the higher parts of their course. Its flesh is said to be well flavoured, on which account it is sought by the Indians, to whom it is known by the name of 'Hokê,' and by the Portuguese it is called 'Mokô.' The *C. rupestris* is superior in size to most other Cavies, stands higher on its legs, and is remarkable in its group for the comparative softness of its fur, and the structure of the nails of its toes.

C. Spixii, Spix's Cavy. Incisor teeth yellow; general colour of the animal gray, with a somewhat indistinct brownish tint on the back; the space between the eye and the ear whitish, a white patch behind each ear, and the throat and abdomen likewise white. It inhabits Brazil, Rio de Janeiro, Bahia, and the neighbourhood of the Amazonas.

The yellow colour of the incisor teeth, and the general gray hue of the fur, combined with a distinct white patch behind, and a second in front of each ear, are the leading characteristics of the species.

C. Boliviensis, Bolivian Cavy; *Galea Musteloides*, Meyen. Incisor teeth of an orange-yellow colour; general hue of the fur gray, with a very faint yellow tinge; throat and abdomen white; feet whitish. It inhabits Bolivia, occuring only at great elevations. Meyen informs us that the lofty plains on the pass of Tarna to the Lake of Titicaca, as well as those of Tajori (on the Andes 18° S. lat.) are inhabited by immense numbers of a small animal, which burrows and so undermines the ground, that every step of the horse was attended with danger. The animal was so shy that he was unable to procure a specimen; and indeed it was only seen from a distance. It is described as having a long and slender body, of a brownish red colour on the upper parts and pale on the under. Its length without including the tail appeared to be about eight inches. To this animal Meyen gives the name *Galea Musteloides*.

The characters of the genus *Galea* are derived from a skull found by Meyen at the entrance of one of the burrows of the little animal just referred to, and judging from Meyen's figures and descriptions it probably belongs to the Rodent named *C. Boliviensis*.

C. australis, the Southern Cavy; *Keredon Kingii*, Bennett. Incisor teeth white; head short, tarsi long; fur rather soft, its general hue gray, by no means dark; the eye edged with white, a whitish spot behind the ear; the chin and edge of the lower jaw likewise white. It inhabits Patagonia, from about the 39th parallel of latitude down to the Strait of Magalhaens. This little gray Cavy according to Mr. Darwin is common along the coast of Patagonia, from Rio Negro to the Strait of Magalhaens.

It is very tame, commonly feeds by day, and is said to bring forth two young at a birth. At the Rio Negro it frequents in great numbers the bottom of old hedges, and at Port Desire it takes up its abode amongst the ruins of the old Spanish buildings.

M. D'Orbigny observed the southern Cavy as far north as 39° S. lat., which it appears is its extreme range in that direction; and this author states that it lives in families, and digs deep burrows in the ground, preferring sandy declivities which are more or less overgrown with bushes; its burrows are said to have several outlets. The food of the southern Cavy consists of seeds and green herbage, and it has been observed to ascend trees to feed upon their fruits.

C. Aperea (Linnæus), Restless Cavy, or Guinea-Pig (*Aperea Braziliensibus*, Marcgrave ?). Domesticated it is called *C. Cobaya* by Marcgrave, Schreber, and Desmarest; *Mus Porcellus*, Linn.; Variegated Cavy, Shaw; Cochon d'Inde, Buffon. The Wild Guinea-Pig has the incisors white; fur long and somewhat coarse, on the upper part of the sides and body distinctly pencilled with black and dirty yellow; chest gray-brown, throat and abdomen pale dirty-yellow, or sometimes brown-gray. It inhabits the banks of the Rio Plata, and extends northward into Paraguay, Bolivia, and Brazil.

According to Mr. Darwin the animal is known by the name of *Aperea*, and it is exceedingly common in the neighbourhood of several towns on the banks of the Rio Plata, sometimes frequenting the sand hillocks, or the hedge-rows formed of the *Agave* and *Opuntia*; but marshy places covered with aquatic plants appear to be preferred. Where the soil is dry it makes a burrow, but otherwise it lies concealed amidst the herbage. It generally comes out to feed in the evening, and if the day be gloomy it will likewise make its appearance in the morning. In Bolivia, Mr. Bridges states this animal is confined to the low lands, and in this respect differs from the *Cavia Boliviensis*, which is always found at a considerable elevation. It is not uncommon in fields in the neighbourhood of Chuquisaca and Cochabamba; and takes shelter amongst the loose stones of the walls by which the fields are inclosed.

Dr. Rengger says that the *Aperea* is found throughout Paraguay, and extends southward as far as 35° S. lat., he has himself not only met with the animal (with which he is well acquainted) in those parts, but likewise in Brazil, both in Bahia and in Pernambuco.

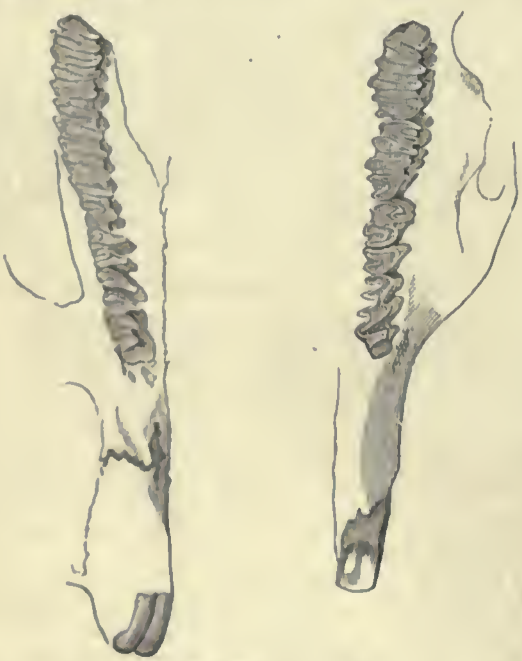
In Paraguay it generally frequents moist situations and near the borders of forests, but it never occurs either in the forests or in the open fields. It lives in little societies (according to the same author) of from six to fifteen individuals, in the impenetrable groves of Bromelias; and its presence is detected by numerous little beaten paths which it forms amongst these plants. It feeds early in the morning and after sunset in the evening, but never strays far from its home. The *Aperea* breeds but once in the year, and then has but one or two young. On this and other grounds Dr. Rengger thinks the *Aperea* is not the origin of the Domestic Guinea-Pig.

C. leucopyga, the White-Rumped Cavy. Incisor teeth white; on the upper parts of the animal of mixed brown black and brownish-yellow colours; throat, chest, and abdomen white. It inhabits Brazil.

Hydrochœrus, Brisson; *Capybara*, Marcgrave; *Capyigoua*, D'Azara; Cochon d'Eau of Des Marchais; Irabubo of Gumilla, Capivard of Froger, Capüguara of Dobritzhof, Cabiai of Buffon, Nümpoon of the Botocudo Indians.

$$\text{Dental formula :—Incisors, } \frac{2}{2}\text{; molars, } \frac{4-4}{4-4} = 20.$$

Molars compound, the posterior teeth the longest, and formed of numerous laminæ, which are simple and parallel; the laminæ of the anterior molars forked.



Teeth of *Capybara*. F. Cuvier.

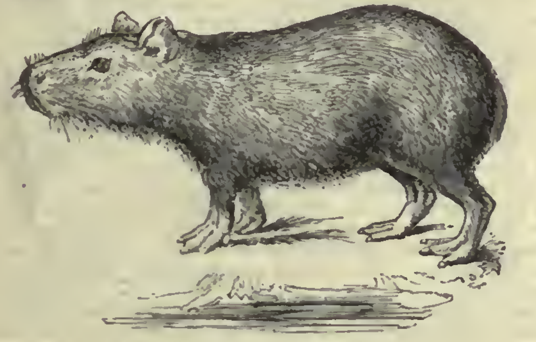
At a meeting of the Zoological Society of London (1832), Professor Owen, on the occasion of exhibiting a large old cranium of the *Capybara* belonging to M. De la Fons, remarked, that perhaps the most extraordinary instance of the enlarged views which result from unwearied observation of the internal structure of animals is afforded by Cuvier's bold enunciation of the affinity of the Elephant to that order of the *Mammalia* which contains the most minute forms of the class; and, in support of that affinity, adduced the alveolæ of the last molar tooth in M. De la Fons's specimen as illustrating an additional analogy between the molars of the Rodent and those of the Elephant, namely, that the number of transverse laminæ increases as the jaw enlarges with age, the whole number not coming into use at once.

"In the *Capybara*," says Professor Owen, "the posterior grinders, like those of the Elephant, present a greater number of component laminæ than the anterior ones, which are of earlier formation. Those of the upper jaw, according to the figure and description in the 'Ossemens Fossiles' (V. pl. 1, p. 24), are composed of eleven laminæ, of which all but the first, which is notched externally, are simple. In the figure too, it is worthy of observation that the last or eleventh lamina is imperfect, and exhibits a construction analogous to the imperfectly-formed laminæ or denticles in the elephant's grinder, namely, a division into component columns. In the work of F. Cuvier, 'Sur les Dents des Mammifères,' the number of laminæ in the last grinder of the upper jaw of the *Capybara* is stated as 'onze ou douze;' but eleven only are exhibited in the figure, and we may suppose therefore the doubt as to the precise number to be founded on uncertainty as to the propriety of considering the first deeply-notched lamina as single or double. In the cranium in the College Museum the number of the laminæ is twelve, the forked one being regarded as single. In M. De la Fons's specimen the alveolæ clearly indicate that the number of laminæ of the last molar had been thirteen, with the rudiment of the fourteenth; the extent of the grinding surface is however proportionally longer than would result from the additional laminæ alone; for as these laminæ do not cease to grow so long as the animal lives, they increase in thickness as age advances." ('Zool. Proc.')

Mr. Morgan ('Linn. Trans.' vol. xvi.) describes the stomach as formed by a single membranous bag; and, as in other mammiferous vegetable feeders in which this simple form of stomach is found, the cœcum as large and complicated in proportion. Finding nothing requiring particular notice in the rest of the alimentary canal, Mr. Morgan proceeded to examine the structure of the mouth and throat. After noticing the considerable extent of the grinding surfaces of the molar teeth, he remarks that it must be obvious how necessary such an arrangement of parts must be to the health of the animal, when the nature of its food and the simple structure and limited functions of its most important digestive organ are considered, a provision being thus made for the proper mastication of the hard vegetable substances upon which the animal must occasionally subsist. But Mr. Morgan found another structure, undescribed up to the time when he made his examination, by which the process of perfect mastication is rendered indispensable to the passage of the food from the mouth to the stomach. This structure, by which the possibility of swallowing any portion of unmasticated nutriment is prevented, is shown in an extraordinary formation of the velum palati mollis, or soft palate. In other animals this membrane generally forms an imperfect floating septum, suspended from the back part of the roof of the palate, and interposed between the cavity of the mouth and pharynx, but it was found in the *Capybara* and in some of its congeners to be much more extensive in its attachments, and different in its form and uses. On separating the jaws the mouth appears to terminate in a nearly blind pouch; for the communication with the pharynx seems as if shut by a strong membrane of a funnel shape, the concavity of which recedes towards the throat. "This membrane is an extended velum palati attached to the whole circumference of the fauces and root of the tongue, and is prevented from forming a complete septum by the existence of a small central circular aperture, by which a communication between the mouth and the pharynx is established for passage of food; so that through this small membranous funnel, or strainer (if I may be allowed the expression), it is physically impossible that any considerable portion of unmasticated nutriment should find its way, by natural means, from the mouth into the alimentary canal; and from this circumstance the first process towards digestion must be rendered certain and complete; for the grosser particles of food must remain in the mouth from the interposition of the membranous sieve or strainer, which is thus placed between the organs of mastication and those of digestion. Mr. Morgan observes that the same provision for the complete mastication of all solid substances, previous to their being swallowed, will be found in others of the same group, but he confines his well-executed descriptions and figures of the anatomy of these parts to the dissections he had made of the *Capybara*. To these descriptions and figures we refer the reader, offering only the conclusion to which Mr. Morgan comes as to the use of this conformation of the velum palati: this appears to him to have reference to the digestive organs, and to be confined almost entirely to the process of deglutition."

The size of the laminæ in the posterior molar teeth, and the increase in their number, indicate some approach to the pachydermatous form, and we find among some of the earlier zoologists who have noticed it a disposition to approximate it to the hogs. Thus Marcgrave says ('Piso,' book iii.), "*Capybara* inter porcos aquaticos sive fluviatiles recipitur, quia figura et natura bimulum porcum emulatur." Brisson's name *Hydrochœrus*, Water-Hog, and Des Marchais' Cochon d'Eau, point the same way. Linnæus, in his last edition of the 'Systema Naturæ' (12th), arranges it under the genus *Sus* (*Belluæ*), as *S. Hydrochœris*, and immediately after the *S. Tajaçu*, or Peccary, next to which animal it is placed in Piso's Marcgrave. Pennant in his 'Synopsis,' calls the *Capybara*, with River Hog (Wafer, in Dampier), as one of the synonyms, the Thick-Nosed Tapir; but in his 'History of Quadrupeds' he makes it the first species of his genus Cavy, giving it a place immediately before the Guinea-Pig. Gmelin (13th ed. 'Syst. Nat.') places it among the *Glires*, as the last species of the genus *Cavia*, immediately after the Guinea-Pig, *C. Cobaya*; by which arrangement the animal comes next to the Beaver (*Castor*). Cuvier makes *Hydrochœrus* a genus of his Rodents, giving it a position between *Lagomys* and the Guinea-Pig. Fischer brings it under the *Glires*, between *Lagomys* and *Dasyprocta*. Dr. Gray places it in the order *Glires*, family *Leporidæ*, sub-family *Hydrochœrina*; *Hydrochœrus* being the only genus of that sub-family, which stands between the sub-families *Caviina* and *Dasyporcina*. M. Lesson arranges it between *Kerodon* and *Cavia* (*Glires*). Mr. Swainson also places it at the head of the Cavies, *Cavia* (*Glires*).

H. Capybara (*Cavia Capybara* of Gmelin, *Sus Hydrochœris* of Linnæus) is the only species. .



Capybara (*Hydrochœrus Capybara*).

It is confined entirely to the New World, and found in the neighbourhood of the great rivers in Brazil, Guyana, and Paraguay; some say that it is found as high as the Isthmus of Darien.

Marcgrave states that the *Capybara* lives upon herbs and fruits; that it is a nocturnal animal, swimming across rivers and torrents in search of food, and raising such a horrible clamour as to have terrified the narrator before he knew the cause. He says that they wander in infinite congregations about the banks of the rivers, and as they are slow of foot, that they save themselves from the hunters by swimming, though, notwithstanding, immense numbers are killed. Pennant, who quotes Muratori, says that it runs slowly, swims and dives remarkably well, and keeps for a long time under water; feeds on fruits and vegetables; is very dexterous in catching fish, which it brings on shore and eats at its ease; sits up and holds its prey with its fore foot, feeding like an ape; takes its food in the night, and commits great ravages in gardens, keeps in large herds, and makes a horrible noise like the braying of an ass.

Some part of this last account seems rather highly coloured. We doubt very much, from the structure of the teeth and digestive organs, the alleged fact of its feeding much on fish; though Bewick, who gives by no means a bad figure of the animal, places a newly-caught fish before it, probably on the authority above quoted.

Marcgrave speaks of the flesh as sufficiently good food, especially if it be roasted: he says indeed that inasmuch as it yields in dignity to that of wild and domestic hogs, the head of the *Capybara* only is considered a delicacy. Pennant, on the contrary, in the account above alluded to, says that it grows very fat, and that the flesh, which is tender, is eaten, but it is added that the flavour is oily and fishy. Cuvier however speaks well of it. "C'est un bon gibier," says that author in his 'Règne Animal.' The majority of authors speak of it as being easily tamed and growing familiar; but one of the Capybaras which died at the Regent's Park was very morose to strangers, and all endeavours at conciliation were answered by stampings, cries, and malevolent attempts to strike with the fore feet and head. There is at present (1854) a specimen in the collection, which, although not very familiar, exhibits none of the malevolence of the first specimens. The habits of an animal however cannot be judged of from an individual shut up in a cage, deprived of all the accessories that make its life agreeable in a state of nature, and with a temper ruined by constant irritation, disappointment, and ill-health. Those who speak of the *Capybara* as being easily tamed had most probably opportunities of observing the manners of some of these quadrupeds where they were allowed that certain degree of liberty and indulgence without which an attempt to gain the confidence of animals is generally hopeless.

Professor Owen observes ('Zoology of the Voyage of H.M.S. Beagle,') that it is interesting to find that the continent to which this interesting aberrant form of Rodent is peculiar, should be found to contain the remains of an extinct genus, characterised by a dentition which closely resembles the Rodent type, but manifesting it on a gigantic scale, and tending to complete the chain of affinities which links the Pachydermatous with the Rodent and Cetaceous orders. [TOXODON.]

The next sub-family in Mr. Waterhouse's arrangement is the *Chinchillina*. An account of them is given under CHINCHILLIDÆ.

Sub-family *Octodontina*.—Molar teeth rootless, having but a single indenting fold of enamel on either side or rarely with an extra fold on the inner side of the molars of the lower jaw; zygomatic arch with angular process on the lower edge; hind feet with five toes or with sometimes four.

The species of this section inhabit the middle and southern parts of South America, occurring on both sides of the Andes. They are of small size, the largest known species scarcely surpassing the Common Squirrel in bulk. Some live almost entirely underground, and have the fore feet strong, and armed with powerful claws, fitted to their burrowing habits; others are found at the roots of trees, occasionally climbing amongst the branches of the shrubs of which the hedges are formed, or even (though rarely) ascending trees.

The *Octodontina* bear the same kind of relationship to the *Echimyina* as do the *Arvicolina* of the northern hemisphere to the true Rats: they agree with the *Echimyina*, in fact, in all essential points, but differ in having the molar teeth rootless, and almost always of a more simple structure. Accompanying the rootless molar teeth, we find that the incisors are almost always broader, and relatively less deep from front to back; and connected with these differences, the structure of the skull denotes increased powers in the muscles of mastication, the zygomatic arch being stronger, and the temporal fossæ more extended; generally in proportion as the incisor teeth increase in size, the cranium assumes a broader and shorter form, is more contracted between the orbits, and has the cerebral cavity proportionately smaller, and it is in those species which burrow and live almost entirely underground that these last-mentioned peculiarities are carried to the extreme.

From the other two sub-families of *Hystricidæ*, which are characterised by rootless molar teeth—the *Caviina* and *Chinchillina*—the Octodons may be distinguished by the hind feet being always provided with five well-developed toes. The presence of a distinct tail will prevent the Octodons from being confounded with the Cavies; and this organ being clothed with short hairs in the Octodons, gives to these animals a very different appearance to that of the bushy-tailed Chinchillas. The skull and dentition likewise furnish good distinguishing characters. The palate, as will be seen on comparing it with those of the Cavies and Chinchillas, is less contracted between the foremost molar teeth, the molar bone has a distinct angular projection on its under side (as in the *Echimyina*), and there is the same strong muscular ridge running obliquely forwards and downwards from the hinder root of the zygoma on the outer surface of the molar bone. The molar teeth are usually indented on each side by a single fold of enamel, and the crown of one of these teeth approaches more or less nearly to the form of the figure 8. The most marked exception is found in the lower molars of the genus *Habrocoma*. Five genera having well-marked distinguishing characters, are included in the present sub-family: their chief external peculiarities are as follows:—

I. Fore feet with four toes; ears very long. *Habrocoma*. [HABROCOMA.]

II. Fore feet with five toes.

- *A.* Ears large, or of moderate size.
  - *a.* Tail as long as the body, slightly bushy at the extremity. *Octodon*.
  - *b.* Tail shorter than the body, clothed throughout with small adpressed hairs. *Schizodon*.
- *B.* Ears very small, almost entirely hidden by the fur of the head.
  - *a.* Incisor teeth moderately broad; nails to the toes of the fore feet shorter than the toes. *Spalacopus*.
  - *b.* Incisor teeth very broad; nails to the toes of the fore feet longer than the toes. *Ctenomys*.

Octodon, Bennett (*Dendrobius*, Meyen).—Ears moderately large; tail nearly as long as the body, with long hairs at and near the point; five toes to the fore or hind feet; the claws small; incisor teeth moderate as to width, or somewhat narrow, convex in front; molar teeth each with a single indented fold of enamel on either side; the hinder half of the upper molars much narrower than the anterior portion; a small vertical plate (to protect the infra-orbital nerve) within the ant-orbital opening of the skull.

O. Degus, Cuming's Octodon; *Sciurus Degus*, Molina; *O. Cumingii*, Bennett, Wagner; *O. pallidus*, Wagner; *O. Cumingii*, Tschudi (?); *Dendrobius Degus*, Meyen; Chilian Squirrel, Shaw. Fur long and moderately soft; upper parts of the body pencilled with black and pale brownish-yellow; sides of the body chiefly of the latter colour; abdomen dirty yellow; feet white, faintly tinted with yellow; tail dusky above, dirty white beneath; the long hairs on the apicle third, black, or dusky. It inhabits Chili.

According to Mr. Darwin this species of Octodon may be seen by hundreds in the hedgerows and thickets in the central parts of Chili, where they make burrows close together, leading one into the other. They feed by day in a fearless manner, and are very destructive to fields of young corn; when disturbed, they all run together towards their burrows, the same way that rabbits do in England when feeding outside a covert. When running they carry their tails elevated; and often they may be seen seated on their haunches, like squirrels. According to Molina they lay up a store of food for the winter, and do not become dormant. According to more than one author, the

Octodon is seen occasionally to climb amongst the branches of the bushes. Mr. Bridges informs us that Cuming's Octodon has a very extended range, that gentleman having met with it as far north as 25° N. lat., and southward to the 35th parallel. In the province of Coquimbo, where the country is sterile, the little animal takes up its abode amongst the loose stones on the sides of the mountains, and is frequently met with in the holes of the Chinchillas. Its food consists of the herbage which grows at the roots of the hedges; in the winter months, when pressed by hunger, it feeds upon the tender bark of the *Mimosa Cavenia*, and also on that of the *Cestrum Palqui*. Mr. Bridges is inclined to believe that it breeds but twice in the year, and states that it has from four to six young at a birth.

O. Bridgesii, Bridges's Octodon. Fur very long and moderately soft; upper parts of the animal strongly pencilled with brown-yellow and black, the black prevailing on the back; abdomen white, suffused with pale brown, yellow, or cream-coloured; tail indistinctly tufted, dusky, excepting at the base beneath, where it is dirty white; feet grayish-white. It inhabits Chili, the province of Colchagua.

O. gliroides, Dormouse Octodon. Fur soft, ashy gray on the upper parts of the body, and white on the under; tail brown-black beneath to the extremity, which is somewhat tufted; feet white above.

Schizodon. — Ears moderate size; short tail, clothed throughout with short hairs: fore feet strong, the claws about equal to the toes in length; incisor teeth stout; molars each with a single deep fold of enamel on either side, dividing the tooth into two oval-shaped lobes, the long diameters of which are placed transversely, the lobes equal in size, or very nearly so, excepting in the hindermost molar of each jaw, in which the posterior lobe is considerably smaller than the rest; skull strong, rather short and broad, with a separate small canal for the infraorbital nerve; toes 5—5.

S. fuscus, Brown Schizodon. Fur tolerably long, moderately soft, and somewhat glossy; its general hue deep brown, pencilled black and yellow-brown; abdomen of a pale dirty yellow hue; feet dusky-brown. It inhabits the Southern Andes, eastern side.

Mr. Bridges, who discovered this animal, informs us that he met with it in the Valle de las Cuevas, on the eastern side of the Andes, about six leagues from the volcano of Peteroa (about 75° S. lat.), at an elevation of from 5000 to 7000 feet. Its favourite abode is stated to be in grassy situations near the mountain streams. In certain parts the ground is completely undermined by the burrows of these little animals, and whilst riding over these the horses of Mr. Bridges's party frequently plunged into the ground almost up to the hock. The valleys inhabited by the Schizodon are so elevated that they are covered with snow at least four months during the year, and Mr. Bridges is inclined to believe that, like the Spalacopus, the Schizodon lays up a store of food for the winter. It is a nocturnal animal, and it would appear lives almost entirely underground.

Spalacopus, Wagler; *Poephagomys*, F. Cuvier; *Psammoryctes*, Pöppig; *Psammomys*, Pöppig; *Bathyergus*, Pöppig. — Ears rudimentary; tail short, and clothed with short hairs; the nails of the toes of the fore feet rather shorter than the toes; incisor teeth moderately broad, those of the upper jaw distinctly directed forwards as well as downwards; molar teeth with the crowns shaped like the figure 8, the anterior and the posterior lobes being equal, excepting in the last tooth, the indenting fold of the enamel of one side of each tooth not meeting that of the opposite side; hindermost molar in each jaw smaller than the rest, and with the posterior lobe smaller than the anterior one.

S. Pöppigii, Pöppig's Spalacopus; *Poephagomys ater*, F. Cuvier, Waterhouse, Eydoux, and Gervais; *Psammoryctes noctivagus*, Pöppig and Wagner. Fur soft and very glossy, black, with an admixture of purple brown, the brown hue most distinct on the under parts of the animal; incisor teeth pale yellow, or yellow-white in front. It inhabits Chili, and lives almost entirely underground.

Ctenomys, De Blainville.—Ear rudimentary; eyes small; tail short; fore feet large and powerful, and armed with nails, which exceed the toes in length: incisor teeth very broad, the upper pair indistinctly convex in front, the lower pair flat at the same part; molars with two unequal lobes, the hindermost molar of each jaw much smaller than the rest, nearly cylindrical; skull very strong, short, and broad, the occipital portion much dilated, no separate canal for the infraorbital nerve. Geographical range from Brazil westward into Bolivia, and southward to the Strait of Magalhaens. It lives underground.

C. Braziliensis, Brazilian Ctenomys, De Blainville and others; *C. torquatus*, Lichtenstein. Fur soft, fine, and rather short, of a deep slate-gray next the skin and bright rusty-brown externally; on the under parts of the animal however the hairs are rusty-white at the point; the hairs on the feet short and harsh, as well as those of the tail, which latter are of a blackish-brown colour; hairs of the moustaches tolerably long. It inhabits Brazil, Paraguay, La Plata, and Bolivia.

There are three other species, *C. Boliviensis*, *C. leucodon*, and *C. Magellanicus*.

Sub-family *Echimyina* (*Echymidæ*, Bonaparte).—Molar teeth complicated, and these (with one or two exceptions only) rooted; malar-bone with a distinct angular process on the lower edge; both fore and hind feet with five toes.

Geographical Distribution.—One species of this section is found at the Cape of Good Hope, and a second in Western Africa. With these exceptions the group is confined to South America and the West Indian Islands. In South America the species of *Echimyina* are only known to occur in the northern and central portions; Paraguay appears to be their southern limit. On the west side of the Cordilleras none have been found.

Capromys; Isodon, Say.—Molar teeth rootless, each upper molar with a single deep fold of enamel on the inner side and two deep folds on the outer; incisor teeth narrow and convex in front; muffle broad, with a mesial longitudinal groove; upper lip slightly cleft; ears moderate; tail of moderate length, and somewhat sparingly clothed with hairs, which do not hide the scaly skin; feet naked beneath, and covered with small tubercles; nails of the toes large, and much curved; pupil of the eye vertical. But two species of this genus are known; they inhabit the island of Cuba.

C. pilorides, the Short-Tailed Capromys; *Isodon pilorides*, Say; *Capromys Fourneiri*, Desmarest. Tail shorter than the body; fur long, very harsh to the touch, strongly pencilled with black and rich yellow, or, on the hinder part of the body, with yellowish rust colour; ears, muzzle, throat, and chest, white, or nearly white; abdomen rusty yellow; toes whitish, or white; tail well clothed at the root with rust-coloured hairs, sparingly clothed with brown hairs beyond.

C. prehensilis, Prehensile-Tailed Capromys. Tail nearly equal to the head and body in length; fur moderate as to texture; on the upper parts of a mixed gray and rufous tint; neck yellowish; forehead, cheeks, and throat yellow-white; chest and abdomen white. Tail rufous at the base. Toes clothed with whitish hairs. It inhabits Cuba.

The *Capromys prehensilis* is known in Cuba by the name of Hutia Carabali, and is said to confine itself to parts of the forests which are remote from the habitations of man, and to be more shy and less tameable than the Hutia Congo, or *C. pilorides*. Like the last mentioned species it is an expert climber, and, according to M. Ramond de la Sagra, it confines itself to the uppermost branches of trees. The tail is prehensile at the extremity; and the animal, assisted by this organ, is enabled to cling with security to the small twigs of the trees, or to the parasitic plants with which they are overgrown, and amongst which it usually conceals itself.

Plagiodontia.—Molars rootless; those of the upper jaw with a single deep fold of enamel on the inner side, running obliquely forwards and inwards from near the posterior angle of the tooth, and a second deep fold entering from the outer side, near the anterior angle, and running in an opposite direction; molars of the lower jaw each with two deep folds on the outer side; toes 5—5; ears small; tail short, destitute of hair, and with a scaly skin. But one species of this genus is known, *P. Œdium*. It inhabits the Island of St. Domingo, and is evidently very nearly allied to the Capromys of the neighbouring island. Its short and naked tail, combined with certain differences observable in the structure of the molar teeth, furnish the chief distinguishing characters.

Myopotamus; Mastonotus, Wesmael.—Molar teeth semi-rooted, of which the hindermost in each jaw are the largest; each upper molar with two external and two internal deep folds of enamel; the lower molars with three internal folds and one indentation entering from the outer side; incisor teeth very large; palate much contracted between the front molar teeth; hind feet webbed; tail of moderate length, sparingly clothed with short hair.

Teeth of *Coypu*.

M. Coypus, the Coypu, *Mus Coypus*, Molina; *M. Castoroides*, Barrow; *Myopotamus Coypus*, Commerson, Geoff.; *Hydromys Coypus*, Geoff.; *Potamys Coypou*, Desmarest; *Myopotamus Bonariensis*, Rengger; *Mastonotus Popelairi*, Wesmael; *Guillinomys Chilensis*, Lesson; *Quoiuya* Azara; Coypu Rat, Shaw. Ears of moderate size; tail nearly equal to body in length; fur long; the under fur very dense and soft; upper parts of the animal pencilled with dusky and hrownish yellow, in about equal proportions; sides and under parts with the prevailing tint, brown-yellow; tip of muzzle and chin white; a yellow patch immediately beneath the ear-opening; feet dusky-brown.

Coypu Rat (*Myopotamus Coypus*).

Immatnre Specimens.—General hue rich brown, on the sides of the body inclining to yellow.

The Coypu is very nearly equal in size to the Beaver, and bears a considerable superficial resemblance to that auimal; its tail however is cylindrical, has a scaly skin, and is scantily clothed with hairs, short and stiff, like that of the Rat. It inhabits the rivers and streams of a great portion of South America, occurring on both sides of the Andes. On the eastern side it extends from Peru southward to the Rio Chupat, in 43° 20′ S. lat. In the eastern portions of Brazil the Coypu was not met with by the Prince of Nieuwied. On the west side of the Andes this animal ranges, according to Mr. Darwin, from the valleys of Central Chili (33° lat.) to 48° S., or perhaps even somewhat farther, but does not extend to Tierra del Fuego. Iu the Chonos Archipelago, Mr. Darwin states, these animals, instead of inhabiting fresh-water, live exclusively in the bays and channcls which extend between the innumerable small islets of that group. They make their burrows within the forest, at a short distance from the rocky beaches.

The inhabitants of Chiloe, who sometimes visit this archipelago for the purpose of fishing, state that the Coypus here do not live solely on vegetable matter, as is the case with those inhabiting rivers, but that they sometimes eat shell-fish. The Coypu is said to be a bold animal, and to fight fiercely with the dogs employed in chasing it. Its flesh is white and well flavoured. At Buenos Ayres an extensive trade is carried on in the skins of the Coypus, there called Nutrias, or Otters.

Cercomys.—The molar teeth of eqnal size, or very nearly so; the crowns of a rounded form; those of the upper jaw with a deep fold of enamel entering from the inner side and occupying the outer half of the tooth; molars of the lower jaw like those of the upper, but with the areas and enamel fold reversed in position; feet uormal; tail long and scaly; ears moderately large; fur moderate as to texture.

C. cunicularius, the Cercomys. Ears moderately large; tail about equal to the head and body in length; tarsus long; fur moderate as to texture; its general tint deep-brown; the sides of the body of a paler hue, and the under parts impure white. It inhabits Brazil.

Petromys.—The molar teeth very nearly equal in size and rooted; their crowns of a quadrate form, placed obliquely in the jaw, so that the inner front angle is the most forward; each tooth with a single indenting fold of enamel on either side; the folds of opposite sides meeting in the mesial line of the tooth; incisor teeth small and compressed, rather deeper than wide, and flat in front. Body clothed in fur of the ordinary kind; ears rather small, hairy; feet small; toes 5—5; the thnmb exceedingly small, but provided with a small nail. Tail about equal to the body in length, well covered with moderately long hairs, which gradually increase in length towards the apex of the organ, where they are longest.

P. typicus, the Petromys. Fur moderately long and soft; prevailing colonr rufous brown; head (with the exception of the muzzle, which is rufous) and fore parts of the body grayish-brown; throat inclining to white; abdomen palish rufous-yellow; tail of the same colour as the body at the root; the remaining portion black. It inhabits South Africa.

Dactylomys.—Four toes to the fore feet, and these armed with short convex nails; the intermediate pair of toes long. The series of molar teeth of opposite sides of the upper jaw converging and nearly meeting in front; all the molars relatively large; those of the upper jaw each composed of two separate lobes, which are contracted and pointed ou the iuner side of the tooth, and broad, and with a deep fold of enamel on the outer side; the foremost molar of the lower jaw with oue external and two internal folds of enamel, and the remaiuing molars each with two lohes, of which oue, forming the hiuder part of the tooth, is narrow and transverse: the other is broad on the inner side of the tooth, where it has a deeply indenting enamel fold.

D. typus, the Typical Dactylomys; *Echimys dactylinus*, Geoffroy, Desmarest, and F. Cuvier; *Loncheres dactylina*, Fischer. Hairs of the fur long and somewhat harsh; upper parts of the body freckled with black and yellow; under parts, as well as the head and feet, dirty yellow-white; the hairs ou the upper surface of the head very long, especially towards the hinder part; tail longer than the head and body taken together. It is probably a uative of Brazil.

Loncheres; *Nelomys*, Jourdan, I. Geoffory, and Pictet; *Phyllomys*, Lund.; *Isothrix*, Wagner.—Short and broad feet; ears somewhat small; molar teeth rather large, and longer than broad; those of the upper jaw each with two prinoipal transverse folds of enamel, often completely dividing the tooth; and those of the lower jaw with one exerual and two internal folds of enamel. Palate narrow, most so between the foremost molars.

L. cristata, White-Crested Loncheres; *Echimys cristatus*, Geoff., and Desm.; *L. paleacea*, Illiger and Lichteustein; *Nelomys cristatus*, aud *N. paleaceus*, Geoff.; *Myoxus chrysurus* (Gilt-Tailed Dormouse), Shaw; *Hystrix chrysurus*, Schreber. Upper parts and sides of the body covered with broad spines; general colour brown; dark on the back, reddish on the sides of the body, and pale on the abdomen; upper surface of the head white; the hairs on this part stiff, and very long, especially towards the occiput; region of eye and occiput black; tail black, with the apical half (or more or less) white. It inhabits Guyana and Para.

L. Blainvillii, the Black-Tailed Loncheres; *Nelomys Blainvillii*, Jourdan and Geoffroy. General hue of the whole of the animal bright sienna-yellow; chin, throat, and in fact the whole of the under parts, pure white; fore feet also white; hiud feet yellow; tail nearly as long as the head and body together, and with black hairs, excepting at the root, where the hairs are of the same yellow hue as those of the body. It inhabits Brazil, in the vicinity of Bahia, and is likewise found in a small island (island of Deos) off the coast of Bahia.

L. armata, Strong-Spiued Loncheres; *Mus hispidus*, Lichtenstein; *Nelomys armatus*, Geoffroy. Upper parts of the body armed with strong and broad spines; tail about equal to the body in length, with spines on the upper surface at the root, and scattered small whitish hairs beyond; general hue brown, but pencilled with yellow; under parts dirty pale yellow; muzzle rufous. It inhabits Guyana.

L. obscura, Dusky Loncheres. Brown freckled with yellow; belly yellowish; tail equal to the head and body in length, and provided with very short scattered hairs. It inhabits Brazil.

L. picta; *Nelomys pictus*, Pictet. Brownish-white; a large oblong browu patch on the upper surface of the head; back and shoulders, as well as the tail, brown; but the latter with the terminal portion, and likewise the basal portion beneath, dirty white; tail rather longer than the head and body taken together. It inhabits Bahia and Brazil.

Echimys (*Echinomys*), Wagner.—The feet narrow and moderately long; upper molar teeth with one internal indenting fold of enamel, and one or two folds on the outer side.

E. Cayennensis, Cayenne Echimys; *E. setosus*, Geoffroy; *E. Myosuros*, Lichtenstein; *E. leptosoma*, Lichtenstein and Brants.; *Mus cinnamomeus*, Lichtenstein; *Loncheres anomala*, Kühl; *L. Cayennensis*, Fischer; *E. longicaudatus* (?), Rengger; *Echinomys leptosoma*, Waguer. Tail nearly as long as the head and body together; ears large; tarsi long, upper parts of the body chiefly covered with spines; sides likewise with spines, but with a considcrable admixture of hairs; upper parts of the animal of a dusky brown colour; sides of the body, aud more especially of the head, suffused with rufous; under parts white. It inhabits Guyana and Brazil.

E. albispinosus, White-Spined Echimys. Tail scaly and with short hairs; head, upper parts and sides of body, with spines, those on the upper parts black at the extremity, and those on the flanks white; general hue on the upper parts brown, and of the flanks rufous; the whole under parts are pure white. It inhabits Bahia and Brazil.

E. hispidus, Strong-Spined Echimys. About equal to the Black Rat (*Mus Rattus*) in size; tail very nearly equal to the head and hody in length, and well covered with longish hairs, excepting at the base; ears small; broad and strong spines cover the whole upper parts and sides of the animal, commencing on the back of the head; upper parts rusty brown; feet, sides, and under parts of the body, rust-coloured. It inhabits Bahia and Brazil.

E. brachyurus, Short-Tailed Echimys; *E. spinosus*, Desmarest and Rengger; *Mus spinosus*, Lichtenstein; *Loncheres rufa*, Licht. Spines narrow and hidden by the fur; ears moderate; tail about as long as the body; tarsus long; general colour rich brown (pencilled black and rufous); under parts dirty white; feet dark brown. It inhabits Paraguay and Bolivia.

E. inermis, the Spineless Echimys. Feet moderately long; tail rather shorter than the head and body taken together, and clothed with long hairs, which entirely hide the scales; fur soft, and without any mixture of soft hairs; general hue brown-yellow; under parts yellowish-white. It inhabits Bahia and Brazil.

E. antricola, the Cave-Echimys; *Nelomys antricola*, Lund.; *E. apereoides*, Lund. Body stout; the muzzle thick; ears short; tail long, and well-clothed with hairs; upper parts of the animal gray-brown, with an admixture of rusty yellow: under parts white; the hairs of the fur harsh and adpressed. It inhabits the interior of Brazil.

Aulacodus.—Four toes to the hind feet; tail short; incisor teeth very broad, those of the upper jaw with one internal fold and two external folds of enamel; skull short and broad, with the occipital crest much elevated, a vertical plate on the upper part of the anterior root of the zygomatic arch, forming the outer boundary of a groove for the infraorbital opening.

A. Swinderianus, the Aulacodus, or Ground-Rat. Body covered with stiff and bristly hairs on all parts; general hue brown, pencilled with black and yellow, or sometimes with dirty yellowish-white; tail dusky above, whitish below. It inhabits Sierra-Leone, the neighbourhood of the Gambia, and South Africa.

Sub-family *Dasyproctina*. — Animals with semi-rooted molars arranged in parallel series, the cranium elongated; nasal bone destitute of a descending process on the lower edge; a tolerably distinct postorbital process formed chiefly by the frontal bone, but in part likewise by the squamosal; scapula with the emargination in the fore parts of the spine, but moderately deep; clavicles wanting; feet formed for running, with the toes 5—3 or 5—5, terminated by sub-solid nails with one but little arched; tail rudimentary; body clothed with hair only; no admixture of spines. Habitat, South America—ranging from the northernmost parts southward to Paraguay and Bolivia; occurs likewise in some of the West India Islands. The species of this sub-family will be found under AGOUTI and CŒLOGENYS.

Sub-family *Hystricina*.—This sub-family embraces the animals familiarly known as Porcupines.

The genus *Hystrix* of Linnæus embraces those Rodents whose covering consists, for the most part, of a kind of offensive and defensive armour, in the shape of spines or quills, instead of hairs.

Cuvier, who places the Porcupines between the genus *Myopotamus* and the genus *Lepus*, observes that they are to be recognised at the first glance by the stiff and pointed spines with which they are armed, after the manner of the Hedgehogs among the Carnassiers. Their molars are, he proceeds to state, four in number, with a flattened crown, variously modified by layers of enamel, which leave deep intervals; their tongue is rough with spiny scales; their clavicles are too small to be applied to the sternum and omoplate, and are only suspended by ligaments. Many of them live in burrows, and have much the habits of Rabbits. Their grunting voice, joined to their large and truncated muzzle, has, he says in conclusion, caused them to be compared to the Hog, whence their French name Porc-Epic, and, he might have added, their English appellation.

He divides the group into—1, the Porcupines properly so called (*Hystrix cristata*, Linn.); 2, *Atherura*, Cuv. (*Hystrix fasciculata*, Linn.); 3, Les Ursons, (Erétisons, F. Cuv.; *Hystrix dorsata*, Linn.); and 4, Les Coendous (Synœthères, F. Cuv.; *Hystrix prehensilis*, Linn.; and *Hystrix insidiosa*, Licht.).

Dr. J. E. Gray makes the *Hystricidæ* the second family of the order *Glires*, with the following character:—Cutting teeth two in each jaw, lower truncated; grinders 4—4 in each jaw, rooted, compound; tongue and body covered with spines; clavicles none.

† Tail short.

1. *Hystrix*. 2. *Acanthia*.

†† Tail elongated.

3. *Erythizon*. 4. *Spygurus*. 5. *Sinethurus*, F. Cuv. (*Synœtheres?*).

This family is placed by Dr. J. E. Gray between the *Muridæ* and *Leporidæ*.

Mr. Waterhouse, in his tabular view of the distribution of the *Rodentia*, laid before the Zoological Society of London, in November, 1839, makes the sub-family *Hystricina* consist of the *Hystricidæ*, the *Octodontidæ*, the *Chinchillidæ*, and the *Caviidæ*. To Europe and North Asia he gives one species of *Hystricidæ* (*Hystrix*); to North America one (*Erethizon*); to Africa one (*Hystrix*); to India and the Indian Islands two, namely, one *Hystrix* and one *Atherura*; to South America and the West Indian Islands he gives five, namely, three of *Cercolabes* and two of *Synœtheres*.

In his 'Natural History of the Mammalia' (1848), Mr. Waterhouse gives the arrangement which we have followed in this article.

Hystrix, Linn.—This genus is distinguished by the head being more or less convex, and by the development of the bones of the nose, which are very much extended; temporal and orbital fossæ very small; parietal bones depressed, occipital and sagittal crests projecting very much; tail short, not prehensile; feet plantigrade, the anterior tetradactyle, the posterior pentadactyle, armed with large nails.

M. F. Cuvier gives to the Porcupines (*Hystrix* and the Acanthions) the following

Dental formula:—Incisors, $\frac{2}{2}$; molars, $\frac{4-4}{4-4} = 20$.

Teeth of *Hystrix*. F. Cuvier.

H. cristata, the Italian or African Porcupine, or Common Porcupine. When full grown about two feet in length; longest spines exceeding a foot. General colour grizzled dusky-black, resulting from an intermixture of various shades of white, brown, and black. Upper part of the head and neck furnished with a crest of long lighter-coloured hairs capable of being raised or depressed at pleasure. Hair on the muzzle and limbs very short, almost black on the limbs; that of the neck and under parts brownish, and of considerable length. On the fore part and sides of the neck a whitish band; all the remaining parts of the back and sides, including the rump and upper parts of the hinder legs, armed with spines, which are longest on the centre of the back. The spines almost of the thickness of a goose-quill in the middle, supported at the base by a slender pedicle, and terminating in very sharp points, striated longitudinally, and ringed alternately with black and white; the rings an inch or more broad. Their usual position is lying nearly flat upon the body with the points directed backwards; when the animal is excited they are raised by means of the subcutaneous muscles almost at right angles with the body, and then present a very formidable appearance. They are not capable of being detached by the animal. The tail-quills are, as it were, cut off in the middle, and consequently open at the ends, and produce a loud rustling noise when the animal agitates its tail. (Bennett.)

This is the Ὕστριξ of Aristotle and the Greeks; and, according to Agricola, the Ἀκανθόχοιρος of the latter; *Hystrix* of the Romans; Istrice of the Italians; Porcépis of the French; Stachelschwein, Dornschwein, and Porcopick, of the Germans; and Porcupine of the British.

The Porcupine is a nocturnal animal, sleeping in its burrow during the day, and coming forth at nightfall to seek its food, consisting principally of roots, fruits, and tender leaves. Thunberg states that its usual food near the Cape, where it is called Yzer-Varken, is the root of that beautiful plant the *Calla Æthiopica*, which grew even in the ditches about the gardens; but he adds that it will frequently deign to put up with cabbages and other vegetables, and sometimes commits great depredations in those gardens. The story of its power of shooting its quills to a distance at its enemy, is merely glanced at by Aristotle ('Hist. Anim.,' ix. 39), but dwelt upon by Pliny with his usual love for the marvellous. ('Hist. Nat.,' viii. 35.) Ælian, Oppian, and Claudian have repeated this tale with exaggerations. In suddenly raising his spiny armour, a loose quill may be detached by the Porcupine; but the power of ejaculation to a distance does not exist. There are usually several openings to the Porcupine's burrow, and it hybernates, but only for a short time. Mr. Bennett quotes Thunberg, not without observation on his credulity, for the use which he was told the Ceylonese Porcupine makes of the tail-quills. Thunberg was informed that it had "a very curious method of fetching water for its young, namely, the quills in the tail are said to be hollow, and to have a hole at the extremity; and that the animal can bend them in such a manner as that they can be filled with water, which afterwards is discharged in the nest among the young."

Pennant says, "These animals produce a bezoar; but according to Seba, only those which inhabit Java, Sumatra, and Malacca. These bezoars were very highly valued, and have been sold for five hundred crowns a piece. It has also been pretended that a stone was procured from the head of this animal infinitely more efficacious than other bezoars (Tavernier); but this may be placed among the many impositions of oriental empiries." In September, 1833, the Secretary of the Zoological Society called attention to a young *Hystrix cristata* which had been recently brought forth in the menagerie, being the first instance of such an occurrence in this species, and respecting which he added that observation of the young while sucking confirmed the correctness of Blumenbach's statement that the nipple is nearly axillary.

Common Porcupine (*Hystrix cristata*).

"Histrices," says Pliny ('Hist. Nat.,' viii. 35), "generat India et Africa." Agricola, in his book 'De Animantibus Subterraneis,' remarks, "Hoc animal gignit India et Africa, unde ad nos nuper allatum est." Pennant states that it inhabits India, the sand-hills on the south-west of the Caspian Sea, Southern Tartary, Persia, Palestine, and all parts of Africa. He adds that it is found wild in Italy, and is brought into the markets of Rome, where it is eaten; but that it is not originally a native of Europe. (For this last he quotes Agricola.) The specimens from Italy are generally rather smaller, and have shorter quills.

Colonel Sykes has described a species under the name of *Hystrix leucurus* (Sayal of the Mahrattas) as *Hystrix caudâ albâ*. He states that the animal appears to be distinct from the European species, which it closely resembles in form and covering. It is nearly a third larger. All the spines and open tubes of the tail are entirely white, which is not the case in *Hystrix cristata*. The spines of the crest also are so long as to reach the insertion of the tail. The ears are much less rounded, and the nails are shorter, infinitely deeper, and more compressed, and with deep channels below. The white gular band is more marked; and, finally, the Asiatic species is totally destitute of hair—spines, where wanting, being replaced by strong bristles even down to the nails. ('Zool. Proc.,' 1830, 1831.) Mr. Hodgson notes this species among the *Mammalia* of Nepaul, as inhabiting the central and lower regions. ('Zool. Proc.,' 1834.) Mr. Waterhouse gives the two following species of *Hystrix*:—

H. Hodgsoni, Crestless Nepaul Porcupine; *H. alophus*, Hodgson. General hue brown-black; head brown; in the visible portions of the quills the black prevails over the white, but numerous very long and slender quills are almost entirely white, the spiny bristles which form the chief covering of the animal are rather long and slender, and have long hair-like points. It inhabits Nepaul.

H. Javanica, Java Porcupine; *Acanthion Javanicum*, F. Cuvier and Van der Hoven; *H. fasciculata*, Muller; *H. brevispinosa*, Wagner; *Acanthion Javanicum*, Gray. Body for the most part covered with stiff and somewhat depressed spines, which are distinctly grooved on the outer surface, and have prickly points; under half of the back and the tail covered with quills, the quills rather short, those at the end of the tail hollow, and pedunculated; general tint brown (or sometimes black), freckled with dirty-yellow; the stouter quills brownish-yellow, with a sub-terminal broad dusky ring; the longer and more slender quills with the exposed ends dirty-yellow. It inhabits Java, Sumatra, and Borneo.

Atherura, Cuv. (*Acanthion?* F. Cuv.).—Neither the head nor the muzzle convex; tail long but not prehensile; feet like those of *Hystrix*.

A. cristata, *Hystrix fasciculata*, Shaw; Le Porcépic à Queue en Pinceau, Buff.

Cuvier describes this species as having the spines of the body hollowed into a furrow forwards, and having the tail terminated by a fasciculus of horny flattened strips (lanières cornées aplaties), constricted at intervals (etranglées d'espace en espace).

Mr. Bennett ('Gardens and Menagerie of the Zoological Society') remarks, that although tolerably described and figured by Buffon, this species had been lost to science until within two years from the time he wrote (1830), when it was recovered almost simultaneously both in its original habitat and in a very distant quarter of the globe. Sir Stamford Raffles, he observes, had cursorily referred to it, and he presumes that the authority on which it was formed into a new genus by Cuvier was a skeleton and skin transmitted from India by M. Diard in the year 1823. Nearly at the same time, he tells us, a living individual was brought to England and presented to the Zoological Society by Lieutenant Vidal, who accompanied the expedition for the formation of the projected colony at Fernando Po, where these animals were found in such plenty as to afford a staple article of food to the inhabitants. It has been conjectured, he adds, on very probable grounds, that they are not indigenous in the island, but had been brought thither from the East by the Portuguese, who were formerly settled there; but he observes that the space interposed between the two regions can scarcely be regarded as conclusive evidence of their having been introduced into the colony, while there are such striking instances of animals common to India and the west of Africa as are furnished by the lion, the leopard, &c.

Mr. Bennett proceeds to state that in the teeth and in the organs of motion it corresponds, as Baron Cuvier has noticed, with the Common Porcupine, from which it differs chiefly in the form of the head; the line of its profile, instead of being elevated into a curve of large extent, passing in almost a straight direction from the occiput to the extremity of the nose. In these respects, Mr. Bennett remarks in continuation, it agrees with F. Cuvier's genus *Acanthion*, founded on this very character observed by the latter on two skulls preserved in the Paris Museum, the one from Java, the other, in all probability, from Africa. These coincidences would have induced Mr. Bennett to consider the two genera as identical, were it not that Baron Cuvier has omitted all mention of that established by his brother, although the materials for comparison were fully at his disposal. F. Cuvier moreover enumerates them both in his genera of *Mammalia*.

Mr. Bennett further observes that Linnæus founded his *Hystrix macroura* on Seba's figure; but Buffon having quoted neither Seba nor Linnæus, Dr. Shaw took it for granted that this was a different animal, and consequently gave it a new name—*H. fasciculata*. Mr. Bennett entertained however but little doubt, notwithstanding some trifling discrepancies in the figures, that Sir Stamford Raffles was right in his conjecture that they both represent one and the same species.

The following is Mr. Bennett's accurate description:—"The differences between this species and the Common Porcupine are obvious at the first glance. Its general colour is nearly the same, but with less intermixture of brown. The upper parts of the body, the outer sides of the limbs, and the head, neck, and face, are of this dusky hue; but the under parts, inside of the limbs, fore part of the neck, and throat, are of a grayish-white, with the exception of a darker band which crosses the breast in front of the fore legs. The spines commence upon the back of the head, where they are little more than an inch in length, and extend to the root of the tail, occupying nearly the whole of the back and sides. The longest are scarcely more than from four to five inches in length, and extend to the root of the tail, occupying nearly the whole of the back and sides. They are mostly white at the base and black towards the extremity, but many of them are black throughout, and others black above and white beneath. All of them are marked on the upper surface by a deep and broad groove running the whole of their length, and terminate in very sharp points. The skin in which they are implanted appears perfectly white, and where the spines are most numerous is scarcely furnished with a single hair. A few slenderer spines running into long black bristles are occasionally intermixed with the others. The greater part of the tail is bare both of hairs and spines, and covered only by flat blackish scales disposed in rings, the tip alone being surmounted by a tuft of long flat bristles having the form neither of hairs nor of quills, but bearing a close resemblance, as Buffon has aptly remarked, to narrow slips of parchment cut in an irregular manner. This tuft is of a whitish colour, and about two inches in length. The entire length of the body in our specimen is little more than a foot, and that of the tail from four to five inches. The whiskers are very long; the eyes small and black; and the ears short, round, and naked."

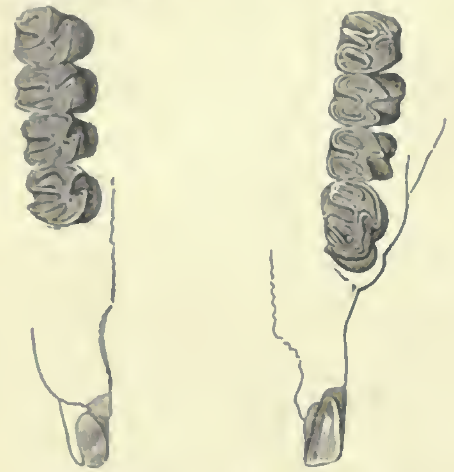
The author last quoted states that, like the rest of its tribe, this species sleeps during the day, and becomes in some degree active only on the approach of night. Its intelligence, he adds, is equally limited, and its manners equally fretful with those of the common species, like which, "it raises its spines when irritated or disturbed, stamps with its feet upon the floor of its cage, and swells and looks big in its defensive armour."

It is found in the Celebes Islands (Seba); Asia (Linn.); Malay Peninsula (Buffon); Isles of the Indian Archipelago (Pennant); Sumatra (Sir Stamford Raffles); Fernando Po (Vidal).

Erethizon (F. Cuvier).—Cranium flat; muzzle short and not convex; tail moderate; quills short and half hidden in the hair.

E. dorsatum; *Hystrix dorsata*, Linn. Ears short, hid in the fur; head, body, legs, and upper part of the tail covered with soft, long, dark-brown hair; on the upper part of the head, back, body, and tail, numbers of sharp strong quills, the longest on the back, the least towards the head and sides, the longest three inches, but all hid in the hair; intermixed are some stiff straggling hairs, three inches longer than the rest, tipped with dirty-white; under side of the tail white; four toes on the fore feet, five behind, each armed with long claws, hollowed on their under side; the form of the body is exactly that of a beaver, but is not half the size. One which Mr. Banks brought from Newfoundland was about the size of a hare, but more compactly made; the tail about six inches long. (Pennant.)

The following is from F. Cuvier's figure of the teeth of *Erethizon*, *Synœtheres*, and *Sphiggurus*.



Teeth of *Erethizon*, &c. F. Cuvier.

These animals vary in intensity of colour. Pennant alludes to one entirely white in the possession of Sir Ashton Lever.

This is the *Cavia Hudsonis*, Klein; *Hystrix Hudsonius*, Brisson; *H. pilosus*, Catesby; *H. dorsata*, Linnæus; L'Urson, Buffon; Canada Porcupine, Forster, Pennant, and others; Cawquaw of the Cree Indians; and Ooketook of the Esquimaux.

The Canada Porcupine is a sluggish animal. Hearne says that the Indians going with packets from fort to fort, often see them in the trees, but not having occasion for them at the time, leave them till their return, and should their absence be a week or ten days, they are sure to find the porcupines within a mile of the place where they had before seen them. Mr. Hutchins states that, in walking, the tail is drawn along the snow, making a deep track, which is often the means of betraying the animal; but that its haunts are most readily discovered by the barked trees on which it has fed, which if barked the same winter, are sure signs of their vicinity. They are, he says, usually found on the branches, and, on approaching them, they make a crying noise like a child. Then the tree is cut down, and the animal killed by a blow on the nose. Sir John Richardson informs us that this species is found on the banks of the Mackenzie, as high as lat. 67°, and that, according to American writers, it ranges as far south as lat. 37°. He adds, that it is said to be very rare in Virginia, but to be numerous in some parts of Kentucky; and that it is reported to have multiplied greatly, of late years, near Oneida Lake in the state of New York. (Cozzens.) Sir John Richardson further states that in the Fur Countries it is most numerous in sandy districts covered with the *Pinus Banksiana*, on the bark of which it delights to feed; that it also eats the bark of the larch and spruce firs, and the buds of various kinds of willow; and that, in the more southern districts, it is said to feed chiefly on the bark and leaves of the *Pinus Canadensis* and *Tilia glabra*, and to be fond of sweet apples and young maize, which it eats in a sitting posture, holding the food to its mouth with the fore-paws. "It is," continues Sir John, "readily attacked by the Indian dogs, and soon killed, but not without injury to its assailants, for its quills, which it erects when attacked, are rough, with minute teeth directed backwards, that have the effect of rendering this seemingly weak and flexible weapon a very dangerous one. Their points, which are pretty sharp, have no sooner insinuated themselves into the skin of an assailant, than they gradually bury themselves, and travel onwards until they cause death by wounding some vital organ. These spines, which are detached from the porcupine by the slightest touch, and probably by the will of the animal, soon fill the mouths of the dogs which worry it, and unless the Indian women carefully pick them out, seldom fail to kill them. Wolves occasionally die from the same cause. The Canada Porcupine makes its retreat amongst the roots of an old tree, and is said to pass much of its time in sleeping. When disturbed, it makes a whining or mewing noise. It pairs in the latter end of September, and brings forth two young ones in April or May. Its flesh, which tastes like flabby pork, is relished by the Indians, but is soon nauseated by Europeans. The bones are often deeply tinged with a greenish-yellow colour. Like other animals which feed on coarse vegetable substances, it is much infested by intestinal worms. The quills or spines are dyed of various bright colours by the native women, and worked into shot-pouches, belts, shoes, and other ornamental articles of dress." ('Fauna Boreali-Americana.')

Synœtheres (F. Cuvier).—Muzzle large and short; head convex in front; spines short; tail very long, naked at the end, and prehensile, like that of an Opossum (Sarigue) or of a Sapajou; feet with only four toes, armed with claws.

S. prehensilis; Hystrix prehensilis, Linn. Nose short and blunt; long white whiskers; beneath the nose a bed of small spines; top of the head, back, sides, and base of the tail, covered with spines; the longest on the lower part of the back and tail, 3 inches in length, very sharp, white, barred near their points with black; adhere closely to the skin, which is quite naked between them; are shorter and weaker as they approach the belly; on the breast, belly, and lower part of the legs are converted into dark-brown bristles; feet divided into four toes; claws very long; on the place of the thumb a great protuberance; tail 18 inches long, slender, and taper towards the end; the last 10 inches almost naked, having only a few hairs on it; has, for that length, a strong prehensile quality. (Pennant.)

This appears to be the Cuandu (major) of Marcgrave and Piso; Orico Cachero and Espinho of the Portuguese; Hoitzlacuatzin of Hernandez (?); the Brazilian Porcupine of authors.

The Brazilian Porcupine appears very much to resemble the Canada Porcupine in its habits, living in woods, sleeping by day, and feeding on fruits, &c. by night. Marcgrave states that its voice is like that of a sow. The quills are stated to have the same penetrating and destructive quality as those of the Canadian species. It is a sluggish animal, climbing trees very slowly, and holding on with its prehensile tail, especially in its descent. It grows very fat, and the flesh is said to be white and well-tasted. Our cut is taken from a living specimen in the Gardens of the Zoological Society, Regent's Park.

Brazilian Porcupine (*Synœtheres prehensilis*).

The genus *Sphiggurus* appears to be founded on the Coui of Azara.

Fossil Hystricidæ.—Cuvier ('Ossemens Fossiles,' vol. v. part 2, p. 518) states that Mr. Pentland found in the Val d'Arno, near San Giovanni, in the same sandy beds which contain so many bones of large quadrupeds, a molar tooth exactly resembling that of a great porcupine, but which appeared to be fossil. Remains of Porcupines have been found by Messrs. Falconer and Cautley in the Sewalik Hills.

HYSTRIX. [HYSTRICIDÆ.]

I

IANTHINA. [JANTHINIDÆ.]

IBACUS. [SCYLLARIANS.]

IBALIA. [GALLICOLÆ.]

IBE'RIS, a genus of Plants belonging to the natural order *Cruciferæ.* It consists of annual, perennial, and slightly shrubby species, chiefly inhabiting Europe, and particularly the northern shores of the Mediterranean Sea. It has the pouch ovate or roundish notched; valves boat-shaped, winged at the back; seeds one in each cell; petals unequal, two outer ones largest; filaments simple. Two are found in the north of Europe, one of which, *I. amara*, is British. The species are remarkable, among other things, for their flowers growing in close corymbs, and being much more developed on one side than the other, next the circumference of the corymb. This irregularity, connected with either a pure white or a rich purple of varying tints, gives the plants a strikingly beautiful appearance; and hence they are in many cases cultivated in gardens as objects of ornament, under the name of Candy-Tuft, in allusion doubtless to their having been first procured from Candia. *I. sempervirens* and *I. Gibraltarica* are particularly well-suited for beautifying rock-work.

IBERITE, a Mineral, allied to *Gigantholite.* [GIGANTHOLITE.]

IBEX. [CAPREÆ.]

IBIS. [ABOU-HANNES; TANTALIDÆ.]

IBLA. [CIRRIPEDIA.]

IBYCTER. [FALCONIDÆ.]

ICELAND-MOSS. [CETRARIA.]

ICELAND-SPAR. [CALCAREOUS SPAR.]

ICE-PLANT. [MESEMBRYANTHEMUM.]

ICE-SPAR. Transparent Crystals of *Felspar, Anorthite,* and *Ryacolite* are called by this name.

ICHNEUMON. [HERPESTES.]

ICHNEUMON, a genus of Insects belonging to the order *Hymenoptera*, section *Terebrantia*, and family *Pupivora*, in the arrangement of Latreille. The genus, as defined by Linnæus, included such pupivorous *Hymenoptera* as are furnished with veined wings (the anterior pair presenting in their disc several complete or closed cells), filiform or setaceous vibratile antennæ composed of a great number of articulations, and an ovipositor of various length and complicated structure. The Linnæan genus now constitutes a group including a great many well-marked genera and an immense assemblage of species. All these are remarkable for the habits of their larvæ, which are parasitic in the bodies of other insects. These bodies the perfect Ichneumons perforate by means of their ovipositors, and there lay their eggs. This destructive habit gave rise to the name by which they are known; a comparison being drawn between them and the Egyptian Ichneumon (*Herpestes Ichneumon*) [HERPESTES], the quadruped celebrated as the destroyer of serpents and crocodiles.

The history of these insects has attracted much attention among naturalists, and many elaborate memoirs have been written upon them. The purpose they serve in the economy of nature has been well described by Kirby and Spence: "The great body of the ichneumon tribe is principally employed in keeping within their proper limits the infinite host of lepidopterous larvæ, destroying, however, many insects of other orders. Such is the activity and address of the *Ichneumonidæ* that scarcely any concealment, except perhaps the waters, can secure their prey from them; and neither bulk, courage, nor ferocity avail to terrify them from effecting their purpose. They attack the ruthless spider in his toils; they discover the retreat of the little bee that for safety bores into timber, and though its enemy ichneumon cannot enter its cell, by means of her long ovipositor she reaches the helpless grub, which its parent vainly thought secured from every foe, and deposits in it an egg which produces a larva that destroys it. In vain does the destructive *Cecidomya* of the wheat conceal its larvæ within the glumes that so closely cover the grain; three species of these minute benefactors of our race, sent in mercy by Heaven, know how to introduce their eggs into them, thus preventing the mischief they would otherwise occasion, and saving mankind from the horrors of famine. In vain also the *Cynips*, by its magic touch, produces the curious excrescences on various trees and plants, called galls, for the nutriment and defence of its progeny; the parasite species attached to it discovers its secret chamber, pierces its wall, however thick, and commits the destroying egg to its offspring. Even the clover weevil is not safe within the legumen of that plant; nor the wireworm in the earth from their ichneumonidian foes." ('Introduction to Entomology,' vol. i. p. 267.)

The development of these parasites within the bodies of other insects was for a long time a source of much speculation among early philosophers, who fancied that occasionally one animal had the power of becoming transformed into another. The eggs of the genus *Ophion* are of a singular form, being somewhat bean-shaped and attached near one end to a long slender and curved peduncle, by which they are attached to the body of the victim. The larva itself, when hatched, retains this position, and thus lives upon the juices of the insect it attacks. The larvæ which reside like intestinal worms within the bodies of caterpillars, as the Microgastere, which infest the caterpillars of the white butterfly, carefully avoid touching the vital organs of the creature they inhabit, living only upon the fatty matter until they attain their full size and are ready to assume the pupa state, when they pierce the skin of the caterpillar (which soon dies), spin for themselves cocoons beneath its body, and undergo their transformations. The larvæ of the majority of these insects spin a silken cocoon, in which they undergo the pupa state. In some cases this is rendered unnecessary by their peculiar habits, as for instance, the *Aphidii*, which undergo their transformations within the indurated skin of the *Aphis*, of which they have devoured the interior.

The perfect insects are found flying amongst trees and plants, and especially frequenting the heads of umbelliferous flowers, whence they derive a great portion of their nourishment. Some species whose females are furnished with a very long ovipositor are found on the trunks of trees, stumps of wood, &c., evidently searching for wood-eating larvæ, in which they deposit their eggs; whereas those which have short ovipositors, seek external-feeding larvæ for the same purpose. When taken in the fingers they immediately disengage their terebra from the sheath and attempt to sting, causing a slight irritation for the moment, but so trifling is it that it is evident no very powerful poison can be introduced into the wound. They fly very rapidly. M. Wesmael has described a remarkable gynandromorphous specimen, having the head and thorax with the organs attached thereto of the female sex, while the abdomen and its appendages are masculine. In the last Linnæan edition of the 'Systema Naturæ,' 77 species were described as belonging to the genus *Ichneumon.*

Modern naturalists have elevated the genus *Ichneumon* into a family *Ichneumonidæ*, which is again divided into two sub-families *Genuinæ* and *Adscitæ.* The former comprises the largest species of the family, and is not only distinguished by having two recurrent nerves, but also by having the nerve which separates the first cubital or submarginal cell from the external discoidal cell, either entirely or nearly obliterated, whereby these two cells become confluent. No genuine *Ichneumon* has yet been described in which this structure does not exist. Moreover the second cubital or submarginal cell (the area specularis of Fallen) is very greatly reduced in size, being sometimes petiolated, but often entirely obsolete. It is in this minute area, or in the space which it should typically occupy, that the second recurrent nerve is inserted. M. Wesmael also adds the existence of an articulation between the second and third dorsal segments of the abdomen.

Amongst the *Ichneumonidæ* may be noticed the genera—*Pimpla*, in which the ovipositor and its sheathe are often greatly elongated, being in some exotic species 3 or 4 inches long; *Ophion*, having the abdomen greatly compressed and sabreshaped; *Euceros* and *Joppa* having the antennæ dilated in the middle (of the former genus males only have been observed); and *Hellwigia*, having the antennæ strongly clavate at the extremity in both sexes. The interesting genus *Agriotypus* is remarkable for its long curved petiole to the abdomen, spotted wings, and spined scutellum; the radial cell is short, whence, as well as in the form of the abdomen, it appeared to Latreille to form the connecting link between the *Ichneumonidæ* and *Proctotrupidæ.* Its palpi and the cubital cell of the fore wings however evidently prove its affinity with the true *Ichneumonidæ;* although Mr. Halliday, on account of the want of articulation between the second and third dorsal segments of the abdomen, has formed it into a distinct family; but this latter character is proved by such genera as *Chelonus, Sigalphus*, &c., to be but of secondary importance amongst the *Ichneumonidæ.*

Ichneumonides Adsciti, or *Braconidæ*, are characterised by having only one recurrent nerve, which unites with the nerve almost always present, extending between the first cubital and externo-discoidal cells; the second submarginal cell being often as large as the preceding, and not receiving a recurrent nerve; and the non-existence of articulation between the second and third dorsal segments of the abdomen.

In *Agathis* and some *Microdi* and *Microctoni* the nerve between the first cubital and externo-discoidal cell is obliterated, as in the genuine *Ichneumon.* M. Wesmael divides this sub-family as follows:—

* *Endodontes.* — Having the teeth of the mandibles directed inwardly; the mandibles meeting together when shut. Divisible into—

1. *Polymorphi.*—Clypeus entire; abdomen 6-7-jointed; posterior part of the vertex convex, second submarginal cell (when present) large.

2. *Cryptogastri.*—Clypeus entire, posterior part of the vertex convex; abdomen dorsally presenting not more than two transverse sections; second submarginal cell (when present) large.

3. *Areolarii.*—Clypeus entire; vertex more or less emarginate behind; abdomen 6-7-jointed; second submarginal cell (when present) very small.

4. *Cyclostomi.*—Clypeus deeply notched, leaving a circular aperture between it and the jaws; abdomen generally 6-7-jointed; second submarginal cell (when present) large.

** *Exodontes.*—Having the teeth of the mandibles directed outwards, the mandibles when closed not touching each other. Mr. Haliday adds as a distinct sub-family the *Aphidii* and allied genera, which have the articulation between the second and third abdominal segments flexible. Mr. Westwood however regards them as a group equivalent with Wesmael's other sections, and which it might perhaps be more natural to arrange either before or after the *Polymorphi*, with which they are united by Wesmael.

The habits of the *I. Adsciti*, or *Braconides*, present no broad distinction from the rest of the family. Many of the genera present peculiarities of structure, as for instance the coalition of the dorsal segments of the abdomen in *Chelonus*, *Sigalphus*, *Rhitigaster*, and the gaping mandibles of *Alysia*; the rostrated front of *Agathis*, and the existence of a stigma on the front margin of the posterior wings of the males in *Heterospilus* and *Hecabolus*.

(Westwood, *Introduction to the Modern Classification of Insects.*)

ICHNOCARPUS (from ἴχνος, a footstep, vestige, and κάρπος, a fruit, in reference to the slender follicles), a genus of Plants belonging to the natural order *Apocynaceæ*. It has a salver-shaped corolla, 5-cleft calyx, and inclosed stamens; sagittate anthers, free from the stigma. The species are climbing shrubs with opposite leaves; the flowers in branched terminal panicles, white, and inodorous.

I. frutescens has a twining stem, oblong-lanceolate leaves tapering to both ends, axillary peduncles very long and racemose. It is a native of Ceylon and Nepaul. The flowers are small and purple; the leaves deep green above and pale beneath. According to Dr. Royle, it is sometimes used in India as a substitute for sarsaparilla, and it is also mentioned by Afzelius in his 'Remedia Guinensia,' as a medicinal plant.

I. fragrans has oblong lanceolate leaves tapering to both ends, and axillary trichotomous spreading peduncles. It is a native of Nepaul, and has large handsome flowers.

I. Afzelii is a glabrous shrub with twining stems, oval acute leaves at the base, oblong or lanceolate as they approach the top. The corollas are white and sweet-scented. It is a native of Sierra Leone, and about the river Bascha, in woods and among bushes.

I. Loureirii has a frutescent stem, ovate oblong leaves, lateral 3-flowered peduncles. It is a native of Zanzibar. All the species of *Ichnocarpus* grow well in a mixture of loam, peat, and sand, and cuttings strike readily in sand under a hand-glass.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica.*)

ICHTHYOLOGY. The branch of science which comprehends a knowledge of the structure, nature, and forms of Fishes is thus called. The general structure and classification of Fishes is treated of in this work under the head of FISH, and all the more important and British genera will be found under their generic names, or the families to which they belong, as AMMODYTES; CORYPHÆNA; CLUPEIDÆ; SQUALIDÆ.

ICHTHYOPHTHALMITE. [APOPHYLLITE.]

ICHTHYOSAURUS, literally Fish-Lizard (Ἰχθύς: Σαῦρος), the generic name given by Mr. König to the extinct fossil animal noticed by the late Sir Everard Home, under the appellation of *Proteosaurus*, and by Wagler under the name of *Gryphus*.

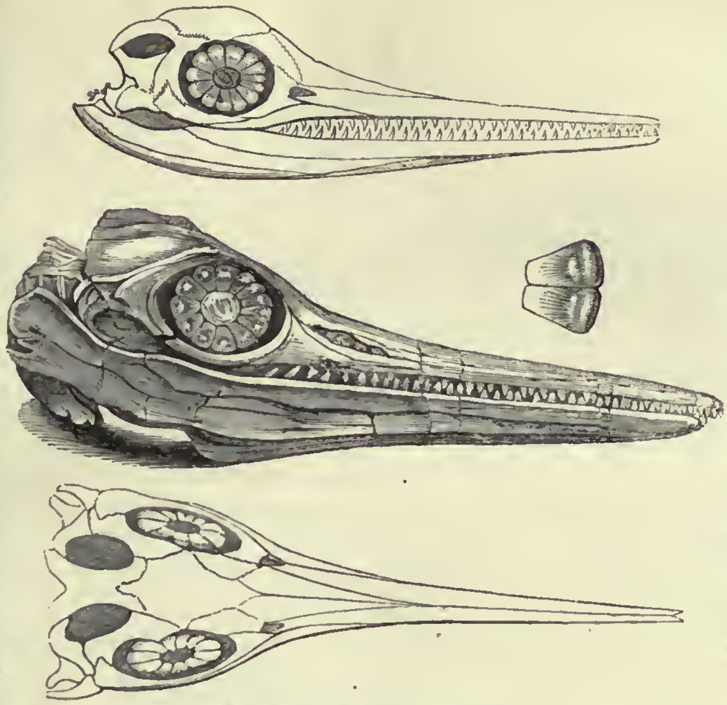
We are indebted to Sir Henry De la Beche and the Rev. W. D. Conybeare principally for pointing out and illustrating the structure of this extraordinary creature; and that at a time when the materials were far more scanty than they are at the present day. Dr. Jäger, Mr. Hawkins, Dr. Buckland, Sir Philip de Malpas Grey Egerton, and Professor Owen, have all contributed to throw light on the organisation of a being that has long ceased to exist; and the anatomy and animal economy of this tyrant of the seas of former ages is now nearly as well known as that of the porpoise which revels in the ocean that washes the shores of our existing continents and islands. We ought also to add that we are deeply indebted for an early knowledge of the remains of this creature to the indefatigable exertions of a lady—Miss Anning, of Lyme Regis, who diligently collected the first remains of the bones of the *Ichthyosaurus* from the cliffs of Lyme Regis.

"If," writes Dr. Buckland, in his 'Bridgewater Treatise,' "we examine these creatures with a view to their capabilities of locomotion, and the means of offence and defence which their extraordinary structure afforded to them, we shall find combinations of form and mechanical contrivances which are now dispersed through various classes and orders of existing animals, but are no longer united in the same genus. Thus, in the same individual, the snout of a porpoise is combined with the teeth of a crocodile, the head of a lizard with the vertebræ of a fish, and the sternum of an *Ornithorhynchus* with the paddles of a whale. The general outline of an *Ichthyosaurus* must have most nearly resembled the modern porpoise and grampus. It had four broad feet or paddles, and terminated behind in a long and powerful tail. Some of the largest of these reptiles must have exceeded thirty feet in length." We shall now endeavour to give a sketch of the organisation of these Enaliosaurians.

The osteology of the head agrees in many points with that of the crocodile, but the orbit of the eye is much larger, and the nostril is not, as in that genus, placed near the point of the snout, but near the anterior angle of the orbit, as in some other lizards. The teeth, which in some cases amount to a hundred and eighty, are not incased in deep and distinct sockets as in the crocodiles, though the rudiments of an alveolar separation may be traced in the small ridges between the teeth running along the furrow of the maxillary bone in which they are set. The succession of teeth is managed much after the same manner as that which obtains in the crocodiles [CROCODILIDÆ], the young tooth budding up at the base of the old tooth, where, as it grows, its lateral pressure sets the absorbents at work; the base of the old tooth is thus partially removed, and, as the new tooth advances, is finally displaced to make room for its more efficient successor. The elongated jaws in which these instruments of destruction are arranged are made up, as in many of the crocodiles and the other lizards, of many thin bony plates, so as to produce a union of lightness, elasticity, and strength. "It is obvious," says Dr. Buckland, in the interesting work above quoted, "that an under jaw so slender and so much elongated as that of a Crocodile or *Ichthyosaurus*, and employed in seizing and retaining the large and powerful animals which formed their prey, would have been comparatively weak and liable to fracture if composed of a single bone. Each side of the lower jaw was therefore made up of six separate pieces, set together in a manner which will be best understood by a reference to the figures. This contrivance in the lower jaw to combine the greatest elasticity and strength with the smallest weight of materials, is similar to that adopted in binding together several parallel plates of elastic wood or steel to make a crossbow; and also in setting together thin plates of steel in the springs of carriages. As in the carriage-spring or compound-bow, so also in the compound-jaw of the *Ichthyosaurus*, the plates are most numerous and strong at the parts where the greatest strength is required to be exerted; and are thinner and fewer towards the extremities, where the service to be performed is less severe. Those who have witnessed the shock given to the head of a crocodile by the act of snapping together its thin long jaws, must have seen how liable to fracture the lower jaw would be were it composed of one bone only on each side: a similar inconvenience would have attended the same simplicity of structure in the jaw of the *Ichthyosaurus*. In each case therefore the splicing and bracing together of six thin flat bones of unequal length and of varying thickness, on both sides of the lower jaw, affords a compensation for the weakness and risk of fracture that would otherwise have attended the elongation of the snout. Mr. Conybeare points out a further beautiful contrivance in the lower jaw of the *Ichthyosaurus*, analogous to the cross-bracings lately introduced in naval architecture."

Hitherto the structure of the skeleton of the *Ichthyosaurus* is, as we have seen, sauroid; but we now come to a part of its bony frame, and a very principal part, which is formed on the ichthyoid or fishy type. The vertebral column, consisting of more than one hundred vertebræ, each of which is hollow and fashioned after the manner of those of fishes, to facilitate the progress of the animal through the watery medium in which it existed, is constructed for a swimming, not a walking animal; and the sauroid type is here departed from in favour of a conformation demanded by the habits of the animal. A peculiarity in this part of the structure is noticed by Sir E. Home, the annular part of the vertebra being neither consolidated with its body, as in quadrupeds, nor connected by a suture, as in crocodiles; but remaining always distinct, and articulating by a peculiar joint, resembling a compressed oval ball-and-socket joint. Mr. Conybeare observes, in addition, that this mode of articulation co-operates with the cup-shaped form of the intervertebral joints in giving flexibility to the vertebral column, and assisting its vibratory motions; for had these parts been consolidated, as in quadrupeds, their articulating processes must have locked the whole column together, so as to render such a motion of its parts impossible; but by means of this joint every part yields to that motion. (Buckland, 'Bridgewater Treatise.')

Sir Philip Egerton, in his paper 'On Certain Peculiarities in the Cervical Vertebræ of the Ichthyosaurus, hitherto unnoticed' ('Geol. Trans.,' 1836), has demonstrated that the first and second cervical vertebræ (in some species at least) are anchylosed; and he further notices a very remarkable feature which at once distinguishes these vertebræ from the other bones of the spinal column. He shows that on the under surface of each bone there exists an unusual enlargement in the form of a solid wedge-shaped process, placed transversely to the smaller diameter of the vertebræ. By this arrangement four triangular planes are produced. "The first and largest is based upon the lower anterior margin of the atlantal socket, having its apex directed downwards and backwards until it meets the apex of a similarly-shaped though smaller plane proceeding downwards and forwards from the posterior margin of the atlas. The third, of like shape and size with the second, extends from the anterior margin of the axis, and joins the apex of the fourth, which inclines forwards from the posterior portion of the same bone. This fourth plane is considerably smaller than the others, and corresponds in size with a fifth, placed on the anterior border of the third cervical vertebra. When therefore the three anterior vertebræ are in their natural position the arrangement of the five planes is as follows:—the first and largest occupies the lower front of the atlas; the second and



Head and Sclerotic Plates of *Ichthyosaurus*.

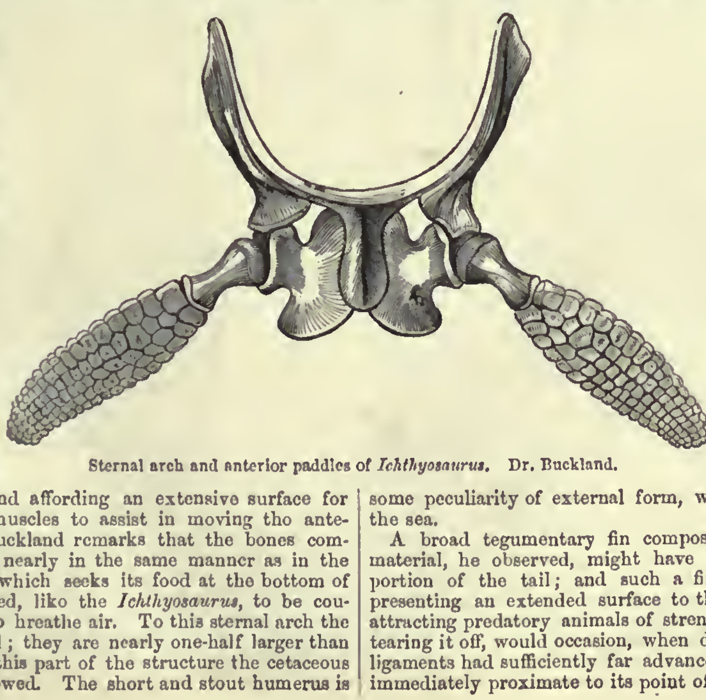
third, by the union of their bases, produce a triangular socket on the under surface of the atlas and axis; and a second smaller socket is formed between the axis and the third vertebra by a similar disposition of the fourth and fifth planes." Sir Philip adds that the second bone of the series is frequently found with the atlas and axis, and is not uncommonly fixed in its position by anchylosis. The third bone he states to be of rare occurrence, in consequence of its diminutive size, and he thinks that in some species it is probably altogether wanting. He designates these bones as Subvertebral Wedge-Bones. The reader will find in the same interesting memoir many valuable observations on the structure and articulation of the cervical vertebræ, the combined result of which, and of the reduction of the intervertebral cavities, must, as Sir Philip remarks, have been a considerable increase of power in this part of the spinal column; and he further states that, proceeding from the lumbar vertebræ towards the head, the column attains its minimum diameter about the fifth cervical vertebra, from which point to the occiput it increases in size very rapidly.

The ribs appear to be constructed more upon the sauroid type, for they are continuous along the vertebral column from the head to

Lower jaw of *Ichthyosaurus*. Dr. Buckland.

the pelvis; they are slender and mostly bifurcated at the end, and many of them are united in front across the chest. Intermediate bones, analogous to the sternal and intermediate costal cartilages in the crocodiles and the sterno-costal arcs in *Plesiosaurus*, united the ribs of the right side to those of the left. Dr. Buckland is of opinion that this structure was probably subservient to the purpose of introducing into their bodies an unusual quantity of air, the animal being by these means enabled to remain long beneath the water without rising to the surface for the purpose of breathing.

In the sternum we find a combination of bones admirably adapted for resistance. Of this part of the bony framework Mr. Conybeare says,—"The form of the sternal arch and the broad surfaces of the clavicles is such as to impart great strength to the chest, enabling the animal to breast the most disturbed waters, and affording an extensive surface for the attachment of powerful muscles to assist in moving the anterior extremities;" and Dr. Buckland remarks that the bones composing this arch are combined nearly in the same manner as in the *Ornithorhynchus* of Australia, which seeks its food at the bottom of lakes and rivers, and is obliged, like the *Ichthyosaurus*, to be continually rising to the surface to breathe air. To this sternal arch the anterior paddles are articulated; they are nearly one-half larger than the posterior paddles, and in this part of the structure the cetaceous type appears to have been followed. The short and stout humerus is followed by the bones of the fore arm; and these are succeeded by numerous regularly-disposed polygonal bones, exceeding, in some species, the number of one hundred, which form the paddle or fin. In form these bones differ both from the phalanges of lizards and whales.



Sternal arch and anterior paddles of *Ichthyosaurus*. Dr. Buckland.

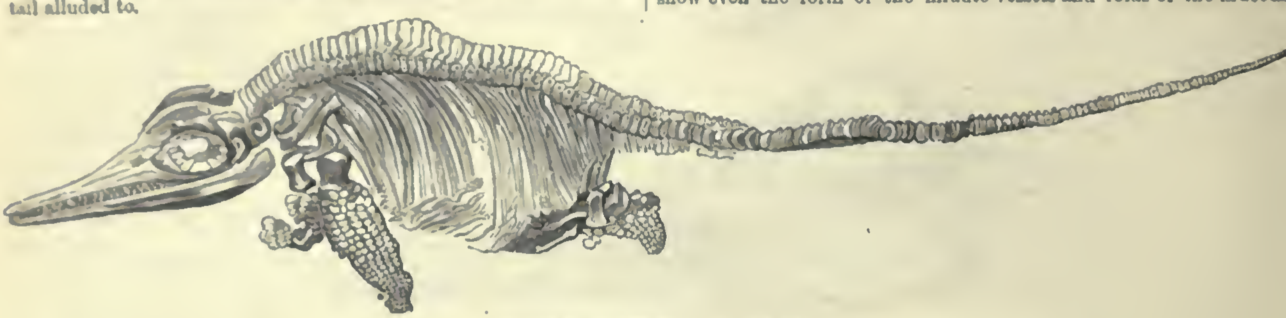
The bones of the pelvis closely resemble those of the crocodile, and, as Sir H. De la Beche and Mr. Conybeare observe, the femoral bone and posterior paddle are altogether analogous to the humerus and anterior paddle; but, contrary to the development of the posterior extremities of quadrupeds in general, they are very considerably smaller, nearly in the proportion of one to two.

Dr. Buckland, with reference to the posterior extremities, or paddles, observes, that these are wanting in the Cetaceans, and that they possibly compensate for the absence of the flat horizontal tail with which those animals are furnished. In a paper, 'On the Dislocation of the Tail, at a certain Point, in the Skeletons of many Ichthyosauri,' read by Professor Owen, before the Geological Society of London, the author commenced his observations by referring to the skeleton of the existing *Cetacea*, and pointing out how slight is the indication afforded by the caudal vertebræ of the large terminal fin, which forms in that class so important an organ of locomotion; and the improbability that its presence would have been suspected had the *Cetacea* been known only by their fossil remains, in consequence of the fin having consisted entirely of decomposable and unossified material.

He stated that the depressed flattened shape of the terminal vertebræ, which gives the only indication of the horizontal fin (and which character is not present in all the *Cetacea*), is not recognisable in the skeletons of the *Ichthyosauri* and *Plesiosauri*; but he proceeds to describe a condition of the tail in the skeletons of the *Ichthyosauri* which, he conceives, affords an indication of a structure in the extinct animal analogous to the tegumentary fin of the *Cetacea*, and which has not been suspected by the authors of the conjecturally-restored figures of the *Ichthyosauri* already published. The condition alluded to is described as an abrupt bend of the tail, about one-third of its whole length distant from the end, and at the 30th caudal vertebra in the *Ichthyosaurus communis*; the broken portion continuing beyond the dislocation as straight as in the part which precedes it. As there is no appearance of a modification of structure in the dislocated vertebræ, indicative of the tail having possessed more mobility at that point than at any other, and as the dislocation has taken place at the same point in seven specimens examined by the author, he conceives that it must be due to some cause operating in a peculiar manner on the dead carcass of the *Ichthyosaurus*, in consequence of some peculiarity of external form, while it floated on the surface of the sea.

A broad tegumentary fin composed of dense but decomposable material, he observed, might have been attached to the terminal portion of the tail; and such a fin either by its weight, or by presenting an extended surface to the beating of the waves, or by attracting predatory animals of strength sufficient to tug at, without tearing it off, would occasion, when decomposition of the connecting ligaments had sufficiently far advanced, a dislocation of the vertebræ immediately proximate to its point of attachment. The two portions of the tail, with the rest of the skeleton, would continue to be held together by the dense exterior integument, until the rupture of the parietes of the abdomen at some yielding point had set free the gases generated by putrefaction; and the skeleton, having undergone certain partial dislocations, from the decomposition of the more yielding ligaments, would subside to the bottom, and become imbedded in the sedimentary deposits, exhibiting the fracture of the tail alluded to.

Treatise' (pl. 14), which shows a large mass of fish scales, chiefly referrible to the *Pholidophorus limbatus*, intermingled with coprolites throughout the entire region of the ribs, and in the more matured coprolites themselves. Dr. Buckland, to whom we are indebted for the history of these curious bodies, says, speaking of the intestinal canal of the *Ichthyosauri*:—"Besides the spiral structure and consequent shortness of the small intestine, we have additional evidence to show even the form of the minute vessels and folds of the mucous



Ichthyosaurus communis. Dr. Buckland.

With respect to the relative position of this conjectured caudal tegumentary fin of the *Ichthyosaurus*, Professor Owen could not perceive any indication of its horizontality in the forms of the vertebræ which he supposes to have supported it; and he regards the superaddition of posterior paddles in these air-breathing marine animals as a compensation for the absence of that form of fin which is so essential in the *Cetacea*, for the purpose of bringing the head to the surface of the sea to inhale the air. On the other hand a vertical caudal fin seems especially required by the short-necked and stiff-necked *Ichthyosauri*, in order to produce with sufficient rapidity the lateral movements of the head, which were needed by those predatory inhabitants of the ancient deep; while in the *Plesiosaurus* such a fin would be unnecessary, in consequence of the length and mobility of the neck; and Professor Owen concluded by stating, that in those skeletons of *Plesiosauri* in which the tail is perfect it is straight, and presents no indication of the partial fracture or bend which is so common in the tails of *Ichthyosauri*.

Figures of the tails of five specimens of *Ichthyosauri*, belonging to the species *I. communis*, *I. tenuirostris*, and *I. intermedius*, accompanied the paper.

Professor Owen has since ascertained that the terminal caudal vertebræ of the *Ichthyosaurus* are compressed or flattened from side to side in a remarkable degree; a circumstance, he observes, confirming the accuracy of the conjecture of the verticality of the caudal fin, and the best proof perhaps of its actual presence in the living animal.

That the *Ichthyosauri* enjoyed the sense of smelling in a considerable degree can hardly be doubted from the structure and position of the nostrils, nor is there any reason for supposing that they were not gifted with the sense of taste; but their power of vision must have been great, and indeed Dr. Buckland justly speaks of the enormous magnitude of the eye as very much exceeding that of any living animal, and as being the most extraordinary feature of the head. He alludes to a skull of *Ichthyosaurus platyodon* in the collection of Mr. Johnson at Bristol, and remarks that in this specimen the longer diameter of the orbital cavity measures fourteen inches. The eye has, as Mr. Conybeare remarks, its sclerotica composed of a bony or rather scaly substance, subdivided into thirteen plates, as will be seen in the cut (cols. 201, 202), where two of these plates are represented separately. Mr. Conybeare, in the passage to which we have referred, goes on to state that he had then before him the eye of a middle-sized lizard from Germany, which has a structure exactly similar, excepting that the plates were more numerous: this, he states, was pointed out to him by the late Mr. Miller; and he adds that the Chameleon and *Iguana* have similar osseous laminæ, as has the Tortoise, but that in this latter animal they form, as in birds, the anterior disc. This conformation was highly important to the adjustment of an organ whose functions were demanded both above and below the surface of the water. [BIRDS.] The sense of hearing appears to have been sufficiently developed, and that of touch was probably about upon a par with the sensations of the modern cetaceans.

An enormous expansion of the jaws, which were so constructed as to bear the shock of the most violent collision, and were furnished with a constant succession of teeth, formed an organ of seizure well fitted to the voracity of an animal that not only preyed upon fishes and other marine animals, but, like the ravenous pike of our fresh-waters, fed upon its own congeners and even species. The prey was transmitted into a stomach, which must have been nearly co-extensive with the cavity of the body, and the contents were thence made to pass through an intestinal canal which appears to have resembled, as Dr. Buckland observes, the spiral intestines of some of the swiftest and most voracious of our modern fishes.

The evidence upon which this assertion is made is to be found in various specimens, like that in the Oxford Museum, from the lias at Lyme Regis, and figured by Dr. Buckland in his 'Bridgewater

membrane by which it was lined. This evidence consists in a series of vascular impressions and corrugations on the surface of the coprolite, which it could only have received during its passage through the windings of this flat tube. If we attempt to discover a final cause for these curious provisions in the bowels of the extinct reptile inhabitants of the seas of a former world, we shall find it to be the same that explains the existence of a similar structure in the modern voracious tribes of sharks and dog-fishes. As the peculiar voracity of all these animals required the stomach to be both large and long, there would remain but little space for the smaller viscera; these are therefore reduced, as we have seen, nearly to the state of a flattened tube, coiled like a corkscrew around itself; their bulk is thus materially diminished, whilst the amount of absorbing surface remains almost the same as if they had been circular. Had a large expansion of intestines been superadded to the enormous stomach and lungs of the *Ichthyosaurus*, the consequent enlargement of the body would have diminished the power of progressive motion, to the great detriment of an animal which depended on its speed for the capture of its prey. The above facts, which we have elicited from the coprolitic remains of the *Ichthyosauri*, afford a new and curious contribution to our knowledge both of the anatomy and habits of the extinct inhabitants of our planet. We have found evidence which enables us to point out the existence of beneficial arrangements and compensations even in those perishable yet important parts which formed their organs of digestion. We have ascertained the nature of their food and the form and structure of their intestinal canal; and have traced the digestive organs through three distinct stages of descent, from a large and long stomach, through the spiral coils of a compressed ileum, to their termination in a cloaca, from which the coprolites descended into the mud of the nascent lias. In this lias they have been interred during countless ages, until summoned from its deep recesses by the labours of the geologist to give evidence of events that passed at the bottom of the ancient seas in ages long preceding the existence of man." ('Bridgewater Treatise.')

Coprolite of *Ichthyosaurus.* Dr. Buckland.

a, Magnified scale of *Pholidophorus limbatus* imbedded therein (internal view); *b*, external view of the same.

The external integument appears to have been a simple naked skin unprotected by any defence; it probably resembled in some degree the dermal covering of the cetaceans.

The structure of these reptiles have been sometimes referred to as supporting the doctrine of the transmutation of species, and these animals have been regarded as transitionary forms from the Fish to the Reptile. Professor Owen thus refers to this opinion, in his 'Report on British Fossil Reptiles,' made to the British Association in 1839 and 1840 :—

"The nearest approximation to the organisation of fishes is made by the *Ichthyosaurus*, an extinct genus which appears to have been introduced into the ancient seas subsequent to the deposition of the strata inclosing the remains of the thecodont lizards. The ichthyic characters of this genus of marine Saurians are not of a very important kind, being limited, like modifications of the mammalian type in whales, to a relationship with locomotion in water, while all the modifications of the skeleton which are connected with the respiratory, digestive, or generative functions, are conformable with the highest or Saurian type of reptiles—such as the cranial anatomy (the large size of the intermaxillary bones excepted), the dental structure, which corresponds with that of the posterior teeth in alligators; the articulation of the neurapophyses to the bodies of the vertebræ; the complicated pectoral arch; the sternum, and complete abdominal cincture of ribs, &c. The circle of numerous imbricated sclerotic bones reaches its maximum of development in the *Ichthyosaurus*; but this is an exaggeration of a structure feebly shadowed forth in some existing Saurians, and more strongly shown in birds, rather than a repetition of the simple bony sclerotic cup in fishes. By no known forms of fossil animals can we diminish the wide interval which divides the most sauroid of fishes from an *Ichthyosaurus*. This most extraordinary reptile is a singular compound in which ichthyic, cetacean, and ornithic characters are engrafted upon an essentially Saurian type of structure. The *Ichthyosaurus* is therefore just such a form of animal as might be expected, were specific forms unstable, to demonstrate a mutation of characters or some tendency towards a progressive development into a higher and more consistent type of organisation; nor is the field for testing the transmutation theory less ample than the subject is favourable. We have the opportunity of tracing the *Ichthyosauri*, generation after generation, through the whole of the immense series of strata which intervene between the new red-sandstone and the tertiary deposits. Not only however is the generic type strictly adhered to, but the very species which made its first abrupt appearance in the lowest of the oolitic series maintains its characters unchanged and recognisable in the highest of the secondary strata. In the chalk formations, for example, the genus *Ichthyosaurus* quits the stage of existence as suddenly as it entered it in the lias, and with every appreciable osteological character unchanged.

"In the different species of the *Ichthyosaurus* founded upon minor modifications of the skeleton, several appear contemporaneously in the strata where the genus is first introduced; and those which remain the longest manifest as little change of specific as of generic characters. There is no evidence whatever that one species has succeeded or been the result of the transmutation of a former species. The tenuirostral *Ichthyosaurus* existed at the same time, and under the same external influences, as the stronger and shorter-jawed *Ichthyosaurus communis*; just as the tenuirostral *Delphinus Gangeticus* co-exists at present with the short-jawed porpoise.

"If the relative periods of existence of the different Enaliosaurian reptiles were not well ascertained, and room were allowed for conjecture as to their successive appearance on this planet, it would be as easy as seductive to speculate on the metamorphoses by which their organic framework, influenced by varying conditions during a lapse of ages, might have been gradually modified, so as to have successively developed itself from an Ichthyosaur to a Plesiosaur, and thence to a Crocodile.

"We may readily conceive, for example, the fish-like characters of the vertebral column of the *Ichthyosaurus* to have been obliterated by a filling up of the intervertebral cavities through ossification of the intermediate elastic tissue, and the Plesiosaurian type of vertebra to be thus acquired. The normal digits of the fin might be supposed to become strengthened and elongated by more frequent reptation on dry land, and thus to cause an atrophy of the supernumerary fingers; phalanges of a more saurian figure might have been produced by the confluence of a certain number of digital ossicles; the head might be shortened by a stunted growth of the intermaxillary bone, and thus be reduced to Plesiosaurian proportions. The teeth might become more firmly fixed by the shooting of bony walls across their interspaces, as in the young Crocodiles.

"If we now elongate the bodies of the vertebræ, reduce some twenty pairs of anterior ribs to hachet-bones, place the fore paddles at a corresponding distance from the head, and the hind paddles proportionately nearer the tail, little more will be required to complete the transmutation of the Ichthyosaur into the Plesiosaur. If next, in adaptation to a gradual change of surrounding circumstances, the jaws of the Plesiosaur become lengthened to the proportions of those of the Tenuirostral Ichthyosaur, but at the expense of the maxillary instead of the intermaxillary bones, preserving the socketed implantation of the teeth; if, to balance the elongation of the jaws the neck at the same time shrank to nearly its former Ichthyosaurian proportions, with some slight modification of the Plesiosaurian type of the vertebræ; if a further development and a more complete separation of the digits of the fore and hind members were to take place, so that they might serve for creeping as well as swimming; if the exposure of the surface to two different media, and of the entire animal to perils of land as well as of sea, were to be followed by the ossification of certain parts of the skin, and the acquisition by this change of a dermal armour—such we might conceive to be the leading steps in the transmutation of the Plesiosaur into the Teleosaur.

"And if the three forms of extinct Saurians, whose changes of specific and generic characters have thus been speculated on, had actually succeeded each other in strata successively superimposed in the order in which they have here been hypothetically derived from one another, some colour of probability might attach itself to this hypothesis, and there would be ground for searching more closely into the anatomical and physiological possibilities of such transmutations. *Ichthyosaurus*, *Plesiosaurus*, and *Teleosaurus* are however genera which appear contemporaneously on the stage of vital existence: one neither preceded nor came after the other. How the transmutation theory is to be reconciled to these facts is not obvious; nor to these other, viz., that the Teleosaur ceases with oolite, while the Ichthyosaur and Plesiosaur continue to coexist to the deposition of the chalk, and disappear together alike unchanged; the Ichthyosaur manifesting as little tendency to develop itself into a Plesiosaur, as this to degrade itself into the more fish-like modification of the Enaliosaurian type."

One of the finest collections of the remains of these animals existing is that in the British Museum. Altogether "there are about thirty very fine specimens, including the most interesting of the separate crania, paddles, vertebral columns, &c., besides a great number of isolated bones, parts of skulls and jaws, coprolites, and other remains of *Ichthyosauri*." (Mantell.)

The following are the species of this genus which have been at present made out:—

I. tenuirostris (Conybeare). It is characterised by the great length and slenderness of the jaws, which resemble in this respect the maxillary organs of the Gavial, or *Teleosaurus*. The length of the mouth is produced by the elongation of the intermaxillary bones and of the dentary bones of the lower jaw. The malar bone is remarkably long and slender. The cranium is flat, and the orbits are very large. The teeth slender, 60 to 90 on each side the upper jaw, and 60 on each ramus of the lower jaw. The anterior extremities, or paddles, are much larger than the posterior pair, and very strong and massive. The shafts of the humerus and femur are relatively long, and their distal ends broad. This species attains a length of 13 or 14 feet; the largest teeth are an inch and a half in length. It was named by Mr. Hawkins *I. chirostrongulostinus* (Round-Boned-Paddle Fish-Lizard). It is figured in his remarkable work on these creatures.

I. intermedius (Conybeare). The teeth are more acutely conical than in *I. communis*, and the striæ less prominent, but are less slender than in the preceding species. The maxillary portion of the skull is relatively shorter, and converges more regularly to the front than in *I. communis*, and the teeth are longer, more slender, and numerous. This species has been the most commonly found, and ranges throughout the Lias formation of England. There are two specimens in the British Museum, one 7 feet in length, the other 6 feet.

I. longipennis. The species thus named in the British Museum is from the Lias of Whitby in Yorkshire. Dr. Mantell says that he is not aware of any description of this species.

I. communis (Conybeare). The skull is wide behind, and rapidly contracts to the base of the jaws, which are prolonged and sub-compressed. The teeth are relatively large, round, conical, and longitudinally furrowed, the base being expanded and deeply grooved, 40 to 50 on each side the upper jaw, and 25 to 30 in each ramus of the lower jaw. The anterior paddles are three times longer than the posterior pair, and are proportionately broader, and contain a greater number of ossicles than in other species. This character induced Mr. Hawkins to call it *I. chiropolyostinus* (Many-Boned-Paddle Fish-Lizard). There are 8 metacarpal bones and 212 ossicles. The humerus is relatively shorter and stouter than in any other species. It has 17 sclerotic plates to the eye. This is one of the larger species of the genus, as some of the specimens indicate a length of 14 feet. It is supposed this species had a large tegumentary caudal fin, which is rendered probable by the laterally compressed form of the terminal caudal vertebræ, as first ascertained by Sir Philip Egerton.

I. platyodon (Conybeare). This is the largest of the species, and specimens have been procured 30 feet in length. The orbit in some specimens is 1 foot in diameter, and the teeth $2\frac{1}{2}$ inches in length. The teeth are distinguished by the form of the crown, which is conical and subcompressed, and has a sharp ridge on each side; the base is not grooved as in the teeth of *I. communis*. This character of the teeth suggested the specific name. The dental formula is $\frac{45-45}{40-40}$. The vertebræ are about 120 in number. The anterior and posterior paddles are equal in size. This structure induced Mr. Hawkins to name this species *I. chiroligostinus* (Few-Boned-Paddle Fish-Lizard). The humerus is short in proportion to its breadth. The femur is proportionately larger than in other species.

I. lonchiodon (Owen). The teeth are more slender in proportion to their length than in the other species. Their base is cylindrical and regularly fluted; the transverse section of the crown is nearly circular, not compressed. The paddle is relatively less than in the last species.

A specimen of this species in the British Museum measures 15 feet in length, and was obtained by Miss Anning at Lyme Regis. The great interest of this fossil consists in the fact that the parts of the os hyoides are in a state of preservation.

I. longirostris. A specimen from Whitby is about 6 feet in length. It has a remarkably slender and elongated muzzle. It is not otherwise in a well-preserved condition, and Dr. Mantell says that it is not figured or described.

I. latifrons (König). It is characterised by the great breadth of the fore part of the cranium and the large size of the parietal foramen. The periphery of the vertebræ is flatter than in those of other species. The upper portion of the circle of sclerotic plates remains in the orbit in the specimen in the Museum.

With regard to the geological distribution of these animals, they abound throughout the Lias and Oolitic Formations. The chief repository has been hitherto considered to be in the Lias at Lyme Regis, but, as Dr. Buckland states, they abound along the whole extent of this formation throughout England, from the coasts of Dorset, through Somerset and Leicestershire, to the coast of Yorkshire. The Lias of Germany and France contains them. "The range of the genus *Ichthyosaurus*," says Dr. Buckland, "seems to have begun with the Muschelkalk, and to have extended through the whole of the Oolitic period into the Cretaceous Formation. The most recent stratum in which any remains of this genus have yet been found is the Chalk Marl at Dover, where they have been discovered by Dr. Mantell: I have found them in the Gault near Benson, Oxon." ('Bridgewater Treatise.')

ICHTHYOSIA'GONES (Rüppel), one of the many names (as *Aptychus*, Von Mayer; *Solenites* and *Tellinites*, Schlotheim; *Trigonellites*, Parkinson; *Lefadites*, Germar) which have been given to the pair of shelly bodies found in many of the Oolitic Rocks, and not unfrequently in the mouths of *Ammonites* at Solenhofen, so as to prove their connection with the animal which inhabited that shell. By Ruppell and Voltz they were conceived to form an operculum. The two valves meet on a strait toothless hinge-line, their free edges forming the remaining two sides of a triangle rounded at its apex. The substance of the shell is transversely fibrous; its inner surface concentrically striated with lines of growth. (Parkinson, *Org. Rem.*, pl. xiii. fis. 9, 10, 12.)

I'CICA, a genus of Plants belonging to the natural order *Burseraceæ*. It has a small obtusely 5-toothed calyx; 5 petals inserted under the disc, recurved, sessile, valvate; 10 stamens shorter than the petals inserted with them; a cup-shaped disc with 10 crenatures at the margin; a sessile 5-celled ovary with two collateral pendulous ovules in each cell; a very short style; a 5-angled stigma; a globose obtuse 1-3-celled drupe with thick and fleshy dissepiments; resinous seeds without albumen. The species are shrubs or trees with unequally pinnate leaves, and white flowers seated on panicled racemes which are terminal or axillary.

I. heterophylla has ternate or pinnate leaves, with stalked, ovate, acuminated, entire, simply-veined leaflets; the racemes simple, rather shorter than the leaves. This plant is the *I. Aracouchini* of Aublet. It is a tree 50 feet in height, growing in Guyana, on the banks of the river Conron, where it is called by the natives Aracouchini. When an incision is made in the bark of this tree a yellow balsamic aromatic fluid exudes, which retains its fluidity a long time after exposure to the air. This fluid is used by the Guyanese as an application to wounds. A resin is found also in the seeds, and the natives of Guyana carry the nuts about with them on account of the scent they give out. These nuts they often send as presents to their friends. The Caribs also use the exudation for mixing with oil, with which they anoint their bodies.

I. heptaphylla has 5-7-stalked oblong acuminated leaflets, with the racemes few-flowered, somewhat corymbose, and six times shorter than the petiole. It is a small tree, a native of the woods of Guyana, where it is called Arbre d'Encens. The whole plant is sweet-scented, and like the last species yields a clear balsamic fluid when it is wounded. It is burned as a perfume, and used as a remedy in dysentery. The seeds are contained in a viscid pulp which hardens into a gray resin, and is used by the natives for burning as a perfume. The Carib name of this tree is Arouaou.

There are several species of *Icica*, all of which yield the same transparent fluid, resembling turpentine in many of its properties. *I. Icicariba*, a native of Brazil, yields a resin, which is brought into the market under the name of Gum Elemi, but is not the true gum of that name. *I. decandra* is found in the woods of Guyana, where it is called Chipa. The fluid which exudes from it yields on evaporation a resin. *I. altissima* grows in Guyana. There are two varieties of this tree, known by the name of White Cedar and Red Cedar. The latter is a very durable wood, and is used for making household furniture, boats, canoes, &c.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*; Lindley, *Flora Medica*.)

ICOSA'NDRIA, one of the classes in the sexual system of Botany invented by Linnæus. The name literally means 20 stamens, but it was only applied by Linnæus to plants having an indefinite number of stamens inserted into the calyx.

ICTERIA. [MERULIDÆ.]
ICTERUS. [STURNIDÆ.]

I'CTIDES, a name given by M. Valenciennes to the Benturongs, a genus of Plantigrade *Mammalia*, which F. Cuvier had previously referred to the genus *Paradoxurus*. It is the *Arctictis* of Temminck.

F. Cuvier, in his 'Dents des Mammifères,' states that he published, under the name of *Paradoxurus albifrons*, in the 9th volume of the 'Mémoires du Muséum,' the figure of an animal which had been sent to him from Calcutta by M. Alfred Duvaucel; and that he conjectured, from the external characters and the general physiognomy, that the animal which it represented belonged to the genus *Paradoxurus*. Having subsequently examined the teeth (an examination which he states he owed to M. Valenciennes, who had found the skin and the head of the animal in the cabinet of Brussels, and had obtained them through the complaisance of the director, M. Drapier), F. Cuvier states that there is much resemblance in the dentition to that of *Paradoxurus*. *Ictides* belongs, he thinks, to the family of Civets, which is characterised by a tubercular molar tooth in the lower jaw, and by two similar molars in the upper jaw; and he thinks that it is 'sans contredit' most approximated to *Paradoxurus*, though it approaches *Procyon* nearer than that genus, that is to say, the teeth of *Ictides* show an increase of thickness, and have become more tuberculous. He places it between the Civets, &c., and the Suricates.

Cuvier, who gives *Ictides* a position between *Ailurus* [PANDA] and the Coatis (*Nasua*), says that it still bears some resemblance to *Procyon* in its dentition; but he remarks that the last three molars of the upper jaw are much smaller and less tuberculous, and that this is especially true of the last of all in each jaw, which is very small and nearly simple.

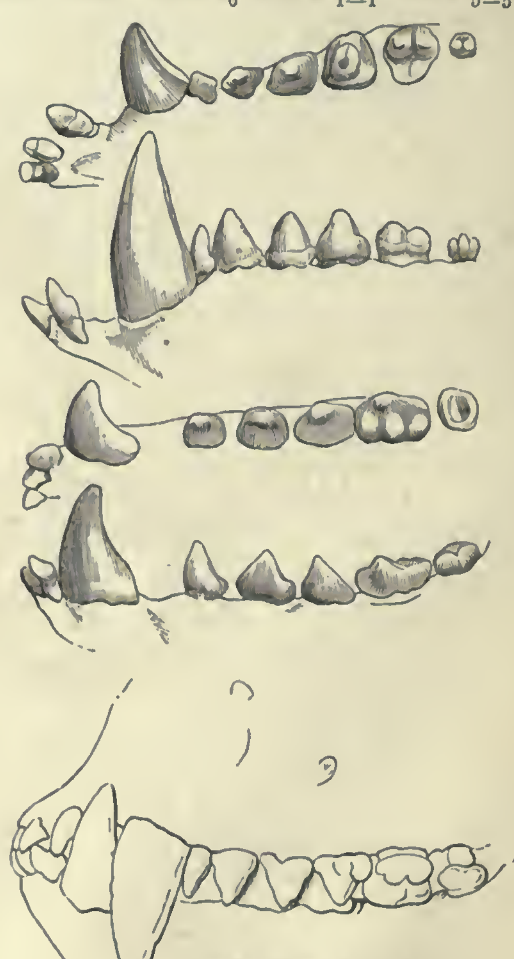
Dr. J. E. Gray gives *Arctictis* as a synonym of *Ictides*, in his subfamily *Viverrina*, the fourth of his family *Felidæ*.

M. Lesson thinks that the genus approaches nearer to *Procyon* than to *Paradoxurus*, but he arranges it between *Ailurus* and *Paradoxurus*.

Mr. Swainson, adopting Temminck's name, which, if it appeared first with a generic description, ought to be retained, makes the form the first genus of his family *Didelphidæ*, or Opossums, observing that it is not marsupial.

It has the following characters:—Head rather short, muzzle pointed; ears, which are small, tufted with long hairs; tail long, hairy, prehensile; feet with five toes on each foot.

Dental Formula:—Incisors, $\frac{6}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{5-5}{5-5} = 36$.



Teeth of *Ictides*. F. Cuvier.
One-sixth larger than nature.

The author of the 'Analytical Notice of Books' ('Zool, Journ.,' vol. ii.) says, when reviewing the 'Histoire Naturelle des Mammifères,' Nos. xli.-l., that between the Viverrine Family and that which is composed of the Racoons and Bears there had existed a considerable gap, which is now in a great measure filled up by the newly discovered forms, the Benturong and the Pauda. The external appearance, he remarks, of the *Ictides* corresponds in some degree with both that of the civets and racoons, having the plantigrade motion of the latter and the slender snout of the former. It is indeed completely plantigrade, and has on each foot five toes armed with strong compressed claws, apparently adapted for climbing. "Its tail, the thickness of which at its commencement is almost monstrous, is prehensile beneath, without being terminated by a naked skin, like that of *Ateles*, but resembling entirely the tail of the Sajous. The eye, like that of the domestic cat, has the pupil vertically elongated; the habits of the *Ictides* are consequently nocturnal. The ears are small and rounded; and the nostrils are surrounded by a muzzle, which is divided into two portions by a deep sulcus. The hairs are long and thick, and a peculiar character is given to the physiognomy by the moustaches, which are very voluminous on the lips, the eyes, and the cheeks, and by the pencil of long and numerous hairs which terminates the ears. The cry is intermediate between those of a cat and a dog." The species are found in India.

I. albifrons. Fur gay; hairs long, silky, black at the base, and white in their extreme third, shorter on the head and limbs; sides of the snout, forehead, pencils of the ears (which are edged with white), black; upper part of the snout and forehead white; iris yellow; belly gray, with shorter hairs than those on the upper parts of the body. Size, that of a very large domestic cat. In another specimen the sides of the snout, and the tail, its extremity excepted, were gray. It inhabits Bootan, Nepaul (Kâchar: though they occasionally occur in the central region of Nepaul. Hodgson).

Sir Thomas Stamford Raffles describes the gait of this Benturong as low and crouching, the body being long and heavy, and the legs short. The tail, thick at its insertion, gradually tapers to the extremity, where it curls upwards. In climbing trees the animal is assisted by this tail, which is strong. One that was kept alive many years by Major Farquhar partook both of animal and vegetable food. Slow in motion, and timid in disposition, the animal sleeps much during the day: the night is the season of its comparative activity. Two other species have been described.

ICTINIA. [FALCONIDÆ.]

IDALIA. [NUDIBRANCHIATA.]

IDE, a Fish. [LEUCISCUS.]

IDIA, Lamouroux's name for a genus of recent *Polyparia*, allied to *Sertularia* (Linn.).

IDMO'NEA, a genus of Animals belonging to the order *Polyzoa*, described by Lamouroux as closing the group *Milleporidæ*. It is ramose, the branches triquetral in section, celluliferous on two faces, cells prominent in transverse rows. One species, the *I. atlantica*, inhabits the British seas. Several have been found fossil in the Oolite and Calcaire Grossier. [POLYZOA.]

IDOCRASE, a Mineral, also called *Vesuvian*, *Pyramidal Garnet*, &c. This mineral occurs crystallised and massive; the crystals are either attached or imbedded. Primary form a square prism. Cleavage parallel to the primary planes, distinct, and less so parallel to the diagonals of the prism. Fracture uneven, slightly conchoidal, or rather undulated. Hardness 6·5. Scratches glass readily, and even quartz. Colour various shades of brown, black, gray, blue, green, and yellow. Streak white. Lustre vitreo-resinous, translucent, and transparent. Refraction double. Specific gravity 3·08 to 3·4. By the blowpipe it is fusible with ebullition into a yellowish transparent globule, and with borax gives a glass tinged green with oxide of iron.

The massive varieties are amorphous; the structure is fibrous, granular, or compact.

Idocrase is met with both in primitive and volcanic countries. It occurs in the masses ejected from Vesuvius: the crystals are sometimes of large dimensions.

It was found originally in the neighbourhood of Vesuvius, and since in many other parts of the world. Different varieties have been called by different names: thus, *Cyprine* is cupreous or blue Idocrase; *Loboite*, greenish-yellow; *Egeran*, found near Eger, in Bohemia, is of a liver-brown colour; *Xanthite*, found at Ainsty, New York. The following are analyses by Klaproth and De Kobell:—

	Klaproth.		De Kobell.
Silica	35·50	42·00	35
Alumina	33·00	16·25	22
Lime	22·25	34·00	36
Oxide of Iron	7·50	5·50	5
Oxide of Manganese	0·25	Trace.	
	98·50	97·75	98
	Vesuvius.	Siberia.	Mussa.

IDOTEA. [ISOPODA.]

IDRIALIN, a Mineral Resin of a grayish or brownish-black colour, with a grayish lustre, occurring in the Cinnabar mines of Idria.

IDYA, Oken's name for those Beröes which are formed after the manner of *Beröe ovata*. [ACALEPHÆ.]

IDYIA (Rafinesque), a genus of *Crustacea* to which Desmarest alludes, among other such genera, as knowing nothing of them beyond their names.

IERAX. [FALCONIDÆ.]

IEREA, the generic name of a fossil Polypifer from the blue clays of the Vaches Noires (Calvados), described by Lamouroux, who is doubtful of its affinities, but ranks it among his *Polyparia actinaria*. Broun places it among the *Siphoniæ*.

IGNATIA, a genus of Plants belonging to the natural order *Loganiaceæ*. One of the species of this genus, *I. amara*, yields the St. Ignatius's Beans of India, where, under the name of Papeeta, they are said to be a remedy for cholera. No proof has been afforded of their efficacy in this disease, and Dr. Lindley ('Vegetable Kingdom') says that convulsions and giddiness are known to follow their exhibition when given in an over-dose.

IGUANA. [IGUANIDÆ.]

IGUA'NIDÆ, an extensive family of Saurians, of which the genus *Iguana* may be considered the type. Messrs. Duméril and Bibron, in their 'Erpétologie' (1837), treat of these reptiles under the name of Lézards Iguaniens, ou Sauriens Eunotes. In 'the Catalogue' of the Specimens of Lizards in the British Museum,' the *Iguanidæ* with the *Agamidæ* [DRACONINA] constitute the tribe *Strobilosaura*.

Before giving the genera and species as arranged by Dr. J. E. Gray, we give a sketch of the organisation of the *Iguanidæ*.

The skull is always articulated by a single condyle situated below the great occipital foramen which opens a passage for the nervous chord. The configuration of the head presents great differences, dependent on the conformation of the bones of the cranium, the face, or jaws.

The number of cervical vertebræ is most frequently six, and this region is generally short, but it is strong. There are often articulated trachelian apophyses, which are in reality the rudiments of ribs. The dorsal vertebræ, meaning by that term the vertebræ which carry the ribs, vary much in number in the different genera. The first lumbar vertebræ are like the dorsal, except that they are without the articular facets which characterise the latter. Generally there are but two pelvic vertebræ, which carry the ileum or pelvis. The ribs are in general slender, weak, rounded, and of the same form, though they vary in their curvature, according as the trunk is cylindrical, depressed or compressed in the thoracic region. The first or anterior ribs are joined to the lateral parts of the sternum, or to a series of small bones which occupy the lower part of the breast; or they are united to each other on the mesial region nearly in the same manner as in the chameleons, for this disposition occurs in *Polychrus* and *Anolis*. In the Dragons the posterior ribs are free and prolonged in the thickness of the skin of the sides, in order to sustain the sort of parachute extended on the lateral parts of the body between the anterior and posterior limbs. All the species of the family have two pairs of limbs always apparent, and terminated by toes, the number of which varies but little. Their conformation and respective length have been used as generic characteristics principally in the case of *Anolis*, and some others which have offered some particularities, such as *Sitana*. The presence of a shoulder formed of two bones, and that of a pelvis, separates these Saurians from the Serpents.

The general form of the body and the disposition of the skeleton scarcely vary, except in the proportions of the different regions of the spinal column, especially in that of the tail and in the configuration of the vertebræ, the spinous and transverse processes of which correspond to the external state of compression or depression. In the greater number of species, as in those of *Lophyrus*, *Basiliscus*, *Polychrus*, and *Iguana*, the region of the back presents a well-defined projection, sustained by the series of spinous apophyses which often form that crest which has caused Messrs. Duméril and Bibron to name the family *Eunotes*. This disposition is most manifest in *Basiliscus* and *Agama*; whilst in *Stellio* and *Uromastix* the dorsal spines project but little. The bodies of the vertebræ which constitute the tail are much shorter in those species in which that part is not long, *Phrynocephalus* for instance, than in those which have it excessively prolonged. In these last, take *Iguana* and *Anolis* for example, there is another peculiarity, namely, that the bodies or central and cylindrical parts of the caudal vertebræ, which are large and dilated at their extremities for articulation, have, at the same time, the mesial portion more slender and fragile, so that it is in this portion that fracture often takes place, which is followed by a reproduction and consequent deformity which the tail often in that case presents. M. Rousseau (père) found in the skeletons of those Saurians which had undergone mutilation of the tail a long cartilaginous cone in lieu of distinct vertebræ; and Carus has remarked, that the spinal chord is not renewed in this cartilaginous stem, which is produced in lieu of the caudal vertebræ.

With regard to the senses, sight and hearing appear to be very well developed in this family; and taste seems to be present in a very fair degree, but not smell; touch moderate. The eyes of all the Iguanians are furnished with moveable lids; the orbit in which they are placed varies in its extent and in conformity with the limits which result from the bones of the face and cranium. The greater part have a superciliary arch, which is sometimes tuberculous and very projecting, as in *Ophryoessa* and *Hypsibates*. Messrs. Duméril and

Bibron state, that up to the time when they wrote they knew of no species in which observers had detected a linear pupil, though it is asserted that some are nocturnal. With the exception of some genera, *Otocryptis* and *Phrynocephalus* in particular, in which the tympanum is not apparent, all the Iguanians have an auditory canal, more or less enlarged at its external orifice on a level with the surface of the head; sometimes, as in some species of *Agama*, it is only a simple slit, the entrance of which is protected by some pointed and as it were spiny scales. The sense of smelling does not seem to be much developed in the Saurians generally, but in the family under consideration it appears to be at a very low rate, for there is no anfractuosity in the air-sinus; the external orifices of the nostrils have but little humidity, and are very small. They are situated generally near the extremity of the muzzle, and approach each other above; they open within the mouth by a simple slit to which the tongue may be applied, and seem principally, if not entirely, destined to aid in respiration.

The tongue is in general short, large, and mobile at its extremity; but it is not deeply divided at its end, which is free. The base is not retracted into a sheath, and this is a character which distinguishes it in particular from that of the Varanians and Chameleons. Wagler has employed the term *Pachyglossi* to denote this disposition. The organ is always humid, and covered with a glutinous secretion: its papillæ, which vary in form, being in some instances conical, and in others scaly, or laid like tiles (entuilées), in a direction from the front backwards, appear to be destined for the perception of sapid substances; but its principal office seems to be to direct the movement of the food submitted to the action of the teeth, and to assist in deglutition. The os hyoides, to which it is fastened, presents important modifications in different genera. Its horns are much prolonged in some species, and serve to support the dewlap, or longitudinal fold of the integuments under the neck and jaw, in *Sitana*, *Basiliscus*, *Draco*, &c., and especially in *Anolis*, as particularly noticed and demonstrated by Mr. T. Bell.

The organs of digestion present nothing very remarkable in this family. The stomach seems to be a continuation of the œsophagus, but the fibres and wrinkles are most often in another direction. There is no true cardia. The ventriculus, properly so called, is often conical, and the pylorus is not distinguishable except by a slight narrowing, which is rather elongated in *Stellio*, *Iguana*, &c. In *Polychrus*, *Galeotes*, and *Lyriocephalus*, the pylorus is but little marked, on account of its shortness and the thinness of its parietes. The intestines vary in length. In species which have the tail very long, as the Iguanas, the extent of the digestive tube is not much more than one-third of the total length of the spinal column. There is no apparent distinction, in some cases, evident between the small and large intestines, so that there is often no cœcum, as in *Cordylus*, *Agama*, and *Sitana*; whilst on the contrary in *Iguana*, *Galeotes*, and *Lyriocephalus*, there is a true cul-de-sac at the termination of the small intestine where it opens into the greater canal. The pancreas is voluminous in *Iguana*, *Istiurus*, and *Lyriocephalus*. The form and situation of the spleen vary. It is most frequently placed at the middle of the mesentery, under the stomach; sometimes on the right, as in *Iguana*; sometimes on the left, or at the middle of the lower portion of the stomach, as is observable in the greatest number.

The organs of circulation and respiration present no remarkable difference from those of other Saurians, and the same may be said of the organs of generation.

The integuments present various modifications. We have the polyedrous tubercles of *Grammatophorus*; the spines of the neck in *Agama*; those of the tail in *Doryphorus*, *Strobilurus*, *Stenocercus*, *Uromastix*, and *Trachycyclus*; the carinated scales of *Ophryoessa*, *Leiosaurus*, *Tropidogaster*, and *Ecphymotes*; the cutaneous expansions of the different regions of the dorsal and caudal crests in the greater number of genera, but especially in *Iguana*, *Istiurus*, and *Basiliscus*; those of the nape on the occiput in *Corythophanes* and *Basiliscus*; of the flanks in *Draco* and *Callisaurus*; and of the neck, under the form of a dewlap, in *Sitana*, *Draco*, and *Iguana*; or in the lateral parts in front of the shoulders, as in *Chlamydosaurus*. The pores, whether of the thighs, sometimes in a simple line, somtimes in two longitudinal and parallel rows, or in front of the anus, are employed by Messrs. Duméril and Bibron in the classification of genera in their synoptical table. The toes are in general elongated and terminated by crooked nails; *Anolis* alone presents a peculiar dilatation under the penultimate phalanges. The shorter the toes and the nails, the less nimble the animal.

Messrs. Duméril and Bibron state that in their anatomical researches they have found the ventriculus of many species filled with debris of vegetables, such as flowers, leaves, and seeds, in considerable quantity, which led them to the conclusion that many are herbivorous; but they remark that this is scarcely in accordance with the form of the teeth, none of which have tubercular crowns, nor composed of apparent enamel and osseous cement. It should however be remembered that the teeth of most of the species are by no means ill-adapted for cropping vegetable substances. The family are generally nimble. The compressed and lengthened tail of many species is most useful as an instrument of progression when swimming across the inundated savannahs, and their crooked nails assist them in climbing trees and pursuing the smaller animals on which they occasionally prey.

The *Iguanidæ* are all inhabitants of warm climates. Only one belongs to Europe, the Common Stellio, which is found also in Africa and Asia. Several inhabit Australia.

The genus *Iguana* is the type of this family. This name was given by Laurenti to a genus of Saurians, in which he included various forms, such as *Agama*, *Lophyrus*, *Calotes*, &c. Daudin separated from this heterogeneous collection *Agama*, *Draco*, and *Basiliscus*; and Wagler, striking out the word *Iguana* from his nomenclature, divided the genus *Iguana* as left by Daudin into the genera *Hypsilophus*, *Metopoceros*, and *Amblyrhynchus*. Messrs. Duméril and Bibron restore the name. The genus *Iguana*, as adopted by them, includes *Hypsilophus* and *Amblyrhynchus* of Wagler, and is thus characterised:—

A very large thin dewlap (fanon) under the neck. Cephalic plates polygonal, unequal in diameter, flat or carinated. A double row of small palatal teeth. Maxillary teeth with their edges finely dentilated. A crest on the back and tail. Toes long and unequal. A single row of femoral pores. Tail very long, slender, compressed, covered with small equal imbricated carinated scales.

Common Iguana (*Iguana tuberculata*).

They give the following description of the genus as thus modified:— The species composing this generic group are principally remarkable for the cutaneous prolongation which constitutes over the whole extent of the lower part of the head and neck a very deep and very thin dewlap or pouch, the free border of which describes a curved line, and is dentilated at the part nearest the chin. The skin is irregularly folded on the sides of this dewlap, behind which there is another transversal fold which is obliquely prolonged upon each shoulder. There are also cuticular folds on the lateral regions of the neck and trunk. The head of the Iguanas is moderately long, and has the form of a pyramid with four faces. The neck is slightly compressed. The upper part of the body is convex and rounded, the under part flattened. The limbs are long. The toes unequal, and sometimes denticulated on their edges; the five toes of the posterior feet are graduated; the third and the fourth of the hand are equal in length. The tail, which is very long and very slender, is flattened slightly from right to left from its origin. The top and sides of the head are protected by polygonal scales varying in size, among which some are convex, some flat, some carinated, and some even strongly tuberculous. The subocular regions however are only furnished with small angular roundish scales with a slightly convex surface. It is worthy of remark that the part of the skull which is situated between the orbits is protected by two longitudinal series of large angular plates, whilst in *Metopoceros* and *Cyclurus* this same part of the cranium is paved with small polygonal scales. A row of strong, angular, oblong, and often carinated scales adheres to the lower edge of the orbital circle. The lips are furnished with large scaly plates, which are ordinarily quadrangular. There is also on each branch of the lower jaw a row of large scales, the last of which is enormous in some cases, presenting a diameter the quadruple of that of the others. The scales which cover the upper part of the neck and the body are slightly imbricated. They are small, square, or lozenge-shaped, surmounted by a keel which does not divide them in the middle, but which extends from their infero-posterior angle to their supero-posterior angle. In stuffed individuals, the skin of which has been distended, there is around the scales of the upper part of the body a circle of small grains which recalls in a degree the mode in which the scaly covering of the Varanians is formed. The lower part of the neck is paved with scales, which are smooth and multifaced. There are rhomboidal and imbricated scales on the dewlap. On the other parts of the body are rhomboidal tile-like scales (entuilées), and those among them which are not carinated are found upon the thighs, the soles of the feet, and the under side of the toes. The inferior region of these is protected by a band of enlarged scutellations which are imbricated, and surmounted with three keels, of which the middle one is weak and the lateral ones very prominent. The upper part of each toe is covered by a single row of scales; but each side of the lateral parts of the anterior toes has two rows, whilst the external side of the posterior toes has three, making six rows of scales on each anterior toe, and seven on each posterior toe. Besides being imbricated the scales of the tail form verticillations, or complete rings, which cease to be distinguishable when they reach towards the extremity.

All the Iguanas have femoral pores, the number of which varies according to the sex, as Messrs. Duméril and Bibron suppose; and they think that the number would in that case be less in the females than in the males. These pores, which are placed in a single row, are surrounded by small scales disposed as the petals of a flower are disposed round its disc.

The *Iguanæ* have the upper parts of the body surmounted by a paleaceous crest of some height, which is continuous from the nape to the extremity of the tail. This crest is composed of strongly compressed scales, which are pointed and sometimes curved backwards, gradually diminishing in height as the end of the tail is approached. The nostrils are situated on the sides of the muzzle, and very near the extremity; their aperture is large, and opened in the middle of a large scale, which forms a convex circle around them, and gives them a tubulous appearance. The tympanal membrane extended over the auditory opening is very large and circular.

The teeth of the *Iguanæ*, which have an especial interest on account of their resemblance to those of the extinct *Iguanodon* [IGUANODON], vary according to the ages of individuals; and Messrs. Duméril and Bibron state that they are assured that fewer exist in young subjects than in adult individuals. The first twelve or fourteen maxillary teeth, both above and below, are nearly rounded, pointed, and a little arched; all the others are narrow and compressed, with an angular summit, which is very finely dentilated on its edges. They are not, Dr. Buckland observes, lodged in distinct sockets, like the teeth of crocodiles, but fixed along the internal face of the dental bone, to which they adhere by one side of the bony substance of their root.

Teeth of *Iguana*. Dr. Buckland.

There is a double row of small teeth on each side of the vault of the palates.

The Iguanas are herbivorous, and indeed the structure of their teeth would lead to the conclusion that herbs formed their staple. Messrs. Duméril and Bibron never found anything but leaves and flowers in the stomachs of the individuals which they opened. Mr. Broderip saw a living *Iguana* about two feet long in a hothouse at Mr. Miller's nursery-gardens near Bristol. It had refused to eat insects and other kinds of animal food, until happening to be near some kidney-bean plants that were in the house for forcing, it began to eat their leaves, and was from that time forth supplied from these plants. Dr. Buckland, who quotes this, states, in addition, that in 1828 Sir Edward Belcher found in the island of Isabella swarms of Iguanas that appeared to be omnivorous; they fed voraciously on the eggs of birds and the intestines of fowls and insects. The Iguanas live a great deal in trees, and will take to the water, swimming with ease. Mr. Broderip saw an *Iguana* enter and cross a small pond in the Zoological Gardens at the Regent's Park. The fore feet were motionless during the passage of the animal across the water. Several specimens of these animals have from time to time been in the collection of the Zoological Society in Regent's Park.

The species of *Iguana* are found in Mexico, South America, and the Antilles. Some are considered as very delicate food.

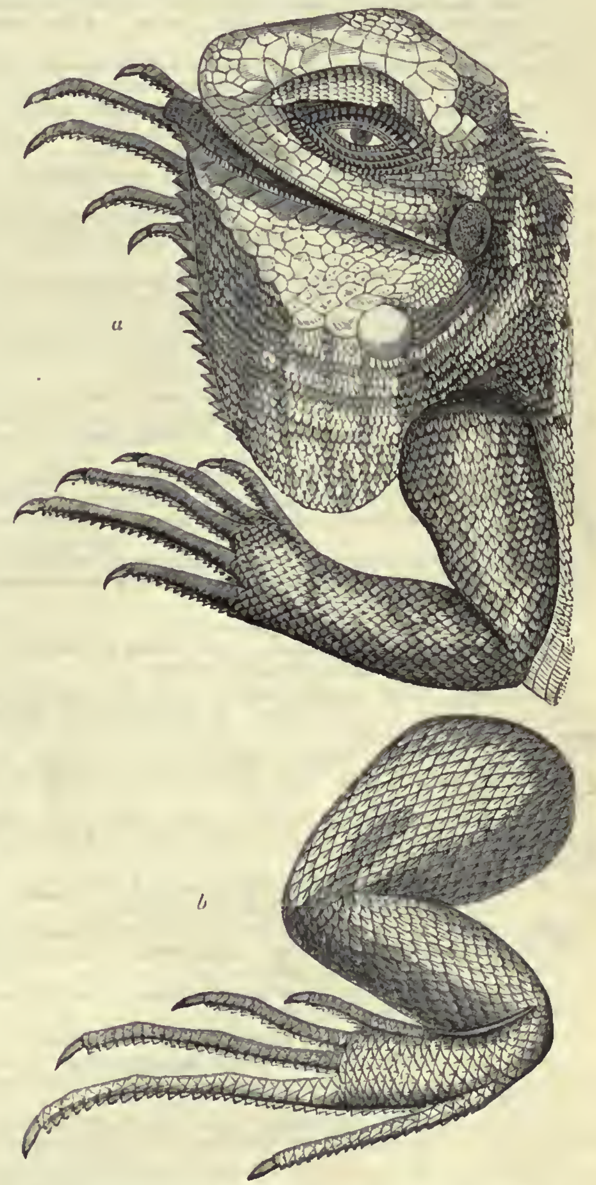
There are only three species admitted by Messrs. Duméril and Bibron:—

I. tuberculata is the Common Iguana. This species has been described by a great many names. Thus, Spix, in his work on the 'Reptiles of Brazil,' has, under the names of *I. squamosa*, *I. viridis*, *I. cærulea*, *I. emarginata*, and *I. Lophyroides*, represented *I. tuberculata* of Laurenti, L'Iguane Ordinaire d'Amerique of Cuvier, the Common Iguana, at five different epochs of its life.

The figures will give some idea of this animal, which is yellowish-green below, and above of a green more or less deep, becoming sometimes bluish, and at others of a slate colour. In general there are on the sides of the body brown stripes or zigzags edged with yellow. There is frequently a line of the latter colour traced obliquely on the front of the shoulder. Some individuals are sprinkled with brown; others have the limbs spotted with brown on a black ground. The tail is surrounded with large brown rings, which alternate with others of green or yellowish. Length seldom exceeding five feet.

It inhabits a great part of South America, and also the Antilles.

It is considered excellent for the table. *Delicatissima* and *sapidissima* are among the specific names that have been assigned to it. It is not however deemed very wholesome, and is even considered injurious to those who have suffered from certain diseases.



a, Head and anterior extremity of *Iguana tuberculata*, two-fifths of the natural size; *b*, hind foot, same size.

Wagler makes this species the type of his genus *Hypsilophus*.

We present a synopsis of the other genera and species of this family from the 'British Museum Catalogue:'—

I. Body compressed, covered with rings of squarish small often keeled scales. Perchers.

A. Nostril lateral, below the eye-ridge; toes slender, simple; back not crested; interparietal plate small.

a. Throat compressed, toothed in front; third and fourth toes nearly equal; eyes prominent.

1. *Polychrus.*—Femoral pores distinct; scales of back and sides equal. *P. marmoratus*, the Camaleao; Brazil and West Indies.

2. *Sphærops.*—Femoral pores none; scales of sides larger. *S. anomalus*, the Brazilian Chameleon.

3. *Urotrophus.*—Scales circular, smooth; tail-end revolute. *U. Vautieri.* Brazil.

4. *Ecphymotes.*—Scales rhombic, keeled; head 4-sided. *E. Fitzingerii*, Fitzinger's Ecphymotes; Brazil. *E. undulatus*, the Waved Ecphymote; Brazil. *E. obtusirostris*, the Blunt-Headed Ecphymote; Mexico. *E. acutirostris*, the Ecphymote; Brazil.

5. *Læmanctus.*—Scales rhombic, keeled; head dilated and rounded behind. *L. longipes*, the Long-Legged Læmanctus; Mexico.

B. Nostril lateral; toes simple or fringed; back crested; interparietal plate small.

a. Femoral pores distinct.

* Throat-pouch large, compressed; tail compressed.

6. *Iguana.*—Scales of back moderate; throat-pouch toothed in front. *I. tuberculata*, the Common Iguana; West Indies. *I. rhinolophus*, the Rhinoceros Iguana; St. Christopher's, West Indies. *I. delicatissima*, the Naked-Necked Iguana; Tropical America.

7. *Aloponotus.*—Scales of back very minute; throat-pouch simple in front. *A. Ricardi*, Aloponotus; St. Domingo.

** Throat rather dilatable, with a cross-fold behind; middle hind toes toothed on the outside.

† Tail compressed with uniform keeled scales.

8. *Brachylophus.*—Head-shields flat; femoral pores 1-rowed. *B. fasciatus*, the Banded Brachylophe; South America.

9. *Metapoceros.*—Head-shields flat; central frontal with a horn; femoral pores 2-rowed. *M. cornutus*, the Horned Iguana; St. Domingo.

10. *Trachycephalus.*—Head-shields convex; hinder outer toe short. *T. subcristatus*, the Rough Head; Charles Island, Galapagos.

11. *Oreocephalus.*—Head-shields conical, very rugose; the outer hinder toe elongate. *O. cristatus*, the Marine Oreocephalus; Galapagos.

†† Tail with rings of spinose scales.

12. *Cyclura.*—Head-shields small, with 2 rows of large shields on the muzzle; tail compressed. *C. M'Leayii*, M'Leay's Cyclure; Cuba. *C. nubila*, the Clouded Cyclure; Mexico. *C. Collii*, Colly's Cyclure; Jamaica.

13. *Ctenosaura.*—Head- and muzzle-shields small, uniform; tail roundish, crested. *C. acanthura*, Shaw's Ctenosaure; California, West Indies, Tropical America. *C. pectinata*, Weigmann's Ctenosaure; Mexico.

14. *Enyaliosaurus.*—Head- and muzzle-shields small, uniform; tail depressed, with 5 longitudinal spinose ridges. *E. quinquecarinatus*, the Armed-Lizard; Demerara.

b. Femoral pores none.

* Hinder toes fringed on the side, outer webbed at the base; throat with a cross-fold behind.

15. *Basiliscus.*—Head elongate, with an erect crest behind; the back and tail with a fin-like crest. *B. Americanus*, the Basilisc; Tropical America, Guyana.

16. *Corythæolus.*—Head elongate, with a low compressed crest behind; back and tail with a low toothed crest. *C. vittatus*, the Corythæole; Honduras.

17. *Thysanodactylus.*—Head short, with a low toothed crest, convex behind; back and tail with a low toothed crest. *T. bilineatus*, the Edged-Toe; South America.

** Toes all slender, simple, or slightly serrated on the sides; outer hind toes quite free; head short.

† Occiput compressed and produced behind; throat-pouch compressed.

18. *Corythophanes.*—Nape crested; throat-pouch toothed in front. *C. cristata*, the Corythophane; Mexico.

19. *Chamæleopsis.*—Nape not crested; throat-pouch simple. *C. Hernandesii*, the Qualtapalcalt; Mexico.

†† Occiput convex; throat with a cross-fold behind.

20. *Enyalius.*—Tail round, not crested; toes all simple. *E. rhombifer*, the Lozenge-Marked Enyalius; South America. *E. bilineatus*, the Two Streaked Enyalius; Brazil.

21. *Ophryoessa.*—Tail compressed; hinder toes slightly serrated on the outer edge. *O. superciliosa*, the Eye-Browed Ophryoessa; America.

C. Nostril superior, above the eye-ridge, subapical; toes dilated under the last joint but one, very unequal, and united together at the base; throat-pouch distinct, largely dilatable; femorial pores none; head sub-shielded; interparietal distinct.

a. Scales of belly granular.

22. *Chamæleolis.*—Back and tail with a bony crest; toes dilated. *C. Fernandina*, the Cuban Chamæleolis; Cuba.

b. Scales of the belly imbricated, flat.

23. *Xiphosurus.*—Toes dilated; tail with a bony crest. *X. velifer*, the Crested Anolis. *X. Ricordii*, Ricord's Anolis; St. Domingo. *X. cristatellus*, the Smaller-Crested Anolis; West Indies.

24. *Dactyloa.*—Toes dilated; back and tail with a crest of compressed scales. *D. equestris*, the Equestrian Anolis; Cuba. *D. Edwardsii*, Edwards's Anolis; Jamaica.

25. *Rhinosaurus.*—Toes dilated; back with a slight fold formed of two series of small scales; rostral plate horizontal; nose produced. *R. gracilis*, the Sharp-Nosed Anolis; Bahia.

26. *Anolius.*—Toes dilated; back simple, or with a slight crest formed of two series of small scales; rostral erect; nose rounded. *A. Leachii*, the Large-Cheeked Anolis; South America and West Indies. *A. occipitalis*, the Occipital Anolis; West Indies. *A. lineatus*, the Lined Anolis; Martinique. *A. Cepedii*, the Alligator Anolis; West Indies. *A. marmoratus*, the Marbled Anolis; Martinique. *A. porcatus*, the Ridge-Nosed Anolis; Cuba. *A. principalis*, the Carolina Anolis; North America. *A. flavescens*, the Yellowish Anolis; North America. *A. Richardii*, Richard's Anolis. *A. punctatus*, the Dotted Anolis; Brazil. *A. nebulosus*, the Clouded Anolis; Cuba and Texas. *A. lineatopus*, the Lineated Anolis. *A. maculatus*, the Spotted Anolis; West Indies. *A. pulchellus*, the Beautiful Anolis; Martinique. *A. vermiculatus*, the Vermiculated Anolis; Cuba. *A. stenodactylus*, the Slender-Toed Anolis; Jamaica. *A. reticulatus*, the Netted Anolis; Tropical America. *A. fusco-auratus*, the Chilian Anolis; Chili. *A. æneus*, the Bronzed Anolis; Tropical America. *A. lucius*, the Pike-Headed Anolis; Cuba. *A. Goudotii*, Goudot's Anolis; Martinique. *A. punctatus*, the Green Anolis; Brazil. *A. bullaris*, the Red-Throated Anolis; Martinique. *A. Valencienii*, Valencienne's Anolis.

27. *Acantholis.*—Toes dilated; back simple, with scattered tubercles. *A. Loysiana*, the Acantholis; Cuba.

28. *Draconura.*—Toes scarcely dilated; back simple; tail round. *D. nitens*, the Shining Draconure; Surinam. *D. chrysolepis*, the Golden Draconure; West Indies.

29. *Norops.*—Toes slender, not dilated; back simple; tail round. *N. auratus*, the Golden Norops; Surinam.

II. Body subtrigonal or depressed. Terrestrial.

D. Body subtrigonal, covered with large generally keeled scales, directed obliquely towards the back; head generally shielded, superciliary and interparietal shields distinct; throat smooth, or with a cross fold behind; toes simple.

a. Caudal and dorsal scales similar.

* Femoral pores distinct; interparietal plate large.

30. *Tropidolepis.*—Back not crested; throat with a fold on each side; nostril superior, subapical. *T. undulatus*, the Waved Tropidolepis; North America. *T. torquatus*, the Collared Tropidolepis; Mexico. *T. formosus*, Mergmann's Tropidolepis; Mexico. *T. spinosus*, the Spinose Tropidolepis. *T. horridus*, the Horrid Tropidolepis; Mexico. *T. grammicus*, the Spotted Tropidolepis; Mexico. *T. microlepidotus*, the Small-Scaled Tropidolepis; Mexico. *T. variabilis*, the Variable Sceloporus; Mexico. *T. aureus*, the Bronzed Sceloporus; Mexico. *T. scalaris*, the Spotted Sceloporus; Mexico.

** Femoral pores none; anal pores distinct, marginal; back and tail not crested; interparietal plate small.

31. *Leiodera.*—Nostril lateral on the face-ridge; scales of the sides of the neck and back large; rhombic sides simple. *L. Chilensis*, the Chilian Leiodera; North Chili. *L. Gravenhorstii*, Gravenhorst's Leiodera; Chili. *L. gracilis*, the Slender Leiodera; Valparaiso and Patagonia.

32. *Leiolæmus.*—Nostril lateral on the face-ridge; scales of the sides of neck granular, of back rhombic, sides simple. *L. cyanogaster*, the Blue-Bellied Leiolæmus; Valdivia. *L. Bellii*, Bell's Leiolæmus; Chili. *L. Bibronii*, Bibron's Leiolæmus; Chili. *L. lineatus*, the Lineated Leiolæmus; Chili. *L. nigromaculatus*, the Black-Spotted Leiolæmus; Chili and Coquimbo. *L. inconspicuus*, the Inconspicuous Leiolæmus; Chili. *L. pictus*, the Painted Leiolæmus; Chili and Valparaiso. *L. tenuis*, the Dotted Leiolæmus; Valparaiso and Chili. *L. signifer*, the Hebrew-Marked Leiolæmus; Peru. *L. maculatus*, the Small-Scaled Leiolæmus; Peru. *L. Fitzingerii*, Fitzinger's Leiolæmus; Patagonia. *L. Darwinii*, Darwin's Leiolæmus; North Patagonia. *L. Kingii*, Captain King's Leiolæmus; Patagonia. *L. Weigmanii*, Weigmann's Leiolæmus; Bahia Blanca, Peru, Monte-Video, and Maldonado.

33. *Ptydogerus.*—Nostril lateral on the face-ridge; scales of the neck granular, of back rhombic; sides with a crest of keeled scales. *P. pectinatus*, the Ptygodere.

34. *Proctotretus.*—Nostril above the face-ridge; scales of the neck granular, of back rhombic; small sides simple. *P. multimaculatus*, the Proctotrete; Bahia Blanca, and Patagonia.

*** Femoral and anal pores none.

† Interparietal plate linear, small; head shields rather regular.

35. *Leiocephalus.*—Back and tail crested; scales of throat, back, and tail, rhombic, moderate. *L. Herminieri*, Herminier's Roquet; Martinique. *L. carinatus*, the Keeled Roquet; West Indies. *L. M'Leayii*, the Cuban Roquet; Cuba. *L. Schreibersii*, Schreibers's Roquet; Cuba. *L. Grayii*, Gray's Roquet; Charles Island and Galapagos. *L. ornatus*, the Shoulder-Spotted Roquet; Tropical America.

36. *Stenocerus.*—Back and tail lowly crested; scales of back rhombic, of the tail large, spinose. *S. rosciventris*, the Stenocere; Bolivia.

37. *Trachycyclus.*—Back and tail not crested; scales of back rhombic,

of tail large, spinose. *T. marmoratus*, the Trachycyclus; Brazil and Rio Grande.

†† Interparietal plate large; back or tail crested.

38. *Taraguira.*—Back not crested; scales of back small, of the throat granular; tail round, with a slight crest, and moderate scales; ear toothed in front. *T. torquata*, the Taraguira; Rio Janeiro and Brazil. *T. Darwinii*, Darwin's Taraguira; Brazil and Abrolhos Inlet. *T. Smithii*, Smith's Taraguira; Brazil.

39. *Microlophus.*—Back and tail lowly crested; scales of the back unequal, small; tail with moderate scales; the ear toothed in front. *M. Peruvianus*, the Microlophe; Peru, Copispo, and Iquique.

40. *Oplurus.*—Nape with a small crest; scales of back large, of the sides small; tail round, with rings of large spinose scales. *O. Braziliensis*, the Brazilian Oplurus; Brazil.

41. *Strobilurus.*—Nape, back, and tail, slightly crested; scales of back moderate; tail with rings of large spinose scales. *S. torquatus*, the Strobilurus; Brazil.

42. *Uraniscodon.*—Nape and back lowly crested; scales of the back large, rhombic; sides of body and throat simple; tail round, slender, with moderate scales, slightly keeled above. *U. pictum*, the Painted Uraniscodon; Brazil.

43. *Plica.*—Nape and back lowly crested; scales of the back small; sides with two folds; the throat with groups of spines; tail round, slender, keeled above with moderate scales. *P. umbra*, the Plica; North America (?) and Georgia (?). *P. punctata*, the Dotted Plica; Tropical America.

E. Body depressed, with small scales; back rarely crested; tail conical.

a. Sides rounded; femoral and preanal pores none; eyebrow scales small.

44. *Leiosaurus.*—Tail with granular scales; scales under the eye all small. *L. Bellii*, Bell's Leiosaurus; South America. *L. fasciatus*, the Banded Leiosaurus; South America.

45. *Diplolæmus.*—Tail with granular scales, with an elongated scale under the eye. *D. Darwinii*, Darwin's Diplolæmus; Patagonia. *D. Bibronii*, Bibron's Diplolæmus; South America and Chili.

46. *Tropidurus.*—Tail round, with rings of large scales; nape lowly crested, interparietal (?). *T. cyclurus*, the False Quetz Palea; Brazil.

47. *Uranocentron.*—Tail depressed with rings of large scales; nape not crested; interparietal small. *U. azureum*, the Doryphore; Brazil.

b. Sides rounded; femoral and preanal pores distinct, near vent.

48. *Phrymaturus.*—Tail round, with rings of large scales; the nape not crested. *P. Palluma*, the Palluma; Chili.

c. Sides with a slight fold; scales uniform; body roundish.

49. *Callisaurus.*—Ventral scales smooth; femoral pores distinct. *C. draconoides*, the Callisaurus; California.

50. *Tropidogaster.*—Ventral scales 3-keeled; femoral pores none. *T. Blainvillii*, the Tropidogaster.

d. Sides serrated; body very depressed; femoral pores distinct.

51. *Phrynosoma.*—Head spinose; back and tail with scattered tubercular scales. *P. Douglasii*, Douglas's Phrynosoma; California. *P. orbiculare*, the Tapayaxin; Mexico. *P. Blainvillii*, the Crowned Tapayaxin; California. *P. cornutum*, the Texian Tapayaxin; Arkansas, North America, and Texas.

IGUANODON (Iguana and ὀδοὺς (ὀδόντος), a tooth), a genus of extinct Reptiles of large size, discovered by Dr. Mantell, and named by him from the resemblance of its teeth to those of the recent *Iguana*. As the discovery of this animal is one of great interest in the records of British Palæontology, and illustrates the success attendant upon accurate investigation in this department of human inquiry, we give the history of it in Dr. Mantell's own words:—

"Soon after my first discovery of bones of colossal reptiles in the strata of Tilgate Forest, some teeth of a very remarkable character particularly excited my curiosity, for they were wholly unlike any that had previously come under my observation; even the quarrymen, accustomed to collect the remains of fishes, shells, and other objects imbedded in the rocks, had not observed fossils of this kind; and, until shown some specimens which I had extracted from a block of stone, were not aware of the presence of such teeth in the stone they were constantly breaking up for the roads. The first specimen that arrested my attention was a large tooth, which, from the worn, smooth, and oblique surface of the crown, had evidently belonged to an herbivorous animal; and so entirely resembled in form the corresponding part of an incisor of a large pachyderm ground down by use that I was much embarrassed to account for its presence in such ancient strata, in which, according to all geological experience, no fossil remains of *Mammalia* would ever be discovered; and as no known existing reptiles are capable of masticating their food, I could not venture to assign the tooth in question to a saurian.

"As my friend Mr. (now Sir Charles) Lyell was about to visit Paris, I availed myself of the opportunity of submitting it to the examination of Baron Cuvier, with whom I had the high privilege of corresponding; and, to my astonishment, learned from my friend, that M. Cuvier, without hesitation, pronounced it to be an upper incisor of a Rhinoceros.

"I had previously taken this tooth, and some other specimens, to a meeting of the Geological Society in London, and showed them to Dr. Buckland, Mr. Conybeare, Mr. Clift, and other eminent men who were present, but without any satisfactory result; in fact, I was discouraged by the remarks that the teeth were of no particular interest, as there could be but little doubt they belonged either to some large fish allied to the *Anarhicas Lupus*, or Wolf-Fish, the crowns of whose incisors are of a prismatic form, or were mammalian teeth obtained from a diluvial deposit. Dr. Wollaston alone supported my opinion, that I had discovered the teeth of an unknown herbivorous reptile, and encouraged me to continue my researches. And, as if to add to the difficulty of solving the enigma, some metacarpal bones which I soon after discovered in the same quarry, and forwarded to Paris, were declared to belong to a species of Hippopotamus. Subsequently a dermal horn, or tubercle, from the same stratum, was declared by competent authorities to be the lesser horn of a Rhinoceros; and Dr. Buckland, with the generous kindness which marked his character, wrote to guard me against venturing to publish that these teeth, bones, and horn were found in the 'iron-sand formation,' with which the Tilgate beds were then classed, as there could be no doubt they belonged to the superficial diluvium; and as the upper beds of the conglomerate in which these first specimens were found was only covered by loam and vegetable earth, there was no clear stratigraphical evidence to support a contrary opinion. Other specimens however were soon procured by stimulating the diligent search of the workmen by suitable rewards, and at length teeth were obtained which displayed the serrated edges, the longitudinal ridges, and the entire form of the unused crown. I then forwarded specimens and drawings to Baron Cuvier, and repaired to London, and with the aid of that excellent man the late Mr. Clift, ransacked all the drawers in the Hunterian Museum that contained jaws and teeth of reptiles, but without finding any that threw light on the subject. Fortunately, M. Samuel Stuchbury, then a young man, was present, and proposed to show me the skeleton of an *Iguana*, which he had prepared from a specimen that had long been immersed in spirits; and, to my great delight, I found that the minute teeth of that reptile bore a closer resemblance in their general form to the fossils from Tilgate Forest than any others with which I was able to institute a comparison. It was not however until I had collected a series of specimens exhibiting teeth in various stages of maturity and detrition that the correctness of my opinion was admitted, either as to the character of these dental organs, or the geological position of the rocks in which they were imbedded." ('Petrifactions and their Teachings.')

From their first discovery the teeth of this animal have excited the greatest amount of interest on account of their peculiar structure. In his report to the British Association, on the 'British Fossil Reptiles,' Professor Owen gives an elaborate account of their structure and functions:—

"The teeth of the *Iguanodon*," says the Professor, "though resembling most closely those of the *Iguana*, do not present an exact magnified image of them, but differ in the greater relative thickness of the crown, its more complicated external surface, and still more essentially in a modification of the internal structure by which the *Iguanodon* equally deviates from every other known reptile. As in the *Iguana*, the base of the tooth is elongated and contracted, while the crown is expanded and smoothly convex on the inner side. When first formed it is acuminated, compressed, its sloping sides serrated, and its external surface traversed by a median longitudinal ridge, and coated by a layer of enamel; but beyond this point the description of the tooth of the *Iguanodon* indicates characters peculiar to that genus. In most of the teeth that have hitherto been found three longitudinal ridges traverse the outer surface of the crown, one on each side of the median primitive ridge; these are separated from each other, and from the serrated margins of the crown, by four wide and smooth longitudinal grooves. The relative width of these grooves varies in different teeth; sometimes a fourth small longitudinal ridge is developed on the outer side of the crown. The marginal serrations which at first sight appear to be simple notches, as in the *Iguana*, present under a low magnifying power the form of transverse ridges, themselves notched so as to resemble the mammillated margins of the unworn plates of the elephant's grinder. Slight grooves lead from the interspaces of these notches upon the sides of the marginal ridges. These ridges or dentations do not extend beyond the expanded part of the crown; the longitudinal ridges are continued farther down, especially the median ones, which do not subside till the fang of the tooth begins to assume its subcylindrical form. The tooth at first increases both in breadth and thickness; it then diminishes in breadth, but its thickness goes on increasing; in the large and fully-formed teeth the fang decreases in every diameter, and sometimes tapers almost to a point. The smooth unbroken surface of such fangs indicates that they did not adhere to the inner side of the maxillæ, as in the *Iguana*, but were placed in separate alveoli, as in the Crocodile and Megalosaur; such support would appear indeed to be indispensable to teeth so worn by mastication as those of the *Iguanodon*. The apex of the tooth soon begins to be worn away, and it would appear by many specimens that the teeth were retained until nearly the whole of the crown had yielded to the daily abrasion. In these teeth however the deep excavation of the remaining fang plainly bespeaks the progress of the successional tooth prepared to supply the place of the worn-out grinder. At the earlier stages of abrasion a sharp edge is maintained at the external part of the tooth by means of the enamel which covers the surface of the crown; the prominent ridges upon that surface give a sinuous contour to the middle of the cutting edge, whilst its sides are jagged by the lateral serrations: the adaptation of this admirable dental instrument to the cropping and comminution of such tough vegetable food as the *Clathrariæ*, and similar plants, which are found buried with the *Iguanodon*, is pointed out by Dr. Buckland with his usual felicity of illustration in his 'Bridgewater Treatise,' vol. i. p. 246. When the crown is worn away beyond the enamel it presents a broad and nearly horizontal grinding surface; and now another dental substance is brought into use to give an inequality to the surface; this is the ossified remnant of the pulp, which being firmer than the surrounding dentine, forms a slight transverse ridge in the middle of the grinding surface. The tooth in this stage has exchanged the functions of an incisor for that of a molar, and is prepared to give the final compression, or comminution, to the coarsely-divided vegetable matters.

"The marginal edge of the incisive condition of the tooth, and the median ridge of the molar stage are more effectually established by the introduction of a modification into the texture of the dentine, by which it is rendered softer than in the existing *Iguanæ* and other reptiles, and more easily worn away; this is effected by an arrest of the calcifying process along certain cylindrical tracts of the pulp, which is thus continued in the form of medullary canals, analogous to those in the soft dentine of the *Megatherium's* grinder from the central cavity, at pretty regular intervals, parallel with the calcigerous tubes, nearly to the surface of the tooth. The medullary canals radiate from the internal and lateral sides of the pulp cavity, and are confined to the dentine forming the corresponding walls of the tooth; their diameter is 1-1250th of an inch; they are separated by pretty regular intervals, equal to from 6 to 8 of their own diameters; they sometimes divide once in their course. Each medullary canal is surrounded by a clear space; its cavity was occupied in the section described by a substance of a deeper yellow colour than the rest of the dentine. The calcigerous tubes present a diameter of 1-25,000th of an inch, with interspaces equal to about 4 of their diameters. At the first part of their course near the pulp cavity, they are bent in strong undulations, but afterwards proceed in slight and regular primary curves, or in nearly straight lines to the periphery of the tooth. When viewed in a longitudinal section of the tooth, the concavity of the primary curvature is turned towards the base of the tooth; the lowest tubes are inclined towards the root, the rest have a general direction at right angles to the axis of the tooth; the few calcigerous tubes which proceed vertically to the apex are soon worn away, and can be seen only in a section of the apical part of the crown of an incompletely developed tooth. The secondary undulations of each tooth are regular and very minute. The branches, both primary and secondary of the calcigerous tubes, are sent off from the concave side of the main inflections; the minute secondary branches are remarkable at certain parts of the tooth for their flexuous ramifications, anastomoses, and dilatations into minute calcigerous cells, which take place along nearly parallel lines for a limited extent of the course of the main tubes. The appearance of interruption in the course of the calcigerous tubes, occasioned by this modification of their secondary branches, is represented by the irregularly dotted tracts in the figure. This modification must contribute with the medullary canals, though in a minor degree, in producing that inequality of texture and density in the dentine, which renders the broad and thick tooth of the *Iguanodon* more efficient as a triturating

Teeth of *Iguanodon*.

a, young tooth; *b*, *c*, teeth further advanced, and worn.

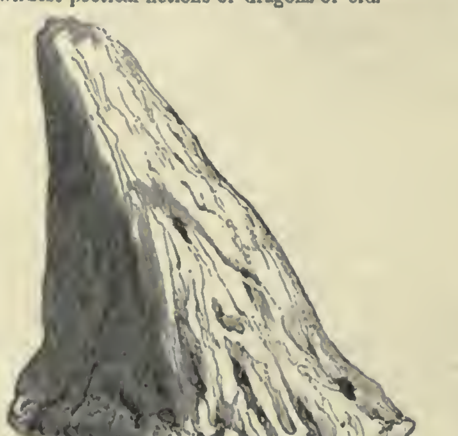
instrument. The enamel which invests the harder dentine, forming the outer side of the tooth, presents the same dirty peculiar brown colour when viewed by transmitted light as in most other teeth; very minute and scarcely perceptible undulating fibres, running vertically to the surface of the tooth, are the only structure I have been able to detect. The remains of the pulp in the contracted cavity of the completely formed tooth are converted into a dense but true osseous substance, characterised by minute radiated cells, whose long axis is parallel with the plane of the concentric lamellæ which surround the few and contracted medullary canals in this substance. The microscopical examination of the structure of the *Iguanodon's* teeth thus contributes additional evidence of the perfection of their adaptation to the offices to which their more obvious characters had indicated them to have been destined.

"To preserve a trenchant edge, a partial coating of enamel is supplied, and that the thick body of the tooth might be worn away in a more regularly oblique plane, the dentine is rendered softer as it recedes from the enamelled edge by the simple contrivance of arresting the calcifying process along certain tracts of the inner wall of the tooth. When attrition has at length exhausted the enamel, and the tooth is limited to its function as a grinder, a third substance has been prepared in the ossified remnant of the pulp to add to the efficiency of the dental instrument in its final capacity."

The size of this giant of the Weald in former ages was enormous. In Dr. Mantell's collection there is a portion of a femur 22 inches in girth in the smallest part. The thigh bone then of the *Iguanodon* exceeded in bulk that of the largest elephant, and its length is on good grounds calculated to have been from 4 to 5 feet. Dr. Mantell carefully compared the bones of the *Iguanodon* with those of the *Iguana*, and by taking an average from eight separate parts of the respective skeletons, he gives the following as the dimensions of the former:—

	Feet.
Length from Snout to the extremity of the Tail . .	70
Length of Tail	52½
Circumference of Body	14½

The thigh bone of the *Iguanodon* is considered by Dr. Mantell to be twenty times the size of that of a modern *Iguana:* but as animals do not increase in length in the same ratio as in bulk, it does not follow that the *Iguanodon* attained the length of 100 feet, although it probably approached 70 feet. (Buckland.) On the snout of this monstrous reptile was a nasal horn, and its appearance must have realised the wildest poetical fictions of dragons of old.



Nasal horn of *Iguanodon*, two-thirds of the natural size.

In the Report above alluded to, Professor Owen gives his reasons for doubting if the *Iguanodon* was so large an animal as is inferred by Dr. Mantell.

"From the comparison," he says, "which the few connected portions of the skeleton of the *Iguanodon* enable us to make between the bones of the extremities and the vertebral column, it is evident that the hind legs at least, and probably also the fore legs, were longer and stronger in proportion to the trunk than in any existing Saurian. One can scarcely suppress a feeling of surprise that this striking characteristic of the *Iguanodon*, in common with other *Dinosauria*, should have been hitherto overlooked; since the required evidence is only an associated vertebra and long bone of the same individual, or a comparison of the largest detached vertebræ with the longest femora or humeri. This characteristic is nevertheless one of the most important towards a restoration of the extinct reptile, since an approximation to a true conception of the size of the entire animal could only be made after the general proportions of the body to the extremities had been ascertained. But it is very obvious that the exaggerated resemblances of the *Iguanodon* to the *Iguana* have misled the palæontologists who have hitherto published the results of their calculations of the size of the *Iguanodon;* and hence the dimensions of 100 feet in length, arrived at by a comparison of the teeth and clavicle of the *Iguanodon* with the *Iguana*, of 75 feet from a similar comparison of their femora, and of 80 feet from that of the claw-bone, which if founded upon the largest specimen from Horsham, instead of the one compared by Dr. Mantell, would yield a result of upwards of 200 feet for the total length of the *Iguanodon*, since the Horsham phalanx exceeds the size of the largest of the recent *Iguana's* phalanges by 40 times. But the same reasons which have been assigned for calculating the bulk of the *Megalosaurus* on the basis of the vertebræ apply with equal force to the *Iguanodon*. Now the largest vertebra of an *Iguanodon* which has yet been obtained does not, as has been before stated, exceed 4½ inches in length; the most common size being 4 inches. The intervertebral substance is shown by the naturally juxtaposed series of dorsal vertebræ in the Maidstone *Iguanodon* to be not more than one-third of an inch in thickness. All the accurately determined vertebræ of the *Iguanodon* manifest the same constancy of their antero-posterior diameter which prevails in Saurians generally; the discovery of the true character of the supposed lacertian vertebræ, 6 inches long, removes the only remaining doubt that could have attached itself to this important element in the present calculation. The cervical vertebræ of the *Iguanodon*, when discovered, if they prove to differ in length from the known dorsal and caudal vertebræ, will be in all probability somewhat shorter, as they are in the Hylæosaur, and in all known Crocodiles and Lizards. It remains therefore to discover the most probable number of the vertebræ and the ribs; and especially the variation in both structure and size which the ribs of the *Iguanodon* already obtained demonstrate to have prevailed in the costal series, renders it much more probable that the number of the costal vertebræ would resemble that of the Crocodiles, than that of the Saurians or other Lizards with unusually numerous dorsal vertebræ, and which possess ribs of a simple and uniform structure, and of nearly equal size. The most probable number of vertebræ of the trunk, from the atlas to the last lumbar inclusive, calculated from Crocodilian analogies, would be 24 vertebræ; which is also the number possessed by the *Iguana*. Twenty-four vertebræ estimated with their invertebral spaces at 5 inches each, give 10 feet; if to this we add the length of the sacrum, namely 17 inches, then that of the trunk of the *Iguanodon* would be 11 feet 5 inches, which exceeds that of the *Megatherium*. If there be any part of the skeleton of the *Iguana* which may with greater probability than the rest be supposed to have the proportions of the corresponding part of the *Iguanodon*, it is the lower jaw, by virtue of the analogy of the teeth and the substances they are adapted to prepare for digestion. Now, the lower jaw gives the length of the head in the *Iguana*, and this equals the length of six dorsal vertebræ, so that as five inches rather exceeds the length of the largest *Iguanodon's* vertebræ yet obtained with the intervertebral space superadded, on this calculation the length of the head of the largest *Iguanodon* must have been 2 feet 6 inches. In the description of the caudal vertebræ it has been shown that the *Iguanodon* could as little have resembled the *Iguana* in the length of its tail as in the anatomical characters of any of the constituent vertebræ of that part; the changes which the series of six caudal vertebræ present in the length and form of the spinous processes, and in the place of origin of the transvers processes, indicate the tail to have been shorter in the *Iguanodon* than in the Crocodile. Assuming however that the number of caudal vertebræ of the *Iguanodon* equalled that in the Crocodile, and allowing to each vertebra with its invertebral space 4½ inches, we obtain the length of 12 feet 6 inches for the tail of the *Iguanodon*.

	Feet.
Length of Head say	3
Length of Trunk with Sacrum	12
Length of Tail	13
Total Length of the *Iguanodon*	28

"The same observations on the general form and proportions of the animal, and its approximation in this respect to the *Mammalia*, especially the great extinct Megatherioid or Pachydermal species, apply as well to the *Iguanodon* as to the *Megalosaurus*."

Since the original discovery of the teeth in Tilgate Forest, several other portions of this remarkable animal have been found. The most interesting of these were discovered by Mr. Bensted, of Maidstone, in a green-sandstone quarry near that town. Other remains have also been obtained from the Wealden of Sussex and the Isle of Wight. On some of these remains Dr. Mantell thus remarks:—

"A recent discovery however supports the idea first suggested by the stupendous size of the bones of the extremities. In a block of calciferous grit, picked up on the sea-shore, I have laid bare a chain of eleven caudal vertebræ, belonging to the middle region of the tail, and the bodies of these bones, instead of being abbreviated, as the shortness of the known anterior caudals led us to infer, are elongated, as in the corresponding part of the skeleton of the recent *Iguana*. The length of four of these vertebræ is equal to that of five dorsals, and their spinous and transverse processes are so well developed as to show that the tail must have been greatly prolonged, probably in the same degree as in the existing Lizards. The length of the femur of this individual is equal to six caudal or eight anterior dorsal vertebræ.

"It is therefore, according to the present state of our knowledge, not at all improbable that the largest *Iguanodons* may have attained a length of from 60 to 70 feet. Although some important points in the osteology of the *Iguanodon* are still unknown, we may safely conclude that this stupendous reptile equalled in bulk the largest herbivorous *Mammalia*, and was as massive in its proportions; for living exclusively on vegetables it must have had the abdominal region greatly developed.

"Its limbs must have been of proportionate size and strength to sustain and move so enormous a carcass; the hinder extremities in all probability resembled the unwieldly contour of the Hippopotamus or Rhinoceros, and were supported by strong short feet, protected by broad ungular phalanges; the fore feet appear to have been less bulky, and adapted for seizing and pulling down the foliage and branches of trees; the jaws and teeth demonstrate its power of mastication, and the character of its food; while the remains of coniferous trees, arborescent ferns, and cycadeous plants, which are found imbedded with its remains, attest the nature of the flora adapted for its sustenance."

Whatever may be the differences of opinion as to the precise size of this creature, all writers agree as to the great interest attaching to its existence in this part of the world during the deposit of the great fresh-water beds that characterise the geology of the British Islands.

The remains of the *Iguanodon* so carefully collected and treasured by Dr. Mantell are now in the British Museum, where they will ever remain a monument of his perseverance and skill, and a means of enabling the student of natural history to come to his own conclusions on the debateable points its structure has raised. To his account of its structure Dr. Mantell adds some physiological inferences as to the structure and economy of the *Iguanodon*, with which this notice may be appropriately closed.

"In instituting a comparison between the maxillary organs of the *Iguanodon* and those of the existing herbivorous Lizards, with the view of obtaining some physiological deductions from their peculiar osteological characters, we are at once struck with their remarkable deviation from all known types in the class *Reptilia*. In the *Amblyrhynchi*, the most exclusively vegetable feeders of the Saurian order, the alveolar process, beset with teeth, is continued round the front of the mouth, the junction of the two rami of the lower jaw at the symphysis presenting no edentulous interval whatever, and the lips not being more produced than in other reptiles; for these creatures chip off and bruise their food, and cannot grind or masticate it: in the Iguanas, as previously shewn, the same character exists. In the carnivorous Saurians the teeth are also continued to the symphysical suture on each side. The extinct colossal Lizards offer no exception to this rule; in the acrodont *Mososaurus* of the Chalk, and in the thecodont *Megalosaurus* of the Oolite and Wealden, the jaws are armed with teeth round the anterior extremity. In short, the edentulous, expanded, scoop-shaped, procumbent, symphysis of the lower jaw of the *Iguanodon*, has no parallel among either existing or fossil reptiles, and we seek in vain for maxillary organs at all analogous, except among the herbivorous *Mammalia*.

"The nearest approach is to be found in certain *Edentata*, as for example in the *Cholœpus didactylus*, or Two-Toed Sloth, in which the anterior part of the lower jaw is edentulous and much prolonged.

"The correspondence is still closer in the gigantic extinct *Mylodon*, in which the symphysis resembles the blade of a spade used by turf-diggers, and has no traces of incisive sockets; and were not this part of the jaw elevated vertically in front, and the two rami confluent, it would present the very counterpart of that of the *Iguanodon*.

"The great size and number of the vascular foramina distributed along the outer side of the dentary bone, and beneath the border of the symphysis, in the *Iguanodon*, and the magnitude of the anterior outlets which gave exit to the vessels and nerves that supplied the front of the mouth, indicate the great development of the integuments and soft parts with which the lower jaw was invested. The sharp ridge bordering the deep groove of the symphysis, in which there are also several foramina, evidently gave attachment to the muscles and integuments of the under lip; while two deep pits for the insertion of the protractor muscles of the tongue, manifest the mobility and power of that organ. There are therefore strong reasons for supposing that the lip was flexible, and, in conjunction with the long fleshy prehensile tongue, constituted the instruments for seizing and cropping the leaves and branches, which, from the construction of the molars, we may infer constituted the chief food of the *Iguanodon*. The mechanism of the maxillary organs, as elucidated by recent discoveries, is thus in perfect harmony with the remarkable characters which rendered the first known teeth so enigmatical; and in the Wealden herbivorous reptile we have a solution of the problem, how the integrity of the type of organisation peculiar to the class of cold-blooded *Vertebrata* was maintained, and yet adapted, by simple modifications, to fulfil the conditions required by the economy of a gigantic terrestrial reptile, destined to obtain support exclusively from vegetable substances, in like manner as the extinct colossal herbivorous *Edentata*, which flourished in South America ages after the country of the *Iguanodon* and its inhabitants had been swept from the face of the earth. Thus in the unlimited production of successional teeth at every period of the animal's existence, in the mode of implantation of the teeth, and in the composite structure of the lower jaw, each ramus consisting of six distinct elements, the Saurian type of organisation is unequivocally manifest; while the intimate structure of the dental organs approaches that of the Sloths, and the sub-alternate arrangement and reversed position of the upper and lower series of teeth correspond with that of the Ruminants; and again, the edentulous and prolonged symphysis, and the great development of the lower lip and the integuments of the jaws, as indicated by the size and number of the vascular foramina, present a striking analogy to the *Edentata*. They who doubt the correctness of this interpretation should remember that it is in this order of *Mammalia* that we find the nearest approach to the *Reptilia;* in the scaly covering of the skin, the imperfections of the dental system, the smallness of the brain, and the long continuance of the muscular fibre after death, which are so many decadences of organisation, so to speak, that indicate a step towards that class of which the *Iguanodon* appears to have been the highest type.

"If the opinion previously advanced be correct that the anterior part of the spinal column consisted of convexo-concave, and the dorsal of plano concave vertebræ, the adult *Iguanodon* must have approached in this part of its skeleton, as well as in its sacrum, in its massive femora, with their large medullary cavities, trochanters, and condyles, and in its short and strong metatarsals and phalangeals, to that of the large herbivorous *Mammalia*. The position of the hinder limbs (the thighs and legs) in relation to the pelvis, cannot be accurately determined from the data at present obtained; but the form of the head and shaft of the femur, and the character of its articulations and processes so closely resemble those of the largest Pachyderms, as to suggest the idea that (unlike the rest of its class) the *Iguanodon* had the body supported as in the *Mammalia*, and the abdomen suspended higher from the ground than in any existing Saurians. In fine, we have in the *Iguanodon* the type of the terrestrial *Herbivora*, which in that remote epoch of the earth's physical history, termed by geologists 'the Age of Reptiles' occupied the same relative station in the scale of being, and fulfilled the same general purposes in the economy of nature as the Mastodons, Mammoths, and Mylodons of the Tertiary period, and the existing Pachyderms."

(Owen, *Report on British Fossil Reptiles;* Mantell, *Petrefactions and their Teachings;* Buckland, *Bridgewater Treatise.*)

ILEUM. [INTESTINES.]

ILEX is a name given to two very different plants. As that of a species, it indicates the Evergreen Oak of the South of Europe, or *Quercus Ilex;* as that of a genus, it belongs to the Common Holly, *Ilex Aquifolium*, the type of the natural order *Aquifoliaceæ*. This latter plant, which constitutes so beautiful a feature in the winter scenery of many parts of England, and whose scarlet or yellow berries render it so universal a decoration of churches (hence the name Holly-Tree, or Holy-Tree) and dwelling-houses at Christmas time, is in Great Britain upon the most northern limits within which it ranges in a wild state. It is however at those limits that it attains its greatest size and beauty; but it occasionally suffers from severe winters. It is common in the middle of Europe, and the southern side of the range of the Caucasus, where it is only a bush, and it probably extends far to the eastward. It is chiefly valued as a shelter in winter, and an ornamental tree, but its fine-grained heavy compact timber is used for a great number of useful purposes, especially by the turner and mathematical instrument maker; the black handles of metal teapots are carved out of its wood. It is also employed medicinally; the leaves and bark possess febrifugal powers of a strongly-marked character: the root and the bark are said to be diuretic and expectorant, but the berries have the discredit of being poisonous, producing purgative and violent emetic effects.

Besides the Common Holly and its numerous varieties, the genus *Ilex* comprehends a large number of species, the most remarkable of which are the *I. Balearica*, or broad-leaved species of Minorca, a very handsome kind, which is hardy in the middle and south of England; the *I. vomitoria*, or Cassena-Tree of the North Americans, whose leaves possess strongly-marked emetic qualities; and the *I. Paraguayensis*, or Maté Plant, of whose leaves a very large consumption takes place in South America, under the name of Tea of Paraguay. [TEA, PARAGUAY.] The leaves are dried, and afterwards used like the tea of the Chinese. (Loudon, *Arboretum Britannicum.*)

ILLÆNUS, Dalman's name for a group of the great genus *Asaphus*, as originally constituted by Brongniart in his work on the *Trilobites*. The caudal plate is one large convex part, nearly corresponding to the anterior shield. From the Transition Strata of Christiania, Ostrogothia, &c. [TRILOBITES.]

ILLECEBRA'CEÆ, *Knotworts*, a small natural order of Exogenous Plants, chiefly consisting of herbaceous weeds, found in the temperate parts of the world: they differ from *Amarantaceæ* in nothing except having stipules and a tendency to produce petals; from *Alsinaceæ* in little more than having stipules; and from *Portulaceæ* in their sepals not being in pairs. This order is one of those which break down the limits between Polypetalous and Apetalous plants, and prove how entirely artificial are such divisions. The species are often conspicuous, especially when dried, for their silvery stipules and shining calyxes, and are sometimes beautiful microscopic objects; but they are too small to be interesting in any other way, and are of no known use. They occur in various parts of the world, especially in the countries bordering on the Mediterranean. The order embraces 24 genera and about 100 species. A few occur at the Cape of Good Hope, and several are found in America. The British representatives are *Corrigiola*, *Herniaria*, and *Illecebrum*. [CORRIGIOLA; ILLECEBRUM.]

Illecebrum verticillatum.

1, a pair of leaves, with the intervening stipules; 2, a flower, seen from above; 3, a flower cut open.

ILLECE'BRUM, a genus of Plants the type of the natural order *Illecebraceæ*. It has 5 sepals slightly cohering at the base and horned at the back. Petals absent or 5, subulate, inserted with the 5 stamens on a perigynous ring; a 1-celled 1-seeded furrowed capsule bursting along the furrows. The only species is a small trailing shrub with opposite leaves having scarious stipules at the base.

I. verticillatum, Whorled Rush-Grass. It has a trailing glabrous stem, roundish leaves, verticillate whorled white minute flowers. It is found in bogs and wet marshy places, chiefly in Cornwall and Devonshire. The seeds of this shrub should be planted in a moist situation, and, if allowed to sow themselves, will spring up regularly every season. It is worth cultivation on account of the delicacy and beauty of its blossoms.

(Babington, *Manual of British Botany;* Don, *Dichlamydeous Plants.*)

ILLICEÆ. [WINTERACEÆ.]

ILLI'CIUM (illicio, I allure), a genus of Plants, so named in consequence of their very agreeable aromatic fragrance; they belong to the Winter's Bark tribe. These are now generally described as a separate family under the name of *Winteraceæ*, and are distinguished by their dotted leaves and aromatic properties from *Magnoliaceæ*, of which they are sometimes made a section. The genus *Illicium* is characterised by having from 3 to 6 petaloid sepals; 27 petals arranged in several rows below the numerous stamens and pistils. The capsules are disposed in a circular manner, and open upwards; each contains a single shining seed. The species are few in number, but widely distributed. Two are indigenous in Florida; and the others in China and the neighbouring islands. *I. Floridanum* is a red-flowered species, of which the leaves are very fragrant, and the capsules smell of anise, though more faintly than the Chinese species. The bark has been proposed as a substitute for cinnamon and sassafras barks. *I. parviflorum* also, a native of North America, has similar properties, especially in its leaves.

The most important species however is *I. anisatum*, or the Aniseed-Tree of China, of which the fruit is exported from Canton, and well known in commerce by the name of Star Anise. In India they are called Badian Khatai, or Chinese Anise. Hence the name Badiane, by which they are chiefly known on the continent of Europe, where they are more employed than in this country; being esteemed, as in the East, for their aromatic and carminative properties. The smell and taste of both the capsule and seed being like that of aniseed, a volatile oil is distilled from them, which may be employed for all the purposes of the oil of aniseed: it is said to give the flavour to Anisette de Bordeaux and to Anisette de Hollande. The Chinese use it in substance both as a condiment and a stimulant medicine, and burn it as incense in their temples. The tree flourishes in China and some of the Philippine Islands, and is found also in Japan, whence Siebold has described a new species. M. Perrotet also mentions that there is an undescribed species at Manilla, which is there called San-ki; that its leaves are mixed with their tea and coffee in the Philippines, and that a liqueur is likewise prepared from its fruit.

ILLUPIE-TREE. [BASSIA.]

ILMENITE. [TITANIUM.]

ILUANTHUS. [ACTINIADÆ.]

ILVAITE, a native Silicate of Iron, identical with *Yenite.* [IRON.]

IMBER. [COLYMBIDÆ.]

IMBRICARIA. [SAPOTACEÆ.]

IMPA'TIENS, a genus of Plants so called from the sudden and elastic force with which they burst their capsules; hence 'Noli me tangere' is the name of one of the species. Another is well known as a highly ornamental annual by the name of Balsam, whence the natural family to which it belongs has been called *Balsaminaceæ.* [BALSAMINACEÆ.] The genus is especially an East Indian one, though single species extend into Europe, Siberia, and North America. Linnæus was only acquainted with 7 or 8 species; but Dr. Wight, in the 'Madras Journal,' vol. ii., states that not less than 100 species are now known, and almost entirely from the mountains of the peninsula of India and the Himalayas; in those from Silhet as far north as the Sutlej, and in 30° N. lat., at as great elevations as 7000 feet. They are absent from the plains of India; some are found on the Malabar coast, little elevated above the sea, but only during the monsoon. Dr. Royle has stated that they are only found in the Himalayas during the rains, and hence inferred that the moisture and moderate temperature, as well as the equability of both during the rainy season, is as favourable to their growth as the heat and moisture of the peninsula; but Dr. Wight has since ascertained that the species are chiefly found at elevations of 4000 and 4500 feet, in a season where there is moisture combined with a moderate but equal temperature. These facts are important as showing the influence of climate on vegetation; and useful as affording hints and principles for the cultivation of these plants at a lower temperature than is necessary for the plants of the plains from the same latitudes, though great success has been attained in the cultivation of Balsams in this country.

IMPERATO'RIA (so named from its supposed imperial virtues in medicine), a genus of Plants belonging to the natural order *Umbelliferæ.* It has no calyx; obovate petals, contracted into an inflexed segment; the fruit flattened at the back, with a dilated flat border. The species are glabrous perennial herbs, with erect hollow terete striated stems. The umbels are large and compound, and the flowers white.

I. Ostruthium has a tuberous fleshy and somewhat creeping root of an aromatic and acrid nature; the lower leaves biternate, the upper ones less compound; the flowers are small, and of a white or pale flesh-coloured hue. It is a native of Europe and Newfoundland in damp meadows and woods. This species is the Masterwort of old English herbalists, and the root has been much celebrated as an antidote against poisons, a diuretic, and sudorific; and Lerango affirms that an infusion of it in wine has cured agues which have resisted quinine. When chewed it excites a copious flow of saliva, and acts as an agreeable stimulant to the gums. It is recommended in cases of rheumatic toothache, and is cultivated in many places for the London market.

I. angustifolia, the Narrow-Leaved Masterwort, has biternate leaves, oblong leaflets, attenuated at the base and deeply serrated. It is a native of the Alps and Piedmont. The blossoms appear in June and July, and are of a white colour. The species of this genus are of easy culture, and may be propagated either by dividing the roots or from seed.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica;* Burnett, *Outlines of Botany.*)

IMPEYAN. [PHASIANIDÆ.]

IMPREGNATION. [REPRODUCTION IN PLANTS; REPRODUCTION IN ANIMALS; STAMEN; PISTIL.]

I'NACHUS, a genus of Brachyurous Crustaceans, placed by M. Milne-Edwards under his tribe Macropodians. [MACROPODIANS.]

INCISORS. [DENTITION; TEETH.]

INCUS. [EAR.]

INDIA-RUBBER, the common name of a vegetable compound which is found in all plants with a milky juice. It is also known by the name of Caoutchouc.

The existence of a milky juice in many plants, which flows from them when their tissues are wounded, is a fact that has been familiarly known from time immemorial. It is however only a matter of recent discovery that this milky juice characterises certain families of plants. Although the great majority of plants which yield this juice in abundance are tropical, yet they are not without their European representatives. The Spurges, Dandelion, and Celandine of our road-sides are instances. The families of plants which furnish this milky juice in the greatest abundance are—*Moraceæ, Euphorbiaceæ, Artocarpaceæ, Apocynaceæ, Cichoraceæ, Papaveraceæ, Campanulaceæ,* and *Lobeliaceæ.*

This juice, which is called by botanists 'the milky juice,' because it has an appearance similar to milk, has also the physical constitution of that fluid. It is an aqueous liquid, charged with soluble matter, in which float globules of a substance insoluble in water, and which are by their tenuity held in suspension in the liquid, but for which they have no affinity, in the same manner as butter is held in suspension by milk. From the difference of the refractive powers of these two substances, each of which taken separately would be colourless or transparent, arise the opacity and white colour of the two: hence the compound is properly called a 'milky juice.'

The analogies which this juice exhibits with the milk of animals and vegetable emulsions are seen in the manner in which it acts when left to itself. Run out into the air, received and preserved in close vessels, it separates itself into two layers, as milk itself would do. The watery part very soon has an insoluble part floating upon it, which collects together and swims at the top as cream swims upon milk, and which forms nearly the half of the entire mass. But with these physical resemblances the analogies cease. That which in milk and in emulsions produced from seeds collects on the surface of the aqueous liquor is, properly speaking, a fatty body, containing oxygen in its composition; while the kind of cream which swims upon the milky juice is a compound of carbon and hydrogen.

This substance has long been known to the natives of both the Old and New World, in Hindustan and South America. It was not however till the expedition of the French academicians to South America in 1735 that its properties and nature were made known in Europe by a memoir upon it by M. de la Coudamine. This notice excited little attention; and subsequently notices of this substance were sent to the French Academy in 1751 by M. Fresnau, and in 1768 by M. Macquer. At the latter end of the last century and the beginning of the present it was brought into this country in small quantities, where, on account of its being used for rubbing out black-lead pencil marks, it acquired the name of India-Rubber.

Although after its application to the water-proofing of garments its consumption gradually increased, the importation into the United Kingdom in 1830 appears not to have been more than 50,000 lbs. In 1842 the import of this article had increased to between 700,000 and 800,000 lbs. Up to the present time the consumption of India-Rubber has prodigiously increased; and one port alone in South America is said now to send to Great Britain nearly 4000 cwts. annually. To the large consumption in the United Kingdom must be added that of America, where the application of Caoutchouc has been much more general and successful than even in our own country.

The particular species of plants which are employed for procuring India-Rubber are very numerous, and it is probable that many yield it which are not yet known to botanists. The tree which supplies most in Continental India is the *Ficus elastica*, a tree belonging to the order *Moraceæ;* it is exceedingly abundant in Asam. All the species of *Ficus* yield Caoutchouc to a greater or less extent in their juices, and even the Common Fig (*Ficus Carica*) of Europe contains it. Species of *Ficus* produce the Caoutchouc brought from Java; and *F. radula, F. elliptica,* and *F. prinoides* are amongst those mentioned as affording a portion of that brought from America. Next to the *Moraceæ* the order *Euphorbiaceæ* yields the largest quantity of Caoutchouc. The *Siphonia elastica*, a plant found in Guyana, Brazil, and extending over a large district of Central America, yields the best kinds of India-Rubber that are brought into the markets of Europe and America. To another order, *Apocynaceæ*, we are indebted for the Caoutchouc which is brought from the islands of the Indian Archipelago. The plant which is the source of this substance in those districts is the *Urceola elastica*, a climbing plant of very rapid growth and gigantic dimensions. A single tree is said to yield, by tapping, from 50 to 60 lbs. annually. Many other plants of this order yield Caoutchouc, and of those given on good authority we may mention—*Collophora utilis* and *Cameraria latifolia*, plants of South America; *Vahea gummifera*, in Madagascar; and *Willughbeia edulis*, in the East Indies. To this order belongs the Cow-Tree, or Hya-Hya (*Tabernæmontana utilis*), of Tropical America, which yields a milky juice that is drunk by the natives of the district in which it grows.

The Caoutchouc, whilst it is in the tissues of the plant, is evidently in a fluid condition; but after its separation from the other fluid parts its consistence becomes changed, and it forms a solid mass similar in its external characters to vegetable albumen. In this state it is dense and hard, but may be separated and rolled out so as to form a sheet resembling leather. It has many interesting and peculiar properties. Insoluble in water and in alcohol, it dissolves in ether, in the sulphuret of carbon, the fat oils, and the liquid carburets of hydrogen.

It is soft and elastic at the ordinary temperature, but at the temperature of 2° above the freezing point it acquires the hardness of wood. A temperature of 100° softens it without altering its form. It then unites with itself with the greatest facility, and two pieces recently cut apart re-unite so as to render it impossible to discover where the junction has taken place. But a higher temperature, approaching 150°, changes it into an adhesive substance, which on cooling does not recover the primitive properties of Caoutchouc.

In the state of recent coagulation, and while still in a pulpy condition, Caoutchouc possesses a degree of plasticity which admits of its receiving, by means of moulds, the most varied forms.

The greater part of the Caoutchouc of commerce is obtained by the natives of the countries in which it is produced in the form of shapeless masses, collected at the foot of the tree which has been incised or cut for the purpose of extracting the juice from it, or solidified in a trench made in the earth, and coagulated in this rude mould in voluminous masses, which often resemble the trunk of a large tree. A part of it however possesses other forms which the rude art of the natives attempts to communicate to it. They model with plastic clay figures of animals, imitations of the human foot, and pear-shaped bodies; and then dipping these moulds in the thickened Caoutchouc, and renewing the connection when the first coat is solidified by exposure to the air, they obtain, by breaking the mould and getting it out in fragments through an opening properly arranged, hollow flasks, figures of animals, rough slippers, &c. They thus make Caoutchouc serve for the manufacture of objects for which we ourselves employ animal membranes and leather.

India-Rubber is obtained from both the Old and New World. The East Indies supplied the original specimens seen in Europe, and have ever since been a source of supply to the British markets. It comes principally from Java, and is often glutinous, and is less esteemed in commerce than that furnished by the equatorial regions of America. Great quantities of Caoutchouc are imported into Europe from Mexico, from South America, and especially from the province of Para in Brazil. That which comes in the shape of bottles is generally preferred; and when it is pure, and the different coats which comprise it are well united, it may be employed immediately for many purposes. But it often happens that the coats which form the pear-shaped masses are badly united. It then becomes necessary, in order to make use of them, to work it up by a process of kneading, so as to obtain it in a coherent or homogeneous mass. This operation becomes especially indispensable when, as most commonly happens, the Caoutchouc is in large impure masses, and mixed with sand and the débris of vegetable matter. These impurities do not entirely proceed from the moulds made in the earth into which the juice has been allowed to exude, and in which it has been left to thicken and solidify; but their quantity and their presence between the coats of the pyriform masses show that the impurity is mainly to be attributed to fraud. The Caoutchouc thus obtained is not applicable to any use until it has undergone a previous purification.

The purification of the Caoutchouc is accomplished by submitting the impure Caoutchouc to the action of cylinders furnished with teeth turning in opposite directions and with unequal velocities, which cause it to undergo a kind of mastication. By this treatment the Caoutchouc becomes softened without being liquified, and a homogeneous mass is formed which is cut in the form of rectangular blocks, which being again cut, constitute those small parallelopipedons used by draughtsmen to rub out the marks of black-lead pencils. This use was in England for a long time the only one to which this substance was applied, but this limited use was far from indicating the extent to which Caoutchouc has been employed in the last thirty years, or the multiplicity of services it has been called upon to perform for sanitary and industrial purposes. To rub out pencil-marks, to form the rude slippers which seemed well adapted to the Indian toilet, but to which a form acceptable in Europe had not been imparted, were in fact the only uses to which Caoutchouc was applied up to 1820. [CAOUTCHOUC, MANUFACTURE OF, in ARTS AND SC. DIV.]

The relations of Caoutchouc to the functions of the plants in which it is found are not understood. Many fallacious views have been offered on this subject. Schulze of Berlin, who has written most extensively on this subject, regarded it as a principle in the juices of plants analogous to the fibrine of the blood, but his views with regard to the milky juice of plants and the laticiferous tissue are now generally allowed to be erroneous. It is not improbable that Caoutchouc is formed as the result of the deoxidation of cellulose, or some other ternary constituent. The chemical composition of Caoutchouc is Hydrogen and Carbon. In what proportion they exist is not known. When distilled, Caoutchouc yields oils which have a composition similar to oil of turpentine—$C_{10} H_8$ or $C_{20} H_{16}$.

(*Reports of the Great Exhibition of* 1851, Class XXVIII., by Dr. Lankester; Schleiden, *Principles of Scientific Botany*; Gregory, *Handbook of Organic Chemistry*.)

INDIAN CORN. [ZEA.]

INDIAN CRESSES. [TROPÆOLACEÆ.]

INDIAN OX. [BOVIDÆ.]

INDIAN SHOT. [MARANTACEÆ.]

INDIANITE. This Mineral occurs in granular masses. It has a hardness 5·0 to 5·5. It scratches glass. The colour is white or grayish; lustre shining; translucent; specific gravity 2·74. It is infusible by the blow-pipe, and gelatinises in acids. It occurs associated with *Garnet*, *Felspar*, *Fibrolite*, and *Hornblende*.

INDICATOR. [CUCULIDÆ.]

INDICOLITE. [TOURMALINE.]

INDIGO. [INDIGOFERA.]

INDIGOFERA, a genus of Plants belonging to the natural family *Leguminosæ*, indigenous in the equinoctial parts of Asia, Africa, and America, and celebrated for some of the species yielding Indigo. The species are about 150 in number; all are small herbaceous or shrubby plants. The leaves are usually pinnate; the flowers small and papilionaceous, in axillary clusters of a purple, blue, or white colour. The calyx is 5-cleft; segments acute; vexillum roundish, emarginate; keel furnished with a subulate spur on both sides. Stamens diadelphous (9 and 1). Legume continuous, one or more seeded. Seeds usually truncated, separated by cellular spurious partitions. There is some difficulty in ascertaining all the cultivated species, as the subject is usually neglected both by naturalists and cultivators.

I. tinctoria is the species generally cultivated in India, whence it has been introduced both into Africa and America. It is suffruticose, erect, branched; leaves pinnate: leaflets 5 or 6 pairs, long-obovate, scarcely pubescent; racemes of flowers axillary, shorter than the leaves. Legumes approximated towards the base of the rachis, nearly cylindrical, slightly torulose, deflexed, and more or less curved upwards; sutures thickened; seeds about 10, cylindrical, truncated at both ends. This species is sometimes called Indigo Franc and French Indigo in the West Indies. It is said to be found wild along the sands of Senegal. ('Flore de Senegambie,' vol. i. p. 178.)

I. Anil. From the name it might be inferred that this was an Asiatic plant; but it is said by De Candolle to grow wild in America, and to be cultivated in both Indies, as also along the Gambia in Africa. The name Anil, which has passed into the Spanish, has evidently the same origin as the Arabic Neel, or Nil. The Spaniards and Portuguese, who had found the way to India by two opposite courses, must there have become acquainted with Indigo, and adopted its Indian name: they were the first to manufacture it in America—the Portuguese in Brazil, and the Spaniards in Mexico. This species is characterised by an erect suffruticose stem; leaves pinnate in 3 to 8 pairs; leaflets oval-oblong, scarcely pubescent on the under surface; racemes axillary, shorter than the leaves; legumes compressed, not torulose, deflexed, curved, with both sutures thickened and prominent, 10- to 12-seeded. Messrs. Wight and Arnot state, "We have not sufficient materials to enable us to determine if *I. Anil* be a distinct species. We know of no distinguishing character, unless it is to be found in the fruit, and the descriptions given of that part in the two species differ in different authors." But the authors of the 'Flore de Senegambie' consider them distinct, as do most botanists.

I. cærulea (Roxb.). This is a new species described by Dr. Roxburgh, and called Karneeli in Telinga by the natives of the peninsula of India. He states that from the leaves of this plant he had often extracted a most beautiful light Indigo, more so than he ever could from the Common Indigo Plant, or even from *Nerium tinctorium*, and in a large proportion. He says it is an erect shrubby species, growing in dry barren uncultivated ground, to the height of 3 feet, and higher in good garden soil. It flowers during the wet and cold seasons. The leaves are pinnate; leaflets 4-paired, obovate, emarginate; racemes rather shorter than the leaves; legumes reflexed, curved, contracted between the seeds, hairy; from 3- to 4-seeded. De Candolle inquires whether this be sufficiently distinct from *I. tinctoria*. Dr. Roxburgh states that it comes near to *I. argentea*, Linn. The process he adopted for extracting Indigo from this plant was similar to that practised with the leaves of *Nerium tinctorium*, or the scalding process.

I. argentea is a species usually stated to be a native of India, and the authority of Dr. Roxburgh might be cited for the fact; but Messrs. Wight and Arnott state that *I. argentea* of Linnæus is not found in India. It is the species cultivated in Egypt and Barbary for the sake of its Indigo, and, according to Humboldt, also in America. The Indian species which has been confounded with it is *I. paucifolia* of Delille, which has alternate leaflets, and linear, slightly compressed, torulose legumes. *I. argentea* is shrubby, with round branches, which appear of a silky whiteness from appressed pubescence; leaves pinnate, 1- to 2-paired; leaflets opposite, obovate, silky-pubescent; racemes shorter than the leaf; legumes pendulous, much compressed, torulose, canescent; 2- to 4-seeded.

I. disperma. This, according to Humboldt, is also one of the species cultivated in America, and seen among the most ancient hieroglyphical paintings of the Mexicans. Dr. Bancroft considers it as the species called Guatemala Indigo, which yields fine pulp, but is less productive than other species. The stem is herbaceous, weak; the branches round; leaves pinnate, 4- to 6-paired; leaflets elliptico-olbong, smooth; racemes slender, larger than the leaf; legumes round, subtorulose, mucronate; 2-seeded.

Plants of other genera are also employed for obtaining Indigo—as *Wrightia* (*Nerium*, Roxb.) *tinctoria*, *Marsdenia tinctoria*, *Galega tinctoria*, but especially the first two. Dr. Bancroft (vol. i. p. 190) also adduces *Spilanthes tinctoria*, *Scabiosa succisa*, *Cheiranthus fenestralis*; also a species of *Bignonia* and a *Tabernæmontana*, on the African coast, with *Amorpha fruticosa* and *Sophora tinctoria*, as all yielding a blue dye, or coarse sorts of indigo. [INDIGO, in ARTS AND SC. DIV.]

INDU. [LEMURIDÆ.]

INFEROBRANCHIA'TA, the third order of Gasteropodous *Mollusca*, in the system of Cuvier, who describes them as having nearly the form and organisation of *Doris* and *Tritonia*, but remarks that their branchiæ, instead of being placed on the back, are arranged in the form of two long suites of leaflets on the two sides of the body under the advanced border of the mantle. He records two genera, *Phyllidia* and *Diphyllidia*.

Phyllidia.—Mantle naked, and most frequently coriaceous; no shell. Mouth a small proboscis, with a tentacle on each side; two other tentacles come forth above two small cavities of the mantle. Organs of generation under the right side forward. Heart towards the middle of the back. Stomach simple, membranous; intestine short. (Cuvier.)

M. De Blainville describes the body of the genus *Phyllidia* as oblong and rather convex; the head and the foot hidden by the border of the mantle; four tentacles, the two upper ones retractile in a cavity which is at their base, the two lower buccal; mouth without an upper tooth; a lingual denticulated mass; branchial laminæ all round the lower border of the mantle, except in front; vent at the posterior and mesial part of the back; orifices of the organs of generation in a common tubercle at the anterior fourth of the right side.

P. pustulosa is a native of the Indian seas, where the other species have also been found.

Phyllidia pustulosa.

Diphyllidia (*Linguella* ? Leach).—Branchiæ nearly the same as in *Phyllidia*, but the mantle is more pointed behind; the head, which is demicircular (la tête, en demi-cercle), has on each side a pointed tentacle and a slight tubercle; vent on the right side. (Cuvier.)

M. De Blainville thus describes *Linguella*, which both Cuvier and himself seem to consider as identical with *Diphyllidia*.

Body oval, very much depressed, the mantle projecting beyond the foot on all sides, except in front; head uncovered. Branchial lamellæ oblique, and only occupying the two posterior thirds of the inferior border of the mantle; vent inferior, situated at the posterior third of the right side; orifices of the organs of generation in the same tubercle, at the anterior third of the same side.

Linguella Elfortii, De Blainv. (*Diphyllidia Brugmansii* ? Cuv.). M. De Blainville says that the locality of this animal is unknown. Cuvier says that *Linguella Elfortii* appears to him not to be different from his *Diphyllidia Brugmansii*.

M. De Blainville further says that it is probable that the genus established by M. Rafinesque under the name of *Arminia* does not differ much from *Linguella*. In his 'Additions and Corrections' to his 'Manuel' he says that M. Otto has discovered a species of *Linguella* in the sea of Naples.

Linguella Elfortii. De Blainville.

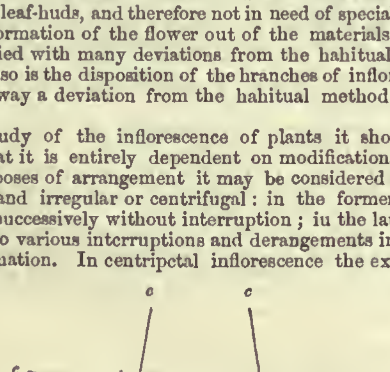
M. Rang observes that *Diphyllidia, Languella*, and *Arminia* being identical, Cuvier's name should be preserved: the two subsequent names should consequently be omitted.

Messrs. Forbes and Hanley, in the Appendix to the 'History of British Mollusca,' give an account of the taking of specimens of *Diphyllidia lineata* in the Shetland Isles and at Whitburn in Durham.

M. Rang included the fresh-water *Aucylus* in this group. It has however pulmonic sacs, and belongs to the *Limneadæ*.

INFLORESCENCE, in Plants, is the manner in which their flowers are arranged. A flower being a body analogous to a leaf-bud, with a similar origin, and capable, under particular circumstances, of reverting absolutely to that condition, it follows that the branching of that part of a plant which bears flowers should be of the same nature as that which bears leaf-buds, and therefore not in need of special explanation. But as the formation of the flower out of the materials of a leaf-bud is accompanied with many deviations from the habitual development of its parts, so is the disposition of the branches of inflorescence often in a similar way a deviation from the habitual method of arranging those parts.

In the study of the inflorescence of plants it should never be forgotten that it is entirely dependent on modifications of the axis. For the purposes of arrangement it may be considered as regular or centripetal, and irregular or centrifugal: in the former all the parts are formed successively without interruption; in the latter the parts are subject to various interruptions and derangements in the progress of their formation. In centripetal inflorescence the external flowers



of a disc, or the lowermost of a cone, are first developed, and consequently first expanded; and hence the course of unfolding proceeds from the circumference to the centre, or, which is the same thing, from the base to the apex. In centrifugal inflorescence the axis of growth is arrested in its progress by the formation of a flower-bud, as at *a*, in the accompanying diagram; two lateral points then develop from below *a*, and lengthen to *b*, where a new flower-bud appears, and stops the growth; two other lateral points are produced from below *b* and lengthen to *c*, where a new flower-bud again arrests the progress of development; and so on. In this case it is clear that *a* in the centre, being first formed, will expand before *b b* and *c c c c*; that *b b* will in like manner open before *c c c c*, and in the same way all the others: hence the order of expansion of the flowers is from the centre to the circumference. To this kind of inflorescence the word Cyme is usually applied. It occurs in the Common Elder, the Laurustinus, &c.

The centripetal inflorescence, in its simplest state, is merely a branch bearing flowers instead of leaf-buds, as in the Hyacinth and the *Ornithogalum*. If the flowers are sessile, it is then called a Spike; if stalked, a Raceme. If the branch of the spike or its axis is so much contracted as to become a broad disc, as in the Dandelion, or Daisy, or common Artichoke, the inflorescence is called a Head or Capitulum; if the same thing happens to a raceme, the Umbel of Astrantia, Fennel, Parsley, &c., is the result. Let the flower-stalks of the raceme be branched or racemose, and the Panicle is produced.

The following is a survey of the kinds of inflorescence and their names, from Professor Schleiden's 'Principles of Scientific Botany.'

A. The Solitary Flower, as terminal or axillary flower (Flos Solitarius, terminalis vel axillaris). The latter may be situated in whorls, and then form a Verticil (Verticillus).

B. Simple Inflorescence.

α. Inflorescentia Centripeta.

1. The Capitulum. The undeveloped axis is here usually enlarged upward, with a fleshy or spongy substance, and the more so if the number of flowers is very great. It may be more minutely designated as simple, discoid, cupulate, lageniform, conical, and cylindrical, as it approaches nearer to one or another. The last form then passes gradually into the spadix. Special varieties are:—

* The Calathium (Anthodium, Ehrh.; Flos Compositus, Linn.), a many-flowered capitulum, whose single flowers stand in the axils of more or fewer stunted bracts, and are surrounded with one or more circles of sterile bracts, as in the family of the *Compositæ*.

** The Cœnanthinum, Nees (Hypanthodium, Link.). Exactly like the preceding inflorescence in some *Urticaceæ*. The cup-shape of the peduncle in *Ficus* is no distinction, since it is wanting in *Dorstenia*; and it exists in some *Compositæ*; the same may be said with regard to the sterile bracts, which are as much stunted in *Dorstenia* as they are clearly present in *Ficus*.

2. The Spike (Spica) in very various forms. The kinds are:—

* The Catkin (Amentum), distinguished by the fact that it falls off entire, or by its imperfect flowers. The male inflorescence of *Cupuliferæ, Salicaceæ, Betulaceæ*, and some few other plants.

** The Spadix, a closely crowded spike, or partially a cylindrical capitulum with fleshy peduncle; in *Araceæ*, Maize, and some other Grasses, and in Palms, in the last of which it is often compound (Spadix Ramosus).

*** The Cone (Strobilus or Conus), a cylindrical capitulum or solid spike, on which the individual foliar organs become woody scales; as in the *Coniferæ*, the *Casuarinaceæ*, the *Betulaceæ*, and some others.

**** The Spikelet (Spicula), the simple inflorescence of the Grasses and *Cyperaceæ*; namely, a few-flowered spike, whose flowers have no bracts, surrounded at the basis by one or two sterile bracts (Glumæ).

3. The Umbel (Umbella) in the *Umbelliferæ*; when compound termed Umbellule (Umbellula).

4. The Raceme (Racemus) occurs in very different forms; it is usual to distinguish in it—

The Corymb (Corymbus), a pyramidal raceme.

β. Inflorescentia Centrifuga.

5. The Cyme or False Umbel (Cyma), is a corymb with Inflorescentia Centrifuga.

That only singular cases are distinguished in these is a proof of the totally unscientific patching together of our terminology. The compound raceme, the compound umbel, and capitulum, with inflorescentia centrifuga are all called a Cyme (Cyma), which is contrary to the commonest scientific laws. De Candolle has further applied the term Cyme to the inflorescence of the *Boraginaceæ*, which, on account of the peculiar manner in which it unrolls itself, he terms Cyma Scorpioides; and he adds the fiction, that the undermost first-blooming flower is really the terminal blossom, and the second, the terminal blossom of side axis, is developed in a disproportionate degree, &c. From the rolling up there is just as little to be deduced as from the same phenomenon in the leaves of *Ficus* and *Cycadaceæ*. The position of the bracts, as seen in *Cerinthe*, contradicts this fiction; and the history of the development, which can alone determine the point, appears to prove that here a one-sided raceme or spike is present, whose unrolling is only a peculiar situation of the buds.

C. Once-Compound Inflorescence.

α. Pure or Homomorphous.

* Inflorescentia Centripeta.

6. The Spike of the Grasses (Spica), several spikes united in a spicate arrangement, as in the Grasses; the component spikes are termed Spikelets (Spiculæ).

7. The Umbel (Umbella). Umbels united in umbels; the components are termed Umbellules (Umbellulæ).

Sound terminology would have long ago rejected these words, and exchanged them for Spica and Umbella Composita.

8. The Panicle (Panicula); see No. 11.

None of the remaining combinations deserve special names, and may probably be classed among those mentioned under 9 and 11.

** Inflorescentia Centrifuga.

9. The Cyme or False Umbel (Cyma); see No. 5 and No. 14.

10. The Anthela; see No. 16.

β. Mixed or Heteromorphous.

* Inflorescentia Centrifuga.

See No. 14.

** Inflorescentia Centripeta.

See No. 11.

D. Many-Times-Compound Inflorescence.

* Inflorescentia Centripeta.

11. The Panicle (Panicula), every many-branched inflorescence; in Grasses universally, and otherwise only in developed pedicels.

12. The Thyrse (Thyrsus), a panicle, with very short pedicels; with the exception of Grasses, found almost universally.

Both terms are applied also to once-compound inflorescences. De Candolle uses the term Thyrsus for those in which Inflorescence Centrifuga and Centripeta are mingled; others differently; all arbitrarily.

13. The Anthurus, an inflorescence that has the kind of aspect of that of the *Amaranthus caudatus* or the *Chenopodiaceæ*.

** Inflorescentia Centrifuga.

14. The Cyme (Cyma), also in manifold combinations, in which however we not consider whether the side ramifications follow the Inflorescence Centripeta or Centrifuga in longer pedicels.

15. The Bunch (Fasciculus), a manifold compound cyme, with short pedicels, and rather crowded.

16. The Anthela, all kinds of inflorescences in the *Juncaceæ* and *Cyperaceæ*.

17. The Glomerule (Glomerulus), many inflorescences that appear almost like a capitulum, and consist only of ill-formed, imperfect flowers, as in some *Chenopodiaceæ*, *Urticaceæ*, and *Juncaceæ*.

We subjoin Professor Schleiden's closing remarks:—

"I leave every one with thinking faculties to draw for himself the sad conclusions which the preceding survey affords; and I think that I have not to defend myself to any one who is acquainted with our literature against the charge that the foregoing is a frivolous vagary of my humour. Röper first attempted a scientific development of the inflorescence. No one that I know of has followed him, except Lindley. Physiologists seem not to have accounted it of sufficient importance. Systematists have too much to do with their herbaria, and it is much easier to coin a new word than to study minutely the progressive development through a large series of plants. For the sake of those unacquainted with these matters I will insert the following examples:—In *Lotus corniculatus*, Koch ('Syn. Fl. Germ.') has a Capitulum, Kunth ('Fl. Berol.'), an Umbella, Reichenbach ('Fl. Excurs.'), actually a Fasciculus. To *Eriophorum vaginatum* Kunth gives a Spica; Koch, a Spicula. For *Cladium Mariscus* Kunth has Umbellæ Axillares et Terminales; Koch, Anthelæ Axillares et Terminales; Reichenbach, Cymæ Axillares et Terminales; in *Isolepis supina* Koch has Spiculis in Fasciculum aggregatis; Kunth, Spicis Conglomeratis. I have here omitted the French and English botanists, or the matter would have been still more glaring."

INFUSORIA. This term has been applied to the numerous minute animals found in water, which are commonly called Animalcules.

The invention of the microscope by Hooke revealed the existence of myriads of living creatures whose presence was before unknown; and this instrument has shown that a drop of water, though it may appear to the naked eye to be perfectly clear, is perhaps swarming with living beings. Ehrenberg (whose labours have principally contributed to the knowledge of the true nature and structure of the infusory animalcules) has described species which are not larger than from 1·1000th to 1·2000th of a line in diameter, and which are separated from one another by intervals not greater than their own size. A cubic inch of water may thus contain more than 800,000 millions of these beings, estimating them only to occupy one-fourth of its space; and a single drop (measuring not more than a line in diameter) placed under the microscope will be seen to hold 500 millions, an amount perhaps nearly equal to the whole number of human beings on the surface of our globe.

If a single drop of water thus swarms with life, what incalculable numbers of animalcules must be contained in every stagnant pond or lake, and in the sea.

When Linnæus arranged all the organised beings known to him in the 'Systema Naturæ,' the structure of these minute animals was not sufficiently understood to enable him to distribute them according to their relations in his several classes; he therefore placed them at the end of his last class, *Vermes*, in a genus which he denominated *Chaos*. Otto Frederick Müller first separated them as a distinct order; and as the greater number of animalcules had been detected in liquids, in which vegetable or animal matters had been dissolved by infusion, he gave them the name *Infusoria*. Müller described many species, and acquired a considerable knowledge of the structure and organisation of these minute beings; but he did not base his arrangement of the different genera on their varieties of structure, but only on the differences of their external form. Gmelin, in the 13th edition of the 'Systema Naturæ,' adopted Müller's arrangement, as also did Lamarck and Cuvier, who only altered the divisions and subdivisions of the class without changing the mode of arrangement or adding any new facts respecting the structure of these animals. Bory de St. Vincent formed a new classification; but he also based his system on their external forms, which later investigations have shown to possess little importance as distinctive characters, for two species very unlike in external form may be almost identical in internal structure.

No new facts of importance respecting the organisation of the *Infusoria* were discovered after the publication of the work of Müller in 1773-74, till Professor Ehrenberg of Berlin directed his attention to the subject. He made numerous observations on the internal structure of these animals by means of feeding them with particles of colouring matter, which he diffused in the water which contained them. The substance which he found to answer this purpose in the most satisfactory manner was pure indigo. It was necessary to use colours not chemically combining with water, but only diffusible through the fluid in a state of minute subdivision, so that the coloured particles might be seen passing through the body of the animal.

The result of Ehrenberg's labours was given to the world in his great work entitled 'Die Infusionsthierchen,' in which he described upwards of 500 species of these minute beings. When first published this work seemed so complete and so exhaustive of the subject, that it was some years before any one doubted either the correctness of the observations or the soundness of the conclusions of its author. The improvement however of the microscope, and the extended use of this instrument, have recently brought a large number of observers into the field, and many modifications of the views of Ehrenberg have been introduced. We present here a summary of the conclusions arrived at by Ehrenberg, as a fit starting-point for a history of the more recent views of naturalists and comparative anatomists on the subject of the *Infusoria*:—

1. All the *Infusoria* are organised, and the greater part of them (probably all) are highly organised bodies.

2. The *Infusoria* constitute two very natural classes of animals, according to their structure, which classes admit of subdivision upon the same principle.

3. The existence of the *Infusoria* in the four quarters of the globe, and the sea, is proved; as also that of individuals of the same species in the most opposite ends of the world.

4. The geographical distribution of the *Infusoria* upon the earth follows the laws observed regulating that of other natural bodies.

5. Most of the *Infusoria* are visible to the naked eye; many are visible as moving points; and the size of the body does not exceed in any case 1·12th of an inch.

6. The minute invisible *Infusoria*, in consequence of their immense and swarming numbers, colour large tracts of water with very remarkable hues.

7. They give rise to one kind of phosphorescence of the sea, though in themselves invisible.

8. They compose (though singly invisible) a sort of mould, through living in dense and crowded masses.

9. In a cubic inch of this mould more than 41,000 millions of single animals exist, and constitute most likely the chief proportion of living bodies upon the face of the earth.

10. The *Infusoria* are the most reproductive of organised bodies.

11. From one of the known propagative modes of the *Infusoria*—that is, self-division—a continual destruction beyond all idea of the individual, and a similar interminable preservation and extension of it, in air and water, ensue, which poetically border upon eternal life and growth.

12. The copulation of *Gemmæ*, which perhaps includes the hitherto-unsolved polyembryonate riddle of the seeds of all plants and vegetable formations, is solved in the family *Closteria*. [DESMIDEÆ.]

13. The *Infusoria*, in consequence of their silicious shells, form indestructible earths, stones, and rocky masses. [DIATOMACEÆ.]

14. With lime and soda we can prepare glass, and swimming bricks, out of invisible animalcules; use them as flints; probably prepare iron from them; and use the 'mountain meal' composed of them as food in hunger. [BERGMEHL.]

15. The invisible *Infusoria* are sometimes hurtful by causing the death of fish in ponds, deterioration of clear water, and boggy smells; but not, as has been supposed, in giving rise to malaria, plague, and other maladies.

16. The *Infusoria* appear to be (as far as is yet known) sleepless.

17. The *Infusoria* partly disappear by the deposition of ova, and thereby undergo, passively, various changes of form.

18. The *Infusoria* form invisible intestinal worms in many animals, and in man, even if the *Spermatozoa* are excluded from amongst them.

19. The microscopic *Infusoria* have also themselves internal and external parasites.

20. The *Infusoria* possess a comparatively long life.

21. As the pollen of the pine falls yearly from the clouds, in the form of sulphur rain, so do the much smaller animalcules appear (from being passively elevated with the watery vapour) floating in a live state in the atmosphere, and sometimes perhaps mixed with dust.

22. In general the *Infusoria* maintain themselves pretty uniformly against all external influences, as do larger organised bodies. It is true that they sometimes consume strong poisons without immediate injury, but not without an after-effect.

23. The weight of the invisible *Infusoria*, light as it is, is yet calculable, and the most gentle current of air or draught can play with their bodies as with the vapour of water.

24. The evident and great quickness of the motion of *Infusoria* is reducible as follows:—*Hydatina senta* moves 1-12th of an inch in 4 seconds, *Monas punctum* the same in 48 seconds, while *Navicula gracilis* takes 26 minutes and 24 seconds to progress the same distance.

25. Linnæus said 'omnis calx è vermibus:' either to maintain or deny 'omnis silex, omne ferrum ve, vermibus,' would be at the present moment unjust.

26. The direct observations as yet known, upon the theory of 'generatio primitiva,' are wanting in necessary strictness. Those observers who profess to have seen the sudden origin of the minutest *Infusoria* from elementary substances, have quite overlooked the compound structure of these organic bodies.

27. The frequent wonderful changes of form of many *Infusoria* are yet to have their limits, and the laws governing them defined.

28. The power of infusorial organisation is instinctively shown by the strong chewing apparatus, with teeth, which they possess, and their exhibition, likewise of a complete mental activity.

29. The study of *Infusoria* has led to a more distinct and conclusive notion of animal organisation generally, and the limits which circumscribe the animal form, from which all plants and minerals, that want the animal organic system, are distinctly separated.

30. Finally, it results from these inquiries, that experience shows an unfathomableness of organic creations, when attention is directed to the smallest space, as it does of stars, when reverting to the most immense.

Under the class *Infusoria* Ehrenberg embraced two very different forms of animal life. This he did not fail to apprehend, and he divided them into *Polygastrica* and *Rotifera*. The latter division included the animals known by the name of Wheel Animalcules. The *Polygastrica*, so-called from the supposition that the typical forms possessed a number of stomachs, included all the remaining species of *Infusoria*.

Subsequently to the first publication of his views, Ehrenberg separated from what he calls the true *Infusoria* several families of animalcules which were formerly included in the same class. The principal genera thus separated are *Spermatozoa*, *Cercaria*, and *Vibrio*, which are now considered by some as part of the class *Entozoa*, and are divided into two families, named *Cercariadæ* and *Vibrionidæ*.

The *Cercariæ* found in vegetable infusions have an ovoid or cylindrical body, furnished with a tail, which is not so long as in the Zoosperms; and in some of the species a mouth, and eye-like specks of a dull red colour have been observed on the anterior part of the body. The family of the *Vibrionidæ*, so-named from their darting or quivering motion, includes the eel-like microscopic animalcules which abound in stale paste, vinegar, &c., together with others which are parasitic on living vegetables, where they have excited particular attention, from the damage which they occasion to ears of corn, as the *Vibrio Tritici*, which infests the grains of wheat, and occasions the destructive disease called ear-cockle, or purples. The *Vibrionidæ*, as well as the *Cercariadæ*, are said to differ from the true *Infusoria* not only in the absence of internal stomachs, but also of external cilia, which prevents them from exciting any currents when placed in coloured water.

On account of the difference in the perfection of structure between the two principal groups of infusory animals, they have been separated and placed in distinct divisions of the animal kingdom by some naturalists. Professor Owen makes the *Polygastrica* the lowest class of the sub-kingdom *Acrita*, and places the *Rotifera* in the division *Nematoneura*. Dr. Grant separates them in the same manner, placing the *Polygastrica* in his lowest group *Cycloneura*, and the *Rotifera* among the *Diploneura*. Ehrenberg, who retains both forms of *Infusoria* in one class, subdivides the sections *Polygastrica* and *Rotifera* into many minor groups, which are founded upon the modifications of different organs: first as to the form of the intestine, whether it is straight or curved, complete or imperfect; secondly, he considers the varieties of the organs of mastication or dental apparatus; thirdly, many of the *Infusoria* have the integuments naked; others are furnished with a crustaceous or horny covering; but both among the *Rotifera* and *Polygastrica* the naked and coated species are intimately connected together, and very often entirely agree with one another in internal and external structure, with the single exception of the consistency of their covering. These characters however, though not separating the animals into distinct divisions, are used as subordinate means of classification: and Ehrenberg has formed two parallel series, named *Nuda* and *Loricata*; which correspond to certain of the *Gymnodes* and *Crustodes* of Bory de St. Vincent. The number of loricated *Polygastrica* is very small, but among the *Rotifera* they bear a nearer proportion to the naked species.

An account of the *Rotifera* will be found under the article ROTIFERA. We here proceed to give Ehrenberg's classification of the *Polygastrica*.

Class *Phytozoaria polygastrica*.

Swimming animals, without vertebræ, apodal, having sometimes a tail, and very often scattered vibratory or rotatory ciliæ: having no heart, but vessels extremely delicate (ténus), reticulated, transparent, and deprived of proper movement; often rudimentary eyes, with red pigmentum, indicating a nervous system, which however is not apparent; mouth nude or surrounded by vibratory ciliæ, and communicating with several ventricules; the phalanx apparent, and generally unarmed; no branchiæ; organs of generation filiform, reticulated, and granular; no distinct male organ; gifted with power of reproduction by spontaneous division.

Legion 1. *Anentera.*

Mouth communicating with several stomachal vesicules; no anus, no intestinal tube.

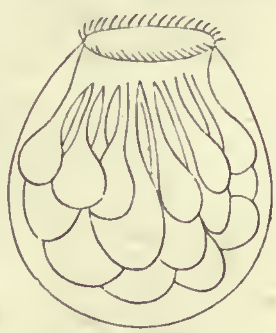
Order 1. *Nuda.*
Body without envelope.

Order 2. *Loricata.*
Body enveloped.

Section 1.—*Gymnica.*

Body not ciliated; mouth with or without ciliæ; no pseudo-pediform prolongations.

§ 1. *Gymnica nuda.*
Fam. 1.—*Monadina.*
Form of the body constant, reproduction by simple transverse division.
A. Without tail.
a. No eyes.
* Mouth truncate, terminal and turned forwards in swimming.
† Individuals solitary.
Genus *Monas.*
†† Individuals solitary when young, afterwards aggregated and again liberated.



Monas atomos.

Genus *Uvella.*
††† Individuals solitary when young, dividing crucially.
Genus *Polytoma.*
** Mouth direct, truncate, and turned different ways in the animal's movements.
Genus *Doxococcus.*
*** Mouth oblique, without edges, and bilobate.
Genus *Chilomonas.*
aa. One red eye.
Genus *Microglena.*
B. With a tail.
b. Body cylindrical.
Genus *Bodo.*
bb. Body angular.
Genus *Urocentrum.*

Fam. 2.—*Vibrionina.*
Body elongate, constant in shape, dividing into many parts, mouth terminal (?)
A. Body filiform, cylindrical, bending itself in undulations.
Genus *Vibrio.*
B. Body filiform, rigid, and rolling itself in spiral.

§ 1. *Gymnica loricata.*
Fam. 1.—*Cryptomonadina.*
Envelope membranous, sub-globular, and oval.
A. Simple.
a. No eyes.
* Mouth ciliated.
Genus *Cryptomonas.*
** Mouth nude.
Genus *Gyges.*
aa. With a red eye.
Genus *Lagenula.*
B. Compound, or reproducing by internal division.
Genus *Pandorina.*

Fam. 2.—*Closterina.*
Envelope round, when rigid, separating spontaneously into two or four parts by transverse divisions, and open at each end.
Genus *Closterium.*
[DESMIDEÆ.]

b. The spiral plane.
Genus *Spirodiscus*.
bb. The spiral helical.
Genus *Spirillum*.
C. Body oblong, fusiform, or filiform, neither undulated nor turned spirally.
Genus *Bacterium*.

Fam. 3.—*Astasiæa*.

Body elongated, becoming polymorphic by contraction, often cylindrical or fusiform, and spontaneously dividing itself in longitudinal or oblique direction.

A. No vestiges of eyes.
Genus *Astasia*.
B. Distinct rudimentary eyes.
b. One eye.
* A tail.
Genus *Euglena*.
** No tail.
Genus *Amblyophis*.
bb. Two eyes.
Genus *Distigma*.

Section 2.—*Epitricha*.

Body ciliated; mouth ciliated or nude; no pseudo-pediform prolongations.

Epitricha nuda.
Family 4.—*Cycladina*.

A. Body with vibratory ciliæ.
a. Ciliæ in simple rows, longitudinal or circular.
Genus *Cyclidium*.
aa. Ciliæ scattered.
Genus *Pantotrichum*.
B. Body deprived of ciliæ, but furnished with hairs not vibratile.
Genus *Chætomonas*.

Epitricha loricata.
Family 3.—*Peridina*.

A. Simple.
Genus *Peridinium*.
B. Compound, reproduced by interior division and rupture of the envelope.
b. No eyes.
* Envelope compressed.
Genus *Gonium*.
** Envelope globular.
† Ciliated.
Genus *Volvox*.
†† Tentaculated.
Genus *Sphærosira*.
bb. With eyes.
Genus *Eudorina*.

Section 3.—*Pseudopodia*.

Body furnished with variable pseudo-pediform prolongations.

Pseudopodia nuda.
Family 5.—*Amæbæ*.
Genus *Amœba*.

Pseudopodia loricata.
Family 4.—*Bacillaria*. [DIATOMACEÆ.]

The envelope dividing with the animal.

A. Free, never fixed.
a. Solitary or agglomerated.
* Envelope oblong.
Genus *Navicula*.
** Envelope wider than long.
Genus *Euastrum*.
aa. United in form of ribands, polymorphous; the individuals of the group have some freedom of movement without becoming detached; cuirass equally thick throughout, and prismatic.
Genus *Bacillaria*.
aaa. United in bundles, and not polymorphous, afterwards disunited.
Genus *Fragillaria*.
aaaa. United in a fan shape, without foot; cuirass thicker in front.
Genus *Exilaria*.
B. Fixed when young, afterwards free.
b. Sessile.
Genus *Synedra*.
bb. Pedicellated, often dichotomous by ramification; body reduced below, cuneiform.
Genus *Gomphonema*.
bbb. Pedicellated, often dichotomous; body contracted towards each extremity, subfusiform.
Genus *Cocconema*.
bbbb. Pedicellated, united in a fan shape, and often dichotomous.
Genus *Echinella*.

Family 5.—*Arcellina*.
Envelope undivided.

A. Envelope urceolate.
Genus *Difflugia*.
B. Envelope scutelliform.
Genus *Arcella*.

1. *Diatoma vulgaris*; *a*, natural size; *b*, *c*, magnified. 2. *Diatoma Swartzii*, magnified; *a*, end view. 3. *Fragillaria unipunctata*, magnified.

Legion 2.—*Enterodela*.

Mouth and anus distinct, opening into an intestine, round which are grouped the stomachal vesiculi.

Section 4.—*Anopisthia*.

Mouth and anus contiguous.

Anopisthia nuda.
Family 6.—*Vorticellina*.

A. Body pedicellated, fixed, afterwards detached, becoming often dichotomous.
a. Pedicle simple or branched, contracting into a spiral.
* Pedicle solid, the interior muscle indistinct.
Genus *Vorticella*.
** Pedicle tubular, the interior muscle often distinct, becoming arborescent by the spontaneous divisions of the animal.
† Animalcula of the same group similar.
Genus *Carchesium*.
†† Animalcula dissimilar in the same group.
Genus *Zoocladium*.
aa. Pedicle not contracting in spiral, rigid, with no interior tube.
Genus *Epistylis*.
B. Body not pedicellated and free.
b. Ciliæ in a single crown.
Genus *Trichodina*.
bb. Ciliæ in a spiral row conducting to the mouth.
Genus *Stentor*.

Anopisthia loricata.
Family 6.—*Ophrydina*.

A. Body surrounded by gelatine and not pedicellated.
Genus *Ophrydium*.
B. Body inclosed in a membranous sheath.
b. Pedicellated.
* Sheath sessile.
Genus *Tintinnus*.
** Sheath pedicellated.
Genus *Cothurnia*.
bb. Not pedicellated.
Genus *Vaginicola*.

Section 5.—*Enantiotreta.*

Mouth and anus terminal and opposite, reproduction effected by transverse division.

Enantiotreta nuda.
Family 7.—*Enchelia.*

A. Mouth terminal, direct, obtuse, generally ciliated; division of the body transverse.
a. Body not ciliated, nor with hairs.
* Simple.
Genus *Enchelys.*
** Double.
Genus *Disoma.*
aa. Body with vibratory ciliæ.
Genus *Holophrya.*
aaa. Body with ciliæ not vibratory.
* Subglobular.
Genus *Actinophrys.*
** Disciform.
Genus *Trichodiscus.*
B. Mouth terminal, oblique, often ciliated.
b. Body without cilia.
* No prolongation of the anterior part.
Genus *Trichoda.*
** Anterior part prolonged into the form of head and neck.
Genus *Lachrymaria.*
bb. Body ciliated.
Genus *Leucophrys.*

Enantiotreta loricata.
Family 7.—*Colepina.*
Envelope oval or cylindrical.
Genus *Coleps.*

Leucophrys patula, with some of the gastric cavities full of food.

Intestinal system of *Leucophrys patula.*

Section 6.—*Allotreta.*

Mouth and anus terminal and opposite, reproduction effected by longitudinal and transverse divisions.

Allotreta nuda.
Family 8.—*Trachelina.*
Mouth inferior, anus terminal.
A. Mouth unarmed.
a. No circle of ciliæ in front.
* Upper lip or front elongate, cylindrical or depressed, prolonged into a narrow trumpet form.
Genus *Trachelius.*
** Upper lip short, depressed, and dilated obliquely.
Genus *Loxodes.*
*** Upper lip compressed, subcarinate, or tumid.
Genus *Bursaria.*
aa. Front with a ring of ciliæ.
Genus *Phialina.*
B. Mouth armed with hooks.
Genus *Glaucoma.*
Family 9. *Ophryocercina.*
Anus inferior, mouth terminal.
Genus *Ophryocercus.*

Allotreta loricata.
Family 8.—*Aspidiscina.*
Genus *Aspidiscia.*

Section 7.—*Katotreta.*

Mouth and anus not terminal, reproduction as in the preceding section.

Katotreta nuda.
Family 10.—*Kolpoda.*
Body smooth or ciliated, unarmed.
A. No eyes.
a. A short retractile proboscis.
* Body partially ciliated.
Genus *Kolpoda.*
** Body ciliated obliquely all over.
Genus *Paramæcium.*
aa. No proboscis.
* Front and tail contracted.
Genus *Amphileptus.*
** Front oblong, tail contracted.
Genus *Uroleptus.*
B. With eyes.
Genus *Ophryoglena.*
Family 11.—*Oxytrichina.*
Body ciliated and hairy, or armed with styles or straight spiculæ and hooks.
A. Body hairy, no styles or hooks.
Genus *Oxytricha.*
B. Body with hooks and no styles.
Genus *Kerona.*
C. Body with styles and no hooks.
Genus *Urostyla.*
B. Body with styles and hooks.
Genus *Stylonichia.*

Katotreta loricata.
Family 9.—*Euplota.*
Body armed with hooks.
A. Head indistinct.
Genus *Euplotes.*
B. Head separated from the body by a contraction.
Genus *Discocephalus.*

At the time this classification was drawn up, the distinctions that limit the vegetable and animal kingdoms were less perfectly understood than at present. One of the first members of this group of organised beings that was withdrawn from the animal kingdom, was the *Desmideæ*, which are now generally recognised as plants. [DESMIDEÆ.] The group of *Pseudopodia loricata* must also be placed amongst doubtful creations, although many physiologists do not hesitate to group them amongst plants [DIATOMACEÆ], whilst the groups *Monadina* and *Volvocina* have recently undergone the most searching investigation, with the result that many of these forms are more decidedly vegetable than animal in their character. [VOLVOX.] Some have even gone further than this, and Agassiz in the 'American Journal of Science,' for 1852, thus writes to Mr. Dana :—"You may remember a paper I read at the meeting at Cambridge, United States, in August 1849, in which I showed that the embryo which is hatched from the egg of a *Planaria* is a genuine polygastric animalcule of the genus *Paramecium*, as now characterised by Ehrenberg. In Steenstrup's work on the 'Alternations of Generation' [GENERATIONS, ALTERNATION OF], you find that in the extraordinary succession of alternate generations, ending with the production of *Cercaria* and its metamorphosis into *Distoma*, a link was wanting—the knowledge of the young hatched from the egg of *Distoma*. The deficiency I can now fill. It is another *Infusorium*, a genuine *Opalina*. With such facts before us there is no longer any doubt left respecting the character of all these *Polygastrica*—they are the earliest larval condition of worms. And since I have ascertained that the *Vorticellæ* are true *Bryozoa*, and botanists claim the *Anentera* as *Algæ*, there is not a single type of these microscopic beings left which hereafter can be considered as a class by itself in the animal kingdom." Few naturalists would perhaps indorse this statement of Professor Agassiz. The *Vorticellæ* are not yet admitted as members of the family *Bryozoa* [POLYZOA]; nor are all the *Anentera* of Ehrenberg regarded indiscriminately as *Algæ*. The passage however indicates the direction in which inquiry is gradually breaking up the great polygastric family of Ehrenberg. It is nevertheless very certain that many of the species enumerated by Ehrenberg are only transitionary forms in which the same being exists. To no one has this department of science been more indebted than to Dr. F. Stein, who in his recent work, entitled 'Die Infusionsthiere auf ihre Entwickelungs-Geschichte untersucht' (Leipsic 1854), has given the result of a long series of investigations on this subject. The following is a summary of Dr. Stein's researches, as recorded in this volume. (It ought however to be premised that Föcke, Dujardin, and Siebold had previously pointed out that the great mass of the Polygastric *Infusoria* were much simpler than Ehrenberg had supposed, and that the internal organs he had described were referrible to the general conditions of unicellular organisms, whether animal or vegetable.)

"In a glass in which were contained a great variety of ciliated *Infusoria*, and among them also numerous individuals of *Euglena viridis*, *Eacus*, and *Edeses*, Dr. Stein remarked, after the lapse of some days, the formation of a thin film on the surface of the water, composed of an interlacement of confervoid filaments and *Oscillatoriæ*. This film swarmed with *Euglenæ*, many of which had lost their beaks, and crawled about with a worm-like movement among the *Confervæ* and *Oscillatoriæ* filaments. Besides these he discovered, to his great joy, a great many transparent gelatinous or quite soft cysts, which sometimes contained only a single *Euglena* contracted into a globular form; sometimes two of a hemispherical form appressed together. The encysted *Euglenæ* proved to be still living, inasmuch as they moved about in the cysts, and if the cysts were ruptured the previously globular individuals reassumed their pristine elongated figure, and crawled about in the same manner as the other beakless individuals among the *Confervæ*.

"For what purpose was this encysting? The cyst was evidently intended for something more than a coffin. Farther observations soon showed that the encysting process of the *Euglenæ* had really reference to their multiplication. The process however appeared to be different in *Euglena* from that in *Gregarinæ*, inasmuch as in the latter case two individuals are conjoined before the cyst is developed, whilst in the *Euglenæ* the case is formed usually around but one; for where two individuals were found inclosed in a cyst, it was at once apparent that they had proceeded from the division of an originally single individual. Whilst thus investigating the *Euglenæ* his notice was also directed to other forms of *Infusoria* contained in the same water, such as *Paramecium aurelia*, *Prorodon niveus*, and *Holophrya discolor*, the latter two of which species he frequently observed inclosed in well-defined gelatinous cysts; and as these *Infusoria* belonged to quite another principal division of the class, he began to hope that the process of becoming encysted would probably turn out to be of general occurrence in the infusory world.

"This proved to be the case, and the work then proceeds to describe the way in which Dr. Stein was led to detect the connection between *Epistylis plicatilis* with a species of Ehrenberg's genus *Acineta*, an observation which pointed the way in his future researches. One of his earliest additional observations was that of the heterogeneous generation of *Epistylis digitalis*. In this species he traced first the metamorphosis of the *Epistylis* into an *Acineta*; and, secondly, observed in the latter the extraordinary fact of the development and evolution of a *Tricodina*, a discovery which Ehrenberg has attempted to explain by the supposition that the *Tricodina* had been previously swallowed by the *Acineta*. Dr. Stein's important researches are continued through the family of the *Vorticellinæ*, and his observations given upon *Actinophrys*, *Podophrya*, the genus *Tricodina*, and on the nature of the *Opalinæ*, the propagation of the *Chlorogonium euchlorum* and *Vorticella microstoma*, and particularly upon the quiescent condition of the latter *Infusoria*; upon *Spirochona gemmipara* and *S. Scheutenii*, and upon the *Acineta* state of *Dendrocometes paradoxus*, *Zoothamnium affine*," &c. &c. ('Quarterly Journal of Microscopical Science,' July, 1854.)

At the present time it would undoubtedly be premature to state that no organisms ought to be referred to Ehrenberg's class *Polygastrica*. It would however be probably better to substitute the term *Protozoa*, to receive organisms having an animal character, and yet presenting the same simple conditions that we find amongst the *Nostochineæ*, and other groups of lowly-developed plants. We may state generally that Ehrenberg's *Polygastrica* embrace the following groups of beings:—

1. True plants, as in the *Desmideæ* (*Closterina*), *Volvocina* (*Cryptomonadina*). and some others. [DESMIDEÆ.]

2. Organisms which the weight of evidence at present assigns to the vegetable kingdom, as *Diatomaceæ* (*Bacillaria*, *Fragillaria*, &c.), and a large number of the *Monadina* and *Vibrionina*.

3. The ova of *Entozoa*, as *Cercaria* and others, and probably even of higher animals.

4. Minute forms of animals referrible to previously-established groups: this seems to be the case with the whole of the *Vorticellina*, which may with more propriety probably be referred to Hydroid than to any other form of polypiferous animals.

5. Dujardin has pointed out the identity between the structure of organisms like *Amœba* with such forms as *Difflugia* and *Arcella*. In all these creatures there is no trace of mouth or digestive cavity, and the entire body is a single cell or an aggregation of cells, which derives it nutriment by absorption from without. Professor Kolliker has recently described the method by which one of these creatures, the *Actinophrys*, takes its food:—

"As regards the vegetable functions," says the Professor, "the mode in which the *Actinophrys* is nourished is one of the highest and most special interest. Although the creature has neither mouth nor stomach, yet it takes in solid nutriment and rejects what is indigestible. This miracle, for so it may almost be called, is thus effected with minute Crustaceans (*Rotifera*, minute species of *Lynceus*, the young of *Cyclops*, &c.) and the lower *Algæ* (*Diatomaceæ*, spores of *Vaucheria*, *Closterium*, &c.). When in its progress through the water it approaches one of these little plants, or when an *Infusorium* has come into proximity with it, both plant and animal, as soon as they touch one of the tentacular filaments, usually adhere to it. Now, as the filament with its prey slowly shortens itself, and the latter approaches the surface of the body, all the surrounding filaments apply themselves upon it, bending their points together so that the captive becomes gradually inclosed on all sides. According to all appearance, these filaments also become more or less shortened. In this way the morsel is gradually brought to the surface of the body, the filament by which it was seized being finally so much shortened as to disappear altogether, and having, as not unfrequently happens, relinquished its hold upon the prey, after the latter has become encompassed by the surrounding filaments. These gradually apply themselves more and more closely together around it, forcing it towards the surface of the body.

"The following proceeding now takes place:—The spot of the surface upon which the captured animalcule is lying slowly retracts, and forms at first a shallow depression gradually becoming deeper and deeper, in which the prey, apparently adherent to the surface and following it in its retraction, is finally lodged. The depression by the continued retraction of the substance now becomes deeper; the imprisoned animalcule, which up to this time had projected from the surface of the *Actinophrys*, disappears entirely within it; and at the same time the tentacles, which had remained with their extremities applied to each other, again erect themselves and stretch out as before. Finally, the depression acquires a flask-like form by the drawing in of its margin, the edges of which coalesce, and thus a cavity closed on all sides is formed in which the prey is lodged. In this situation it remains for a longer or shorter time, gradually however approaching the central or nuclear portion, and at last passing entirely into it, in order to await its final destination. In the meanwhile the external portion of the *Actinophrys* regains in all respects its pristine condition. The engulphed morsel is gradually digested and dissolved, as is readily seen by its change of appearance from time to time. If entirely soluble, as for instance an *Infusorium*, the space in which it is contained contracts as the dissolution of its contents goes on, and finally disappears altogether. Should there be however an indigestible residue (a membrane composed of cellulose, a portion of chitine, a shell of a *Lynceus*, or case of a rotifer, &c.), a passage for its exit is formed, and it is expelled by renewed contractions of the homogeneous substance, and in the same direction, or nearly so, as that which the morsel followed in its introduction. The passage and the opening through which the expulsion was effected disappear again without leaving any trace."

In the *Actinophrys* we have an animal closely resembling the creature which inhabits the shell of the large family known now as *Foraminifera* [FORAMINIFERA], and Dujardin suggests that the loricated forms of *Difflugia* and *Arcella* are transitions to the more decided forms of *Foraminifera*. Hence he proposes to include several forms of Ehrenberg's *Infusoria*, with the *Foraminifera* or *Polythalamia*, under the term *Rhizopoda*. Little therefore is left us to say of what may be regarded as true *Polygastrica*. They all appear to have a distinct mouth or entrance to the cavity of the body, and this is usually surrounded by vibratile cilia, as seen in the cuts of *Monas atomos* and *Leucophrys patula*. These cilia apparently bring the food to the mouth of the animal. An anal orifice is described by Ehrenberg in the majority of species. When finely divided soluble colouring-matter as carmine or indigo (a writer in the 'Microscopical Journal' recommends the red pigment which lines the cornea of the common house-fly) is introduced into the water in which they are contained, the transparent body of the animalcule is speedily seen to be studded with coloured globules, consisting of an aggregation of the particles of colouring matter. Ehrenberg regarded these globules as distinct sacs, which he supposed were given off from a central intestinal canal, as seen in *Leucophrys patula*. Regarding these sacs as so many stomachs, he gave them the name of *Polygastrica* (many-stomached). It is however still a question as to whether in any case these masses are contained in a distinct sac. The whole body of the animalcule is often covered with vibratile cilia (see cut of *Leucophrys*), and it is to the constant action of these organs that the varied movements of these animalcules are due. [CILIA.] The movements thus effected are perfectly automatic, and in no way connected with any intelligent consciousness. All the movements of these animals are not due to cilia, as the whole of the tissue of the animal is observed to contract in *Amœba*, *Amphileptus*, and the stalk of the *Vorticellina*.

Although Ehrenberg has described a complicated apparatus for reproduction, no instances of conjugation are recorded amongst the true *Polygastrica*. Their modes of multiplication are by fission and gemmation. In a large number of cases a simple division of the unicellular organism into two equal parts takes place. This process goes on so rapidly that, according to Ehrenberg, a single *Paramecium* could produce 268,000,000 of cells in a single month. From analogy we must suppose this process would not go on continually, and, as in plants, we must regard the separate cells thus produced as belonging to the same individual. Further observation is probably only needed to demonstrate the existence of a union of two cells—a sperm cell and a germ cell—as is now known to be almost universal in the vegetable kingdom. In the account above given of Stein's researches it will be seen, that it is not improbable that one of the modes by which these beings are enabled to spring suddenly into existence, is the production of winter-eggs, or reproductive bodies of a kind that will resist the influence of an absence of moisture from the spots in which they ordinarily abound.

The true *Polygastrica* seem universally diffused. Wherever organic matter exists in a decomposing state, there they abound. They exist in incredible numbers in the waters of the ocean, in rivers, lakes, ponds, pools, and ditches. They are found in the secretions of the higher animals, and even in man. Wherever the organic elements, carbon, hydrogen, nitrogen, and oxygen, are capable of uniting to form water, carbonic acid, and ammonia, there they may be expected to be found. The composition of the liquids in which they are found seems to determine the forms they assume. One set of forms inhabits salt-water, another fresh. Every mineral spring has its peculiar inhabitan. The sulphureous springs of the Pyrenees, the chalybeate waters of the Rhine, the siliceous, calcareous, and aluminous waters of Europe, all contain them. They are found with the red snow of the Alps and the poles, and with the *Conferva thermalis* of the hot springs of Aix and Baden. They are always accompanied with plants. Perhaps it would be wrong to call any beings animals that are not found feeding on plants, as it seems to be a law of organic existence that plants should subsist on mineral matters, and animals on organised matters.

What are the uses of these beings? To this question Professor Owen gives the following reply:—"Consider their incredible numbers, their universal distribution, their insatiable voracity, and that it is the particles of decaying vegetable and animal bodies which they are appointed to devour and assimilate. Surely we must in some degree be indebted to those ever-active invisible scavengers for the salubrity of our atmosphere. Nor is this all: they perform a still more important office in preventing the gradual diminution of the present amount of organised matter upon the earth; for when this matter is dissolved or suspended in water, in that state of comminution and decay which immediately precedes its final decomposition into the elementary gases, and its consequent return from the organic to the inorganic world, these wakeful members of nature's invisible police are everywhere ready to arrest the fugitive organised particles and turn them back into the ascending stream of animal life. Having converted the dead and decomposing particles into their own living tissues, they themselves become the food of large *Infusoria*, as the *Rotifera*, and of numerous other small animals, which in their turn are devoured by larger animals, as fishes; and thus a pabulum, fit for the nourishment of the highest organised beings, is brought back by a short route from the extremity of the realms of organic matter.

"There is no elementary and self subsistent organic matter, as Buffon taught; the inorganic elements into which the particles of organic matter pass by their final decomposition, are organically recomposed and fitted for the sustenance of animals through the operations of the vegetable kingdom. No animal can subsist on inorganic matter. The vegetable kingdom thus stands, as it were, between animal matter and its ultimate destruction; but in this great office plants must derive most important assistance from the Polygastric *Infusoria*. These invisible animacules may be compared, in the great organic world, to the minute capillaries in the microcosm of the animal body, receiving organic matter in its state of minutest subdivision, and, when in full career to escape from the organic system, turning it back by a new route towards the central and highest point of that system."

Fossil Infusoria.

Many of the species of the *Polygastrica* of Ehrenberg, are covered with a siliceous shield or shell, which is quite impenetrable. These forms are those which are now recognised as belonging to the *Diatomaceæ*. [DIATOMACEÆ.] The forms of *Infusoria* which are found fossil belong chiefly to this section. They are frequent in all the varieties of water which have been exposed to air and light, and in all the conditions of this element between the extremities of terrestrial temperatures, not absent even from snow, ice-covered streams, or the ejections of volcanoes, they have been recognised in all the regions of the globe. Lakes, rivers, and the sea are in places richly replenished by them, and their siliceous integuments falling through the water accumulate into extensive deposits. In regard to such accumulations in the sea, we have the evidence of soundings by Captain Sir J. Ross in the course of the antarctic voyage ('Annals of Nat. History,' Oct. 1845) and Ehrenberg's examination of the deposits at Cuxhaven; and their abundance in fresh waters is matter of universal occurrence. These deposits consist of the siliceous integuments of the *Infusoria*, and as only a small proportion of the families are protected with siliceous coverings, and as the waters which nourished them contain but little silica, while the deposits are very extensive, we naturally associate with these facts the idea of long-elapsed time.

On turning to the marine and fresh-water deposits of earlier date, this impression of the long duration of natural agencies becomes much heightened. When, conducted by Ehrenberg, we find beneath the Bohemian Mountains, and in the plains of North Germany, pleiocene deposits many feet in thickness, composed of little else than the thin flinty loricæ of *Microzoaria*, and following Professor Rogers and Mr. Bailey, who dug up myriads of other forms from the meiocene strata of Virginia, while Mantell and Reade exhibit to us *Infusora* from the chalk and the Kimmeridge clay of England, we must add to the historic time during which it can be proved these organisms have lived the large indefinite geological periods of Cainozoic and Mesozoic formations.

The source of the siliceous matter which enters the organisation of these beings is not difficult of discovery. Most of our fresh-waters contain silica, though not in abundance, derived, it is probable, from the decomposition of felspar and other mineral silicates. Silicate of soda and silicate of potash, thus occasioned, may by intermediate vegetative processes yield the silica in a state suitable for being organically solidified. In the hot waters of volcanic foci, silica is dissolved abundantly, and it is necessary to keep this fact in view while considering the extensive flint beds in chalk, the thick Polierschiefer beds of Bilin, and other siliceous masses, the result of organisation. The distinction of marine and fresh-water races, which runs through all the larger animals and plants with such regularity as to be termed a law of nature, obtains also, but less absolutely, in the *Infusoria*. Some species live both in fresh and salt water, and many at the junction of rivers with the sea. By comparing the living oceanic and lacustrine races on a large scale, enough of difference appears in their siliceous shields to authorise conclusions more or less positive as to the marine or fresh-water origin of infusorial deposits which contain identical or analogous forms belonging to earlier periods. Thus the rich deposits of Richmond in Virginia appear to have been formed beneath the sea; the famous deposits of Bohemia, Berlin, and Santa Fiora contain admixtures of marine and fresh-water tribes; while those of the Bann, in the county of Down, and Gainsborough and Bridlington, contain a more considerable proportion of fresh-water species.

Infusoria of marine or æstuary origin have been found in a fossil state very extensively in Europe, Asia, Africa, and America. Ehrenberg has described many species from Greece (Zante and Egina), Italy (Caltasinetta and Cattolica), and Africa (Oran), which occur in calcareous marls, referred by Ehrenberg to the age of the true chalk deposits. These deposits are very extensive in Africa, occupying the whole coast of Oran and large tracts in Egypt and Arabia. (Portions of this tract have however been described by M. Rozet as tertiary.) In the undoubted white chalk of Denmark (Rügen), of France (Meudon), of England (Gravesend and Brighton), *Infusoria* also occur, but less abundantly. North America has yielded a great variety of marine or partly marine *Infusoria*, especially at Richmond and Petersburg in Virginia, at West Point in Connecticut, Rhode Island, Massachusetts, and Maine. Brazil has also yielded similar deposits.

Infusoria partly of marine and partly of fresh-water origin have become familiar to us in the Polierschiefer (polishing slate) of Bilin and Planitz in Bohemia, and of the Habichtwald near Cassel, the Bergmehl of Santa Fiora in Tuscany, the white marls in the peat of Franzenbad near Egra in Bohemia, the peat deposits of Gainsborough in Lincolnshire, and at the base of the Mourne Mountains in Ireland. We find them to occur also in considerable plenty, but in limited distribution, in the lacustrine deposits of the east coast of Yorkshire. The Mauritius is added to these localities by Ehrenberg, and New Zealand by Mantell, all the occurrences belonging to supra-tertiary eras.

Infusorial remains are very unequally congregated. The siliceous marl (Kieselguhr) of Franzenbad consists mainly of *Navicula viridis* (*fig.* 6), now recent; that of the Mauritius, of *Bacillaria vulgaris* (*fig.* 7); that of San Fiora, of *Synedra capitata* (*fig.* 9); while that of Bilin is composed of *Gaillonella distans* (*fig.* 8) almost exclusively. (Ehrenberg.)

Infusoria are mentioned in the moya (volcanic mud) of Mexico, and in the edible clay of the river Amazonas, by Ehrenberg; in the rock-salt and the marl which accompany it at Cardona in Spain, by Marcel de Serres; they are assumed by Ehrenberg to enter largely into the composition of flint, which indeed readily shows *Xanthidia* and *Pyxidiculæ*. The bog-iron ore (Raseneisenstein) common near Berlin is composed chiefly of *Gaillonella ferruginea*. A kind of semiopal lying in nodules in the Polierschiefer of Bilin is composed of the same siliceous reliquiæ (*Gaillonellæ*) as the true polishing slate, but they are cemented together and filled by infiltrated siliceous paste. With the *Gaillonellæ* Ehrenberg finds spiculæ of sponges. The Precious Porphyry Opal of Kaschau, and the Serpentine Opal of Kosernitz in Silesia, has appeared to Ehrenberg of analogous composition. The following tabular view given by Ehrenberg of some of these facts will be useful:—

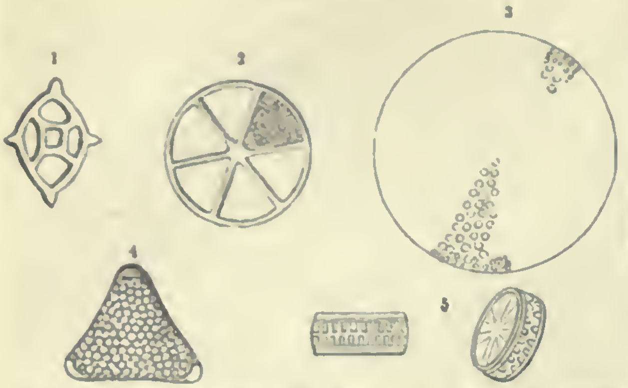
1. Bergmehl	Newest Formation.
2. Kieselguhr	
3. Polierschiefer	Tertiary Formation.
4. Saugschiefer	
5. Semiopal of Polierschiefer	

The above consist entirely or partly of the shells of *Diatomaceæ*.

6. Semiopal of the Dolerite	Pyrogenous Rock.
7. Precious Opal of the Porphyry	
8. Flint of the Chalk	Secondary Strata.
9. Gelherde (yellow earth)	Newest Formation.
10. Raseneisenstein	
11. Certain kinds of Steinmark, investing the Opal of Kaschau	

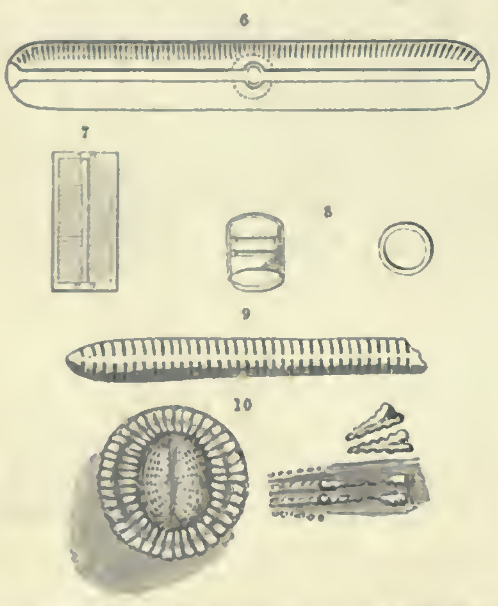
The above are probably of the same nature.

As examples of undoubted marine Infusorial Fossils, the following figures of some of the forms most frequent in a white deposit from Richmond may be taken:—



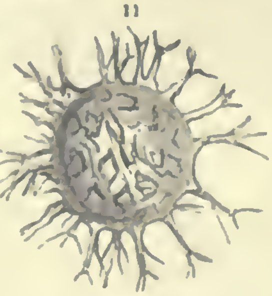
1. *Dictyocha fibula*. 2. *Actinocyclus senarius*. 3. *Coscinodiscus radiatus*. 4. *Triceratium favus*. 5. *Gaillonella sulcata*.

And for comparison the following outlines of mixed marine and fresh-water species common in the Polierschiefer of Bilin and the Peat and Kieselguhr of Franzenbad, Egra, San Fiora, &c.



6. *Navicula viridis*. 7. *Bacillaria vulgaris*. 8. *Gaillonella distans*. 9. *Synedra capitata*. 10. *Campylodiscus clypeatus*.

These are tertiary forms, and below is a specimen of a group referred to the recent genus *Xanthidium*, and frequent in the flint nodules which occur in chalk.



11. *Xanthidium ramosum*.

List of species of *Infusoria* from the Kieselguhr of Franzenbad:—*Navicula viridis* (plentiful), *N. gibba*, *N. fulva*, *N. librile*, *Gomphonema paradoxum*, *G. clavatum* (fresh-water species now living near Berlin), *N. viridula*, *N. striatula* (now living in the sea, the second also lives in the Carlsbad water), *Gaillonella varians* (?).

Species of *Infusoria* in the Peat-Bog of Franzenbad:—*Eunotia granulata* (plentiful), *Navicula viridis* (rare), *Bacillaria vulgaris*, *Cocconeis undulata*, *Gomphonema paradoxum*.

Species which occur in the Kieselguhr of Mauritius:—*Bacillaria vulgaris* ? (plentiful), *B. major*, *Navicula fulva* (?), *N. gibba*, *N. bifrons* (living near Berlin).

In the Bergmehl of Santa Fiora:—*Synedra capitata* (plentiful); with this are *S. ulna* (living both in fresh-water and the sea), *Navicula inæqualis*, *N. capitata*, *N. viridis*, *N. gibba* (fresh-water species); *N. viridula* (living in the Baltic), *Eunotia granulata*, *Navicula follis* (extinct), *Cocconeis undulata* (marine), *Gomphonema paradoxum*, *G. clavatum*, *G. acuminatum* (living near Berlin), *Cocconema cymbiforme* (fresh-water), *Gaillonella italica*, Spicula of *Spongiæ*, or *Spongillæ*.

In the Polierschiefer of Bilin:—*Podosphenia nana* (plentiful), *Gaillonella distans*, *Navicula scalprum*, *Bacillaria vulgaris* ? (probably all marine!)

In the Leaf Tripoli:—*Gaillonella distans* (plentiful), *Podosphenia nana*, *Bacillaria vulgaris* ? (probably marine.)

At Bann, in the county of Down, Captain Portlock found under Peat *Naviculæ*, *Bacillariæ*, *Eunotiæ*, with fragments of *Achnanthes* and *Conferræ*. ('Microscopical Jonrnal,' 1841.) At Gainsborough Mr. Binney found under Peat abundance of *Gaillonella*. At Bridlington, in white and brown Marls, *Eunotia serra* (?), *Bacillaria vulgaris*, *Navicula inæqualis*, *N. viridis*, *N. phœnicenteron*, *Cocconema lanceolata*, *Campilodiscus zonalis*, &c.

The North American localities have yielded to Bailey and Ehrenberg a large catalogue of Diatomaceous *Infusoria*. Ehrenberg enumerates—

Amphiphora—one species.
Cocconema—two species.
Eunotia—seven species.
Fragillaria—three species.
Gomphonema—four species.
Himantidium—one species.
Navicula—eighteen species.
Staurosira—two species.
Tabellaria—three species.

With these are three forms of Spongoid Spicula and two species of *Thylacium*.

These are mostly derived from beds lying under Peat—

The Richmond earth (of miocene date) yields—

Coscinodiscus radiatus and other species (*fig.* 3)	Mr. Quckett has found several of these recent in the North Sea. Mr. Lee has discovered *Coscinodisci* and *Dictyochæ* in the Barnacle and Scallop.
Actinocyclus senarius and others (*fig.* 2)	
Naviculæ, several species . .	
Gaillonellæ	
Dictyocha fibula (*fig.* 1) . .	

In the chalky marls of Oran, Sicily, Greece, &c., occur many living forms, as—

Actinocylus—ten species.
Amphitetra—two species.
Biddulphia—one species.
Cocconema—one species.
Coscinodiscus—seven species.
Dictyocha—four species.
Eunotia—two species.
Gaillonella—one species.
Grammatophora—four species.
Haliomma—one species.
Navicula—six species.
Striatella—one species.
Synedra—one species.
Tessella catena—one species.
Triceratium—one species.

In the white chalk and flint of Europe, and also living—

Fragillaria rhabdosoma. Gravesend.
F. striolata. Gravesend.
Gaillonella aurichalcea. Rügen.
Peridinium pyrophorum. Gravesend.
Xanthidium furcatum. Gravesend.
X. hirsutum. Gravesend.

Dr. Mantell has been unable to discover *Fragillaria* in the chalk of Gravesend, but *Xanthidia* occur in the chalk of Dover. ('Ann. Nat. Hist.,' Aug., 1845.) *Gaillonella aurichalcea* has been regarded as an *Oscillatoria*; and it appears doubtful whether the so-called *Xanthidia* of the flints and chalk are really to be referred to that fresh-water genus.

From the preceding notices we may gather as general facts the occurrence of the remains of siliceous *Infusoria* in the following stratifications:—

Cainozoic period	Recent Fluviatile and other sediments.
	Lacustrine deposits of the Elk period.
	Deposits of the 'Lehm' period.
	Miocene Tertiaries.
	Eocene Tertiaries.
Mesozoic period	Chalk deposits.
	Oolitic deposits.

The relative abundance of the *Infusoria* in these several deposits is inversely as their antiquity; they are rare in the oolitic and cretaceous rocks, and abundant in the upper tertiaries. It is true that Ehrenberg, by assigning to the cretaceous era the calcareous marls of Oran, Sicily, and Greece, gives a large catalogue of Mesozoic *Infusoria*, and that in favour of such reference of those marls are the *Rotaliæ*, *Textilinæ*, &c., which occur both in the true chalk and in such marls. But on the other hand, remembering the long scale of geological time through which these genera of *Polythalamiæ* extend, and taking into consideration the fact that some species which occur in the chalk of Europe are quoted by Ehrenberg from unquestionably miocene strata in America, we shall hesitate to admit those richly infusorial marls as truly coeval with the white chalk, in which comparatively very few remains of the group occur, and these not of the same species as those which abound in the other deposits.

Another point on which the authority of Ehrenberg has not been received without hesitation, is the absolute specific identity of a large proportion of the fossil and recent *Infusoria*. The previous discoveries of geology had prepared an easy admission for the opinion that many of the tertiary forms of *Infusoria* were undistinguishable from living races; such is the fact in regard to all the invertebral races; but with very few and those not always allowed exceptions, the secondary strata had been found to contain only extinct forms of life, till Ehrenberg examined the minute *Polythalamiæ*, and found many of them similar to living types, and confirmed this inference by independent researches among the *Infusoria*. Supposing these opinions of the Prussian microscopist to be confirmed by future inquirers, we shall find that they involve no infraction of the relations of zoological forms to geological time, which have been established from examinations of the other classes of the animal kingdom. The systems of life in each successive system of strata are not separate and distinct creations, but successive terms of a creative series; each of these terms is compound, and (to speak exactly) its constituent quantities (the several classes, orders, families, genera, or species) have their own coefficients and exponents; that is to say, have their own times of duration, their own periods of abundance, their own peculiar relations to earlier and later organisations.

A rule drawn from Fishes cannot be applied to *Mollusca;* a law based on *Crustacea* cannot be received for *Microzoaria*, without scrupulous examination; and palæontology is full of examples of the unequal periods of duration which belong to the different organisations, and the unequal degree of development and unequal geographical diffusion which characterise these organisations at the same epochs and during the same periods.

Admitting the authority of Ehrenberg's determination of species, we find another curious and unexpected result—the frequent, if not general, admixture of marine and fresh-water tribes in the comparatively level regions of Europe. In the plains of North Germany, round the Bohemian and Harz Mountains, in Tuscany, and Yorkshire, we find this admixture of supposed marine and supposed fresh-water races in the supra-tertiary deposits. Is this to be explained by supposing those deposits to have happened while the relative level of land and sea was different from what it is at present, and the sea was near to the place of deposition, so that by some of the many natural modes of diffusion which are effective in this class of life the organisms of the sea might be carried into lakes, as well as mixed in æstuaries, and along the course of languid rivers? Probably so. The deposits of *Infusoria* which now happen so abundantly at the mouth of the Elbe are mostly derived from the sea; and it has been found in the river Hudson that species once imagined to be truly marine live in juxtaposition with the species of fresh waters. There may probably be, in a class of beings associated with silicated waters, a greater independence of the saline qualities of water than in other races which have little need of silica, and which require the extrication of lime from a state of solution in the waters which they inhabit. In confirmation of this view we find the *Spongiæ* of the sea matched by the *Spongillæ* of fresh water, each extracting silica from the liquid, but the calciferous Polypean races of the ocean are almost unrepresented in our inland lakes and streams.

(Ehrenberg, *Die Infusionsthierchen; Memoirs of the Berlin Academy*, and Translations in Taylor's *Scientific Memoirs;* Reade, Quekett, Roper, Brightwell, Gregory, and others, in the *Microscopic Journal*, and *Quarterly Journal of Microscopical Science;* Mantell, *Medals of Creation and Annals of Natural History;* Pritchard, *Infusorial Animalcules;* Owen, *Lectures on Comparative Anatomy;* Carpenter, *Principles of Physiology;* Dujardin, *Histoire des Zoophytes Infusoires;* Stein, *Die Infusionsthiere*, &c.)

INGA, a genus of Plants belonging to the natural order *Leguminosæ*, which, though it has been separated from *Mimosa*, yet contains upwards of 100 species. These are found in the tropical parts of Asia, Africa, and America. They are distinguished by their legumes being broadly linear, compressed, and 1-celled. The seeds are usually covered with pulp, more rarely with farinaceous matter or a pellicle. The species form shrubs or trees, and are commonly unarmed. The flowers are in spikes, or are capitate, and of a red or white colour. From the number of species in this genus, as well as in *Acacia* and *Mimosa*, and from their having been removed from one to the other, there is some confusion in the synonyms. A few of the useful species have been further separated into the genus *Parkia;* but many still remain which are important in the countries where they are indigenous, either for astringent properties, like many Mimosas and Acacias, or for the edible nature of the fecula or pulp which surrounds their seeds. Thus *I. cochliocarpus* has bitter and astringent bark, which is used in tanning and also in medicine. It is taken to Portugal, where it is called the Brazilian Bark, and used even as a substitute for that of the *Cinchona*. Martius distinguishes from this species, which he calls *I. Jurema*, another which he has named *I. astringens*, and of which the bark has similar properties. The bark of these trees is considered by some authors to be the Cortex Astringens Brasiliensis of old pharmacopœias. *I. salutaris* is another astringent species, a native of New Granada, of which the bark is much used in the form of decoction for various complaints in which astringents are indicated, and for the same purposes as Ratany Root. Some of the species, as before mentioned, are esteemed for the sweetish edible pulp with which their seeds are surrounded, as *I. dulcis* in India and *I. insignis* in the province of Quito, where it is called Guabo, or Guabas, but Pacaes in Peru. So *I. Camatchili*, according to Perrotet, is similarly esteemed in Manilla, and *I. Faroba* in Western Africa, in the neighbourhood of the Senegal. *I. vera* contains tannic acid, and is one of the numerous leguminous plants used for obtaining Catechu. The pulp of the fruit of this species also is purgative. *I. fæculifera* yields in its pods a laxative pulp called Pois-Doux in St. Domingo. It has a sweet taste. The pulp also of the pods of *I. tetraphylla* is sweet and mucilaginous. (Lindley, *Vegetable Kingdom.*)

INIA. [CETACEA.]

INOCERAMUS (Sowerby; Goldfuss), a remarkable genus of Fossil *Conchifera monomyaria*, allied to *Crenatula*, *Gervillia*, &c., originally named by Mr. J. Sowerby in the 'Linn. Trans.' The name *Catillus* was given to the larger species by M. Brongniart. The two valves approach to equality; both are convex; the hinge-line straight, often extended into a wing, and thickened with many transverse grooves to receive a divided ligament; shell fibrous; beaks recurved. *Inoceramus dubius* occurs in the Lias; *I. concentricus* in the Gault; *I. Cuvieri* and many other species in the Chalk.

INSECTA, one of the classes of Invertebrate Animals. The Latin term Insecta, like the Greek Entoma, which has been applied to these animals, has reference to the insected or divided appearance of the body; hence the English name Insect, the French Insecte, and the German Insect. Invertebrate Animals are divided by Lamarck into two groups, which he calls Animaux Apathiques, and Animaux Sensibles. The latter, or the Sensitive Animals, contain six classes, of which Insects are the first. According to Latreille's arrangement in the 'Règne Animal,' the class *Insecta* forms the third great division of articulated animals—articulated referring to the innumerable joints of which this class of animals is composed.

True Insects may be thus defined:—Articulated animals possessing six legs, two antennæ, two compound eyes; a small brain at the anterior extremity of a double medullary chord. Circulation effected by a pulsating dorsal vessel provided with numerous valves. Respiration by tracheæ, which form two lateral trunks, and ramify through the body; generation oviparous; two distinct sexes; adult state attained through a series of metamorphoses.

Insects generally possess two pairs of wings; the trunk in the adult animal is usually composed of three chief parts, the Head (Caput), Thorax, and Abdomen; or the trunk of an insect may be described as consisting of thirteen segments, of which one constitutes the head, three form the thorax, and the remaining nine compose the abdomen. The head includes the organs of sensation and manducation, and its principal parts have received the following names:—the Clypeus, Vertex, Occiput, Genæ, Canthus, Gula, Oculi, Stemmata, Antennæ, and the Trophi.

Fig. 1.

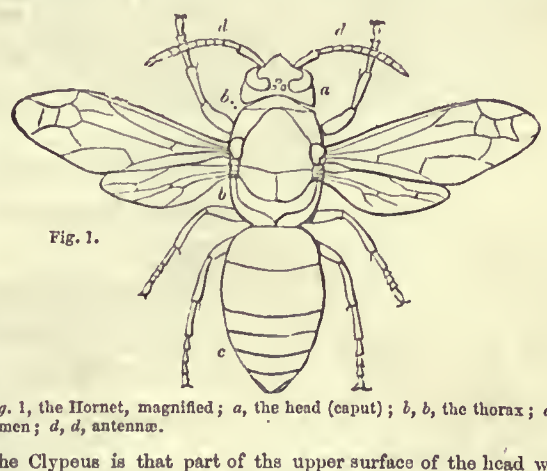


Fig. 1, the Hornet, magnified; *a*, the head (caput); *b*, *b*, the thorax; *c*, the abdomen; *d*, *d*, antennæ.

The Clypeus is that part of the upper surface of the head which joins the labrum. It is called by Kirby nasus, and in the *Lamellicornes* it is usually the foremost part of the head when viewed from above.

The Vertex is the summit of the head.

The Occiput is the hinder portion of the head, or that adjoining the thorax.

Genæ (the cheeks). "Those parts which lie on the outer side of the anterior half of the eyes, and intervene also between them and the mandibula." (Kirby).

Canthus, a name applied by Kirby to a process of the head which encroaches upon the eyes.

The eye in certain insects is encroached upon by a narrow process of the head in such a manner as to render it kidney-shaped, instead of its ordinary round form, and in some instances this organ is divided by the canthus into two parts.

Gula, the hindermost portion of the head beneath.

Fig. 3.

Fig. 2.

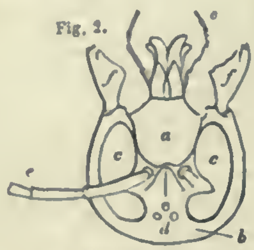

Fig. 2, Head of Hornet, magnified; *a*, the clypeus; *b*, the vertex; *c*, *c*, the eyes (oculi); *d*, the eyelets (stemmata); *e*, the antenna; *f*, *f*, mandibula. *Fig.* 3, the same, viewed from beneath; *g*, the occiput; *h*, the gula.

Oculi (the eyes). These are almost invariably two in number, placed one on each side of the head, and composed of hexagonal lenses.

Stemmata (the eyelets), minute simple eyes. They may be seen in the orders *Hymenoptera*, *Orthoptera*, and *Hemiptera*, and are generally placed vertically on the head. The larvæ of Coleopterous Insects generally possess them, and they are usually placed on each side of the head close to the antennæ.

Antennæ, jointed organs, two in number, most commonly springing from the upper surface, or side of the head near the eyes. These organs vary much in every way, not only in the various species of insects, but in the sexes of the same species they often differ.

There is much difference of opinion as regards the use of these organs. Some have come to the conclusion, from anatomical researches, that they are organs of hearing, whilst others maintain they are organs of touch or smell. When however we see so much difference in the structure of the antennæ in insects, and perceive that some use them in touching surrounding objects, as is the case in many of the *Hymenoptera* (particularly the *Ichneumonidæ*, and Bees and Ants), whilst others carefully avoid so doing, we are naturally led to the conclusion that they are used for different purposes. It is certain that insects possess the sense of smell, but in those insects which possess it apparently in the highest degree we can trace no similarity in the structure of the antennæ. A *Silpha*, a *Staphylinus*, and a common fly, appear to be equally attracted by the scent of a piece of putrid flesh, and yet their antennæ bear no resemblance. The same remark will apply to the antennæ of those insects which emit sound; the Grasshopper, the *Sphinx Atropos*, many of the *Cerambycidæ*, and numerous other insects might be enumerated which emit voluntary sound, but their antennæ do not differ from those of the species to which they are most closely allied, and which emit no sound that we can perceive. As regards touch, there can be no doubt that the antennæ of many insects are used as organs of touch, and it appears highly probable that, through the means of the antennæ, some insects can perceive the state of the atmosphere. The delicately plumed antennæ of the gnat, and of the nocturnal Lepidopterous Insects, seem to be well fitted for receiving impressions of this nature. The arguments in favour of their being organs of hearing are also at least worthy of attention. [ANTENNÆ.]

An Antenna may be divided into the following parts:—

Torulus, the cavity or socket in which the base of the antenna is planted.

Scapus, the first and in many cases the most conspicuous joint of the antenna.

Pedicellus, the second joint of the antenna.

Clavola, the remaining joints taken together.

In describing the species of the *Curculionidæ*, the term Funiculus is often used to designate that portion of the antenna between the long basal joint, or Scapus, and the Club (called Capitulum or Clava), which in these insects usually terminates the antenna.

The principal modifications in the form of antennæ are figured and described in the article COLEOPTERA.

The Trophi, or parts of the mouth (called by Fabricius Instrumenta Cibaria), consist of six principal portions:—The Labrum, Labium, Mandibulæ, and Maxillæ.

The Labrum, or upper-lip, is a corneous plate, which terminates the head anteriorly, and covers the mouth above; its posterior margin is united by a membranous hinge to the clypeus.

The most common form of the labrum is represented in *fig.* 8; it

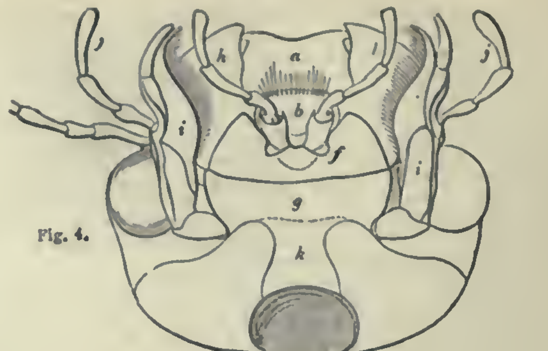

Fig. 4.

Fig. 5.

Corresponding letters refer to the same parts as in *figs.* 4, 5, and 6.

is however very variable in shape, and in the *Lamellicornes* a tribe of Beetles which feed upon vegetable substances, instead of being of the ordinary horny texture, it is soft and membranous, and hidden beneath the clypeus (*fig.* 9, *a*). In some of the *Cicindelidæ* (predaceous insects) it is more or less elongated and notched at the sides and apex (*fig.* 10). In the genus *Cicindela* a small projecting tubercle may be observed on the anterior margin of the labrum. In the Hornet (*Vespa Crabro*) the labrum is produced in front into an elongated pointed process (*fig.* 11). In the *Lepidoptera* it is extremely minute, and the *Hemiptera* possess a long, slender, and pointed labrum.

Fig. 9.

Fig. 11.

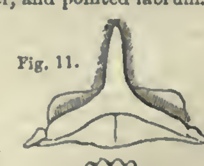

Fig. 12.

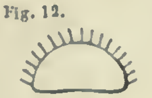

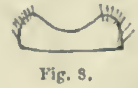

Fig. 8.

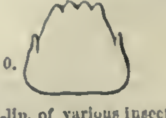
Fig. 10.



Figs. 8, 9, 10, 11, and 12, labrum, or upper-lip, of various insects.

The Labium, or under-lip, is opposed to the labrum, and generally serves to close the mouth beneath.

The labium is a very complicated organ, consisting of several parts which are variously developed in the different tribes of insects, &c. There is much confusion in the nomenclature of these parts, especially as regards the portion which is to be considered the true labium; for although the whole apparatus is often called the labium, yet when treated of in detail most authors agree in applying this term to some particular portion, but differ as to which particular portion the term shall be applied, and consequently the neighbouring parts are differently named. The confusion has arisen from the circumstance of entomologists having applied the name labium to the whole apparatus, and likewise to a particular part of it. We shall therefore use the term labium to express the whole apparatus, and describe the several parts under the three heads Palpiger, Mentum, and Stipes.

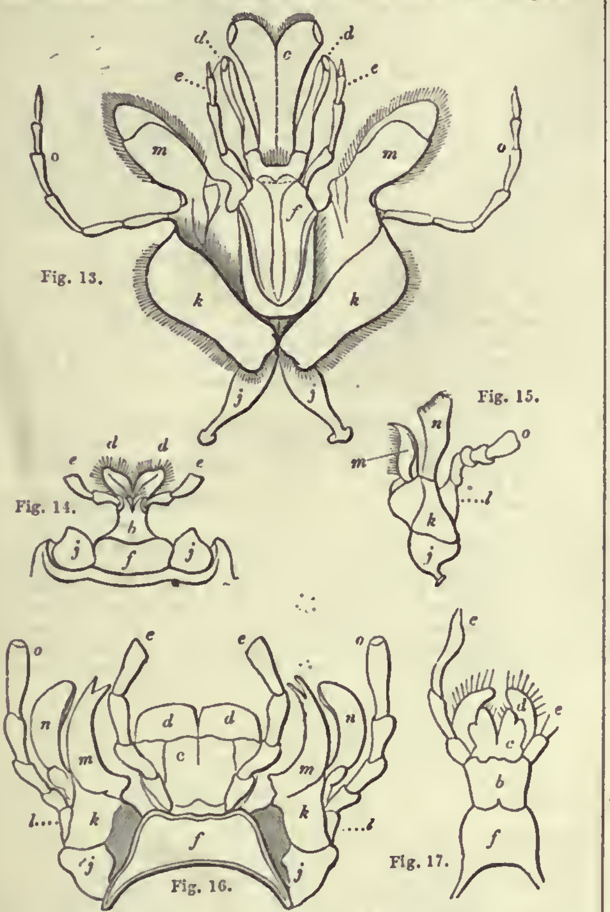


Fig. 13. Fig. 14. Fig. 15. Fig. 16. Fig. 17.

Fig. 13, Labium and maxillæ of the Hornet. *Fig.* 14, Labium of *Cerambyx moschatus*. *Fig.* 15, Maxilla of the same insect. *Fig.* 16, Labium and maxillæ of a Locust. *Fig.* 17, Labium of another species of Locust. In all these figures the letters refer—*b* to the palpiger; *c*, lingua; *d*, paraglossæ; *e*, palpi-labiales; *f*, mentum; *j*, cardo of maxilla; *k*, stipes of ditto; *l*, palpifer; *m*, lacinia; *n*, galea; *o*, palpi-maxillares.

Palpiger, or palpi-bearer. This name was first applied by Mr. Newman ('Entomological Magazine,' vol. ii.) to a portion of the part called lingua by Kirby, and labium by M'Leay and others. It will be used in this article as the name of the whole apparatus to which the labial-palpi are attached, including the lingua, paraglossæ, and palpi-labiales.

The several parts of the labium therefore will be thus divided :—

Labium.
- Palpiger (*b*).
  - Lingua (*c*).
  - Paraglossæ (*d*).
  - Palpi-labiales (*e*).
- Mentum (*f*).
- Stipes (*g*).

If we examine the underside of the head of any insect in which the various parts of the mouth are well developed, the palpiger will be readily distinguished from the other two portions of the labium by its bearing a pair of palpi, the palpi-labiales. In *Dytiscus marginalis*, a common water-beetle, the palpiger is of a square form, or nearly so. The broad piece furnished with bristly hairs along its anterior extremity is the lingua. On each side of this piece there is a small plate (apparently divided), which has its posterior margin recurved, so as to lie close to the underside of the lingua, and furnished with a fringe of hairs. These small pieces we conceive to be the analogue of the parts called by Kirby paraglossæ, and which are distinct in the bees, wasps, &c. They also appear to represent the two leaf-like appendages at the apex of the palpiger in *Cerambyx*, the lingua here being nearly obliterated, and consisting only of an extremely minute divided process furnished with hairs.

The palpiger is not very distinct in the *Hymenoptera;* its appendages however are often greatly developed. In the hornet the lingua is very large, broad, and divided at the extremity; the paraglossæ are also large. The labial palpi are long, and composed of four joints. The lingua in many bees is of great length, and the paraglossæ are often long. The labial-palpi in the typical bees are flattened, and have the basal joint long.

Orthopterous Insects have a well-developed palpiger: the lingua, paraglossæ, and palpi are distinct.

Mentum, or chin, by which we mean the part so called by M'Leay, Westwood, and indeed most modern authors, but which is the labium of Kirby and Newman. The mentum is the piece below the palpiger, and generally articulated to the stipes by a membranous hinge. This part is very variable in shape, and is consequently often referred to in descriptions of insects, or rather in definitions of the genera. It is generally distinct in mandibulate insects.

In *Dytiscus marginalis* it is of a transverse form, and emarginated on the fore part. In the hornet, as well as in the bees, the mentum is long, and nearly cylindrical.

Stipes. This name is applied by M'Leay to that piece which is below the mentum. It is the mentum of Kirby, the 'pièce prebasilaire' of Straus-Durckheim, and the insertio of Mr. Newman.

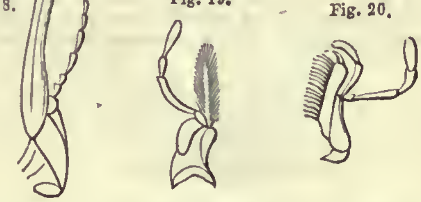
The stipes is generally soldered to the jugulum, so that its boundaries cannot be detected. Such is the case in the water-beetle, the head of which is selected to illustrate this article. Its lower boundary is indicated in the figure by a dotted line. In the common Cockchafer (*Melolontha vulgaris*) however it forms a well-defined piece. In *Amphimalla solstitialis* (*fig.* 7), an allied insect, it is also distinct. In the *Hymenoptera* the stipes is small, and generally of a triangular shape.

The Mandibles (Mandibulæ) come next under consideration. These, the representatives of jaws, are situated immediately below the labrum. They are two in number, and have a vertical motion.

In the *Mandibulata* the mandibles are almost invariably of a hard horny nature, often of a triangular form, or nearly so, and furnished with pointed processes (which have been compared to teeth) on their inner side.

In Carnivorous Insects the mandibles are usually of moderate length, sharply pointed, and armed internally with acute processes. Wood-boring insects, such as the *Cerambycidæ*, have short stout mandibles; and in those insects which feed upon vegetable substances (the *Phyllophagi*, &c.) the mandibles often present a broad grinding surface on their inner side near the base.

Fig. 18. Fig. 19. Fig. 20.



Figs. 18, 19, and 20, Maxillæ of various insects.

The Maxillæ, or feeler-jaws, like the mandibles, under which they are placed, are opposed to each other horizontally. They are joined at their base to the labium, and distinguished by their giving attachment to the maxillary palpi, on which account Mr. Newman has applied to them the name of feeler-jaws. The maxillæ are variable in form, and hence the characters of genera and larger groups are not unfrequently derived from them. A perfect maxilla presents five distinct portions—the Cardo, Stipes, Palpifer, Lacinia, Galea, and Palpi-Maxillares.

Cardo (the hinge) is a small piece, often of a triangular form, upon which the maxilla sits. It is the Insertio of Newman.*

Stipes (the stalk). Kirby applies this name to the "corneous base of the maxilla, below the palpus," and in his detailed account of this part refers both to the palpifer and another portion which is generally situated within the palpifer. We shall confine the name stipes to that part of the maxilla which is joined to the cardo, and is either within or below the palpifer. It is the Maxilla, or Disc, of Mr. Newman.†

Palpifer. This part, to the summit of which the maxillary palpi are always attached, is usually a narrow piece running parallel with and joined to the outer side of the maxilla at the base.

Lacinia (the blade). This is the chief part of the maxilla. It is situated above the stipes, is usually of an elongated pointed form, and furnished with bristly hairs along its inner margin, and generally has one or more pointed claws at the extremity: these claws are called the Ungues. The name Lacinia is applied to this part by Mr. M'Leay, and according to Kirby it is the Lobus Inferior.

Galea (the helmet), or the Lobus Superior of Kirby, is a lobe which is attached to the palpifer, and lies between the galea and the maxillary-palpi. It is jointed in the predaceous beetles, and resembles a palpus.

* Mr. Newman has applied a new name to this part without sufficient reason, since it is well defined by Kirby. The name insertio is also objectionable, since it might create confusion, the same name having been also applied by Mr. Newman to a part of the labium.

† By the same rule that we do not apply the name labium both to the whole labial apparatus and at the same time to a part, we reject the name maxilla as applied to a part of the maxillary apparatus.

Palpi-Maxillares (the maxillary-palpi), joined organs, two in number, one to each maxilla, situated on the outer side of the maxillæ and springing from the palpifer.

In the order *Diptera* the maxillæ are long, slender, and pointed. In the *Hemiptera* they are still more slender, resembling bristles. The long slender proboscis of the *Lepidoptera* consists of the maxillæ. In the order *Hymenoptera* the maxillæ are usually large, and when closed form a sheath which covers the various parts of the labium.

The oral apparatus, or Trophi, of the various Haustellate orders of insects have each received names from Mr. Kirby. In the order *Hemiptera* the oral instrument is termed the promuscis. The same part is termed the Proboscis in the *Diptera*, Antlia in the *Lepidoptera*, and Rostulum in the *Aphaniptera*. The several parts representing the mandibles, maxillæ, labium, &c., have also received additional names in each of these orders, but we have already sufficient.

The term Thorax is applied to all that part of an insect which lies between the head and the abdomen, and to which the legs and wings are attached.

Fig. 21.

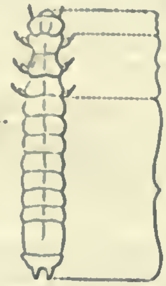


Fig. 21, Larva, showing the three segments of the thorax and the nine segments of the abdomen; *a*, the thorax; *b*, the abdomen.

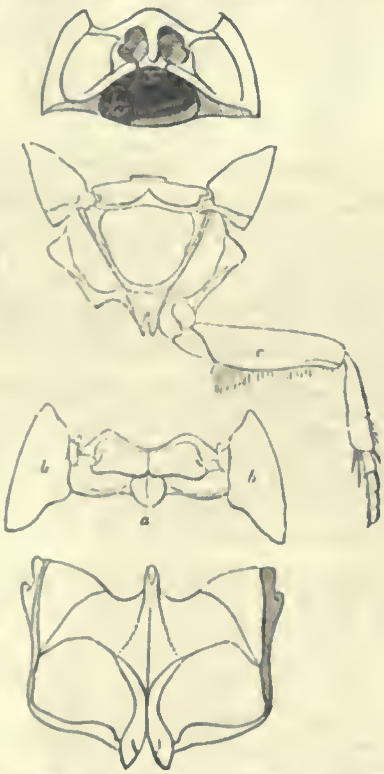
We have before said that the thorax is composed of three segments; these are generally distinct in those larvæ which do not resemble the perfect insect and which possess legs—such as the larvæ of the *Lepidoptera*, *Coleoptera*, and certain *Hymenoptera* (*Tenthredinidæ*): here each of the segments in question possesses a pair of legs.

Fig. 22.

Fig. 24.

Fig. 23.

Fig. 25.



Parts of thorax of a Water-Beetle (*Dytiscus marginalis*).
Fig. 22, the under side of the prothorax, called prosternum. *Fig.* 23, the upper side of the mesothorax, called mesonotum: *a*, the scutellum; *b*, *b*, basal portions of the elytra. *Fig.* 24, posterior view of the same: *c*, one of the middle pair of legs. *Fig.* 25, under side of the metathorax, called metasternum.

The term Prothorax is applied to the foremost of the thoracic segments, Mesothorax to the next, and Metathorax to the hinder one, or that which joins the abdomen. In the perfect insect we find the three simple thoracic rings of the larvæ replaced by the same number of segments, but each divided into several distinct parts; these three segments however are never uniformly developed, but generally two of them are more or less perfected, and exert an inverse influence on the third, and sometimes one of the segments is greatly developed at the expense of the remaining portions.

The Prothorax bears the anterior pair of legs and is articulated to the head. It is large in the *Coleoptera*, and is the part called thorax in descriptions of insects of this tribe; it is likewise well developed in the *Orthoptera* and *Hemiptera*. In the *Lepidoptera* it forms a narrow ring, which is easily distinguished by the scales with which it is covered being erect, those on the next segment being adpressed. In the *Hymenoptera* the prothorax sometimes forms a distinct neck, but generally it is a narrow plate, and extends back on each side to the base of the anterior wings.

The upper surface of this segment is termed by Burmeister the Pronotum, and by Audouin and M'Leay the Tergum of the prothorax. The latter authors state that the tergum, when perfect, is composed of four parts, to which M. Audouin gives the names Præscutum, Scutum, Scutellum, and Postscutellum, so named according to their succession, commencing at that nearest the head of the insect. These parts however are seldom to be seen, unless it be in certain Orthopterous Insects.

The underside of the prothorax is called by Burmeister and Kirby the Prosternum, and by Audouin the Pectus of the prothorax. To the prosternum the legs are attached, and hence this part is always tolerably well developed.

Besides the above parts there is an internal piece called the Antefurca.

The Mesothorax, or middle segment of the thorax, is more complicated than the prothorax, owing to its giving attachment to the anterior pair of wings in addition to a pair of legs. The mesothorax is well developed in nearly all insects, and in the order *Diptera* attains its largest size, and indeed forms the principal part of the thorax. Its upper surface is termed by Burmeister the Mesonotum (Tergum of Audouin), and the under part the Mesosternum (Pectus, Audouin).

Fig. 26.

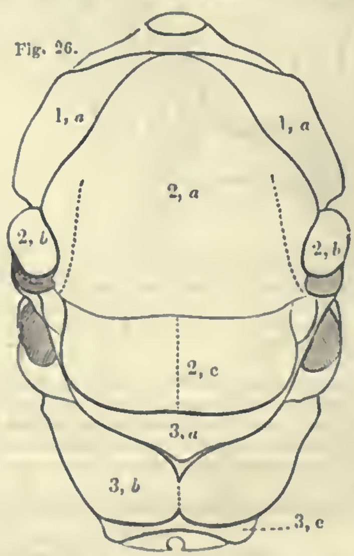


Fig. 26, upper view of thorax of *Vespa Crabro*. 1, prothorax; 2, mesothorax; 3, metathorax. 1, *a*, scutellum; 2, *a*, scutum; 2, *b*, squamula; 2, *c*, scutellum; 3, *a*, præscutum; 3, *b*, scutellum; 3, *c*, postscutellum.

Fig. 27.

Fig. 27, side view of thorax of *Vespa Crabro*. The figures and letters refer to the same parts as in *fig.* 26, to which may be added—1, *b*, præscutum and scutum; 1, *c*, situation of the anterior pair of legs; 2, *d*, sternum; 2, *e*, situation of the middle pair of legs; 2, *f*, situation of the anterior pair of wings; 3, *d*, metasternum; 3, *e*, situation of the posterior pair of wings; 3, *f*, insertion of posterior pair of legs; 4, abdomen.

At its maximum of development it consists of four pieces above and eight below, to which Audouin applies the names Præscutum, Scutum, Scutellum, and Postscutellum, to the upper pieces, or tergum; and Paraptera, Sternum, Episterna, Epimera, and Medifurca, to the mesosternum. The metathorax, as it bears the posterior wings, is well developed in those insects which possess them, but where they are wanting, as in the order *Diptera*, it is of small size. Its upper surface is called Metanotum, and the under surface Metasternum. When perfect it contains the same number of parts as the mesothorax. To this segment are attached the posterior pair of legs.

The various parts of the thorax will perhaps be better understood by their being placed in a tabular form, thus—

Thorax.	Prothorax.	Tergum, or Pronotum.	Præscutum.
			Scutum.
			Scutellum.

From the thorax we are naturally led to the wings and legs of insects.

The greater portion of the insect tribe possess four wings; some however only possess two, and others are quite destitute. These organs consist of two membranes applied closely together, and inclosing numerous nervures or hollow tubes which contain tracheæ.

The various descriptions of wings may be described under the following heads—Elytra, Tegmina, Hemelytra, and Halteres. The term elytra is applied to the anterior wings. "When they are without nervures and uniformly of a thicker and harder substance than membrane," they are peculiar to the *Coleoptera*. [COLEOPTERA.]

Tegmina is the name applied to the upper organs of flight when of a uniform coriaceous texture, and furnished with nervures as in the *Orthoptera*. [ORTHOPTERA.]

Hemelytra, the upper organs of flight when they are coriaceous at the base and membranous at the apex, as in the *Hemiptera*. [HEMIPTERA.]

The Halteres are two minute organs situated behind the wings of Dipterous Insects, and supposed to represent the posterior wings; they consist of a slender stalk with a round or oval knob at the extremity. [DIPTERA.]

The Legs in true insects are invariably six in number, but in certain butterflies the anterior pair are minute. Each leg consists of a Coxa, Trochanter, Femur, Tibia, and Tarsus, all of which parts are figured and described in the article COLEOPTERA.

The Abdomen. Although the nine segments which compose the abdomen are generally distinct in larvæ, we seldom find more than seven or eight visible joints in the perfect insect, the remaining one or two being generally hidden, and in fact converted into parts of the organs of generation. The number of segments to the abdomen sometimes differs in the males and females of the same insect, as in the Aculeate *Hymenoptera*. As these segments in the perfect insect bear no organs of locomotion, they are of a more simple structure than those of the thorax, consisting chiefly of an upper plate called the Dorsum, and an under plate called the Venter.

The substance of the abdominal segments is almost invariably less hard and more flexible than that of the head and thorax.

In the *Coleoptera* and *Hemiptera*, where the upper parts are protected by elytra, or hemelytra, they are softer than on the under surface which is exposed. In certain species however where the elytra do not cover the abdomen they are of the same substance throughout, as for instance in the *Staphylinidæ* and several minor groups of Coleopterous Insects. The articulation of the abdomen to the thorax offers some curious modifications, some of which are constant throughout whole groups, and hence afford distinguishing characters. When the abdomen is closely applied to the thorax it is termed sessile; and when the first segment, or more, is narrow and elongated, and forms a kind of stalk, it is termed petiolate.

The abdomen is often furnished with appendages at its extremity; thus in the Earwig (in which Mr. Westwood discovered one more than the usual number of segments) there is a pair of forceps which serve as weapons of defence, and in the male sex of *Panorpa*, where the apex of the abdomen is considerably elongated, there is also a pair of forceps. In the Dragon-Flies there are small flattened appendages, and likewise in the *Staphylinidæ*, which are called Stylets. Indeed the various kinds of appendages are too numerous to be here described, but are noticed in the accounts of the various groups of insects contained in this work. The modifications of the ovipositor are likewise noticed where they occur in the different groups. When it is of a long and compressed form it is termed ensate; and when it consists of several tubes retractile within each other, like the pieces of a telescope, it is called telescopiform. The term aculeiform is applied to this organ in the Hymenopterous Insects.

We now come to the internal anatomy of insects.

The Digestive System of insects is well developed, and consists of an intestinal canal, in which a crop, gizzard, stomach, and small intestine are generally distinct; but, as in the higher orders of animals, these parts vary according to the nature of the food.

Fig. 28.

Fig. 28, Intestinal canal of *Cicindela campestris*: *a*, œsophagus; *b*, crop; *c*, gizzard; *d*, stomach; *e*, *e*, hepatic vessels; *f*, small intestine.

In a predaceous beetle (*Cicindela*) the intestinal canal passes nearly straight through the body, the œsophagus dilates into a wide crop, which is succeeded by a minute gizzard, and then by the stomach, which, as well as the crop, is covered by numerous minute follicles; at the pyloric extremity of the stomach the biliary ducts pour their secretion into the cavity through four orifices, which are situated two on each side. The small intestine is short, and opens into a wide colon which terminates the canal.

In a vegetable-feeding insect the stomach is very voluminous and much convoluted, and the biliary ducts are proportionately long. In the common cockchafer these ducts have the secreting surface increased by innumerable minute secæ.

The salivary glands are distinct in many insects.

The circulation of the blood in insects is carried on in part by means of distinct vessels, and in part by channels excavated in the tissues. Its central organ is the dorsal vessel, which is segmentally divided; the compartments are separated by valves, which do not allow the blood to pass in any other direction than from behind forward. This segmental division however in the perfect insect does not extend into the thorax, the dorsal vessel in that region being converted into an aortic trunk, which carries the blood onwards, that it may be distributed to the head and thoracic appendages. From these it returns backwards along the limbs and body to re-enter the dorsal vessel, either by veins which open into its several chambers, or by larger vessels that collect the whole to convey it into the posterior chamber. In its course however it is brought into very close relation with the air that is conveyed through the whole interior of the body by the complex tracheal apparatus; for it appears from recent observations that the blood not only bathes the exterior of the air tubes, but moves through that space between the outer and inner membranes in which a spiral filament winds (as in the spiral vessels of plants) to keep them from being closed by lateral pressure.

These air-tubes form a complex system, which is distributed with the most elaborate minuteness throughout the body, commencing from lateral Stigmata, or breathing pores, of which each segment normally contains a pair, though some of them are frequently closed up, so that the number is greatly reduced. Between all the parts of the system there is the freest communication; and in some parts of it, especially in insects of rapid flight, we find the air-tubes dilated into large air-sacs, which both serve as reservoirs of air and contribute to diminish the specific gravity of the body. By this extraordinary development of the respiratory system the apparent imperfection of the circulating apparatus is compensated, since the chief demand for a very rapid movement of the blood in animals, which (like birds) put forth a vast amount of muscular energy and activity, arises not so much out of the demand for nutrition as from the necessity for a constant supply of oxygen to the tissues, which is here provided for by the penetration of the air itself into their substance.

Fig. 29.

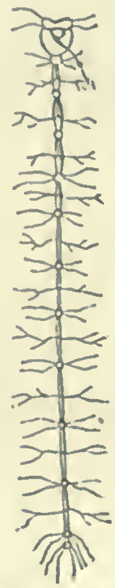

Fig. 30.

Fig. 29. Nervous System of the Common Cockchafer (*Melolontha vulgaris*). *Fig.* 30. Nervous System of a Caterpillar, or Larva.

The nervous system in insects consists of a double nervous chord, which is situated in the ventral portion of the body (being the reverse in this respect to the vertebrate animals). This double chord is joined at intervals by ganglia, which in larvæ correspond in number to the joints of the body, namely, thirteen. As the larva is about to assume the pupa state the abdominal ganglia gradually approach the thorax, and consequently are nearer to each other, a circumstance owing to the longitudinal contraction of the segments at this time, at least such is the case in Lepidopterous larvæ. In the pupa state the ganglia are still more approximated, and the nervous chords are curved and distorted: the same number of ganglia however are generally to be found; but in the Imago state of Coleopterous Insects several of the ganglia have become confluent, so that the number is considerably reduced. In the Common Cockchafer (*Melolontha vulgaris*), which may be taken as an illustration of the general character of the nervous system in insects, there is one large transverse ganglion in the head, consisting of two chief portions joined laterally, and which are expanded on their outer side to form the optic lobe. From this large transverse ganglion the two nervous chords extend downwards and backwards, and form a ring which encircles the œsophagus, beneath which they are united by the second ganglion. These two ganglia together send off the nerves which supply the various parts of the head and its appendages, the trophi, antennæ, &c. From the lower part of the second ganglion the nervous chords are continued to the thorax, where we find three large ganglionic masses, from which all the nerves which supply the thorax and abdomen have their origin.

The development of the organs of sense, and especially of the visual apparatus, attains a high degree of development. The eyes are here aggregated into large compound masses, usually of nearly hemispherical form, which are so large as to occupy a considerable part of the sides of the head. The structure of each individual eye (which is nearly of cylindrical form) seems most perfectly adapted to bring to a focus the rays which impinge upon it in the direction of its own axis, and by the mode in which the single eyes of each hemispherical mass are disposed, the range of vision is extended in every direction, although the eyes themselves are perfectly motionless. This multiplication of cylindrical eyes precisely similar to each other to gain an end, which is answered in vertebrated animals by a single globular eye, endowed with the power of motion on either side, is in remarkable accordance with the general plan of structure, characteristic of the *Articulata*, and is sometimes carried to a most wonderful extent; the number of single eyes in a common House-Fly being 4000, in the Cabbage-Butterfly 17,000, in the Dragon-Fly 24,000, and in the Mordella-Beetle 25,000. Besides the great compound eyes most insects have a few simple eyes disposed on the top of their head, in the narrow space between the aggregate masses, which appear to be of considerable use in directing their upward flight. There can be no doubt that insects are possessed of the sense of hearing, for though the precise organ which is subservient to it has not been determined, there is ample evidence that they are guided and influenced by sounds, one of the most striking instances of which is that the male of some insects (such as *Cicadæ*, Crickets, &c.), emit peculiar sounds, which attract the females to them. These sounds are produced entirely by mechanical means, and cannot be regarded as vocal. It would seem probable, as has been hinted above, that some part of the base of the antennæ is the auditory organ. There is similar evidence that insects possess the sense of smell; thus the Flesh-Fly deposits its eggs in the thick fleshy petals of the *Stapelia* (Carrion-Flower), deceived by its odour, which resembles tainted meat. The sense of touch is very delicate in some insects; such is the principal purpose of the antennæ, and the feet in some cases are furnished with peculiar organs, such as a soft cushion or a delicate expanded sucker, that is adapted to receive tactile impressions from the substances to which it is applied.

The muscular system of insects is highly developed, being entirely made up of the striated muscular fibre in its most perfect form, and consisting not only of muscles for the contraction and elongation of the trunk by the approximation or separation of its segments, but also of numerous muscles which give motion to the legs and wings. In insects of rapid and powerful flight these latter are so highly developed as almost to fill the cavity of the thorax. The joints are for the most part constructed so as to admit of but two kinds of movement, namely, flexion and extension; and the muscular apparatus has consequently not that variety of action which is seen where the ball and socket joint, which permits movements of circumduction, takes the place of the simple hinge joint. Nevertheless there are no animals which surpass insects in command over the organs of flight. "Even the swallow cannot match the dragon-fly, which often eludes its feathered pursuer as it can fly backwards and forwards, right or left without turning. When we compare the space traversed by an insect in a given time, with the dimensions of its body, we find it vastly exceeds the similar ratio in the bird, and thus we perceive that the locomotive powers of insects are far higher than those of any animal whatever.

"This power is most remarkably developed in the orders *Neuroptera* (Dragon-Flies, Termites, &c.), and *Hymenoptera* (Bees, Ants, &c.), and it is remarkable that these are the very orders in which we find the most extraordinary manifestation of those instinctive tendencies, the high development of which, with an almost complete absence of intelligence, is a striking characteristic of the articulated series in general, and of the class of insects in particular.

"These tendencies may be considered as dependent upon an association between sensory impressions and muscular movements, which arises from the original constitution of the nervous systems of these animals; and they may thus be regarded as necessities of their nature, not in the least indicative of intelligence, design, or voluntary choice on their own parts, but rather indicating the wise adaptation, by which they have been constructed to work out plans of most admirable elaborateness with the most wonderful perfection. Now these and all other instinctive actions have for their object the maintenance of animal life, as distinguished on the one hand from the mere organic life of plants, and on the other from the mental or psychical life of higher beings. And thus, if we consider the animal kingdom as holding an intermediate position between the vegetable world on the one side, and the domain of mind on the other, we should be led to regard the class of insects, and especially the orders *Neuroptera* and *Hymenoptera*, as its type." (Carpenter).

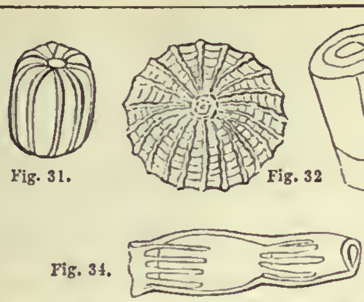
Insects are endowed with great powers of multiplication; this is accomplished with only one exception, by means of the sexual process of generation. The exception referred to is that of the *Aphis* [APHIS], which is capable of propagation by a process that appears to be analogous to that of gemmation amongst the lower animals.

The eggs of insects are extremely variable in shape: the more common form is oval; they are however often round, sometimes cylindrical. Those of the common white butterfly are conical. In many moths they are lenticular. The eggs of *Hemerobius* and several other insects are placed upon footstalks.

The surface of the eggs is generally smooth or nearly so, but it not unfrequently happens that they are uneven, and display a great variety of sculpture.

White, yellow, and green are the predominant colours of the eggs of insects: they are deposited in various situations, but always where the young larvæ may find appropriate food when hatched. Thus we often find them attached to the leaves or stems of plants. The *Ichneumonidæ* deposit their eggs in or on the bodies of caterpillars, and their larvæ when hatched feed upon these animals.

No insects come forth from the egg in their perfect condition, and their state in many cases at the time of their being hatched is quite



Figs. 31, 32, 33, and 34, Eggs of various insects.

embryonic, so that it is usually not until a series of very considerable changes have taken place in external configuration and internal structure, together constituting what is known as the Metamorphosis that the complete development of the specific type is attained. The amount of this metamorphosis, and the mode in which it is accomplished, vary considerably in the different orders of insects; but these stages are usually marked out more or less distinctly in the life of each individual. The term 'Larva,' in the ordinary language of Entomology, is applied to the insect from the date of its escape from the egg, up to the time when the wings begin to appear; the term 'Pupa' is in like manner employed to mark the period during which it is acquiring wings; and from the time when these and other organs characteristic of its perfect state are complete, it is spoken of as the 'Imago.' The grade of development however at which the insect comes forth from the egg is very different in the several orders and families. In all cases the embryonic mass within the egg is first converted into a footless worm, resembling the higher *Entozoa* or the inferior *Annelida* in its general organisation, but possessing the number of segments, thirteen, which is typical of the class of Insects. Such, in the *Diptera* and *Hymenoptera*, and in some of the *Coleoptera*, is the condition of the larva at the time of its escape from the egg; and it is remarkable that many of the larvæ of the first of these groups resemble *Entozoa* in their parasitic habits. The head in larvæ of this kind, which are known as maggots, differs but little from the segments of the body, the eyes in many cases not being developed, and the mouth being furnished with a mere suctorial disc. In the *Lepidoptera* and most of the *Coleoptera* however, the larva at the time of its escape possesses the rudiments of the three pairs of thoracic legs, although they are little else than simple claws, save in the carnivorous beetles; whilst in addition to these, several of the abdominal segments are furnished with fleshy tubercles or prolegs, generally to the number of four or five pairs, which are peculiar to the larva state. In such larvæ, which are commonly designated as 'Caterpillars,' we observe a remarkable equality in the different segments both as to size, form, and plan of construction, which reminds us of the *Annelida*. The alimentary canal occupies nearly the whole of the cavity of the body, and passes without flexure from one end of it to the other. The compartments of the dorsal vessel, the respiratory organs, the nervous centres, and the muscular bands, are repeated with great regularity, and there is as yet no distinction between the thoracic and abdominal portions of the trunk. The head however is usually protected by a horny covering, and is provided with simple or clustered eyes like those of the higher *Annelida* and *Myriapoda*, and the mouth is furnished with powerful cutting jaws for the division of the food, which is

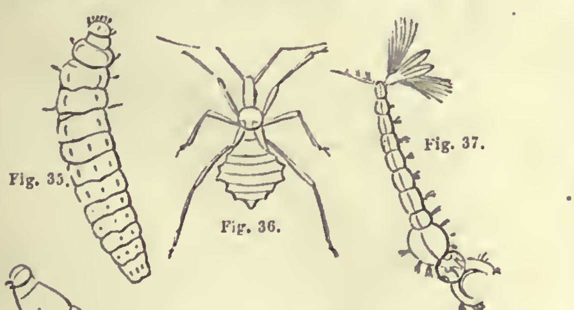


Fig. 35, a Coleopterous Larva (*Telephorus*). *Fig.* 36, Larva of an Hemipterous Insect (*Zelus*). *Fig.* 37, Larva of a Dipterous Insect (*Culex*). *Fig.* 38, Larva of a Lepidopterous Insect (*Sphinx*).

usually vegetable in its nature. In the Orthopterous and Hemipterous orders however, these stages of development are passed through within the egg, and as the young insect does not emerge thence until it has attained a higher grade, in which it presents a close resemblance to its parents in almost every particular save the want of wings, it cannot be regarded as having the characteristics of a real larva. This is the case too with some of the *Coleoptera*, in which we find a considerable variety as regards the stage of development at which the embryo quits the ovum. In the true larva condition, the whole energy seems concentrated upon the nutritive functions; the quantity of food consumed is enormous, and the increase in the bulk of the body is very rapid. During this rapid growth the caterpillar throws off and renews its epidermis several times, but the larvæ of the *Hymenoptera* and *Diptera* do not undergo this exuviation until they pass into the pupa state, their integument being soft enough to yield to the distension from within.

The principal variations in the larvæ of insects have been arranged in the following tabular form by Messrs. Kirby and Spence ('Introduction to Entomology,' vol. iii.):—

I. Larvæ without legs.
- i. With a corneous head of determinate shape.
  Coleopterous and Hymenopterous Apods—*Culicidæ*. Some *Tipulariæ*, &c., among the *Diptera*.
- ii. With a membranous head of determinate shape.
  (*Muscidæ*, *Syrphidæ*, and other *Diptera*.)

II. Larvæ with legs.
- i. With legs only and without an anal proleg.
  (*Neuroptera* and many *Coleoptera*.)
  1. Joints short and conical. (*Elater*, *Cerambycidæ*.)
  2. Joints long and subfiliform. (*Staphylinus*, *Coccinella*, *Cicindela*, &c.)
- ii. Prolegs only. (Many *Tipulariæ*, and some subcutaneous Lepidopterous larvæ, &c.)
- iii. Both legs and prolegs. (*Lepidoptera*, *Serrifera*, and some *Coleoptera*.)
  1. Without claws. (*Serrifera*, &c.)
  2. With claws. (*Lepidoptera*, &c.)

In the Pupa state insects exhibit two principal modifications: those which in general form resemble their larvæ, and those which are wholly unlike their larvæ.

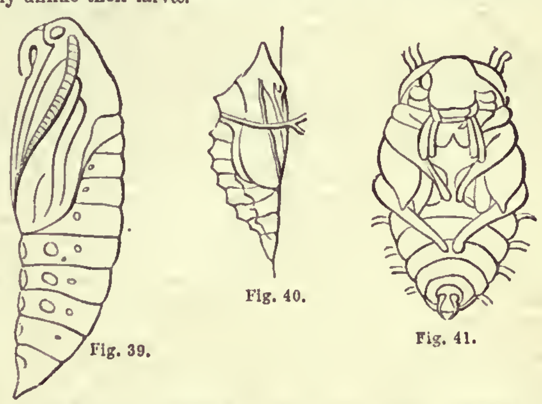

Fig. 39, Pupa of a Lepidopterous Insect (*Sphinx*). *Fig.* 40, Pupa of a Butterfly. *Fig.* 41, Pupa of a Beetle.

The former of these divisions Burmeister subdivides into incomplete pupæ and sub-incomplete. Incomplete pupæ are those without alary appendages: to these belong the Lice and Bugs (*Pediculus* and *Cimex lectularius*). Sub-incomplete pupæ are those which possess rudiments of wings. These comprise all the pupæ of the winged genera of the orders *Hemiptera* and *Orthoptera*.

In the second division, comprising those insects in which there is a complete metamorphosis, the pupa, with very few exceptions, is inactive, and does not take the least nourishment. They are divided into Pupa Coarctata, or those which are covered with a case in which no traces of the future insect can be perceived, as in *Musca* and many other Dipterous Insects; Pupa Obtecta, where the thorax and abdomen are distinct and inclosed in a horny case, as in the *Lepidoptera;* and Pupa Incompleta, where the parts are covered by a membrane, but distinct, as in the order *Hymenoptera* and some Dipterous Insects.

In the *Coleoptera*, *Lepidoptera*, *Hymenoptera*, *Diptera*, and some *Neuroptera*, the pupa state is one of complete inactivity as regards all manifestations of animal life; although the formative processes are carried on with extraordinary energy. The imperfect larvæ of these orders are truly embryonic in their condition; and the processes of development which were commenced in the egg, and which were then only carried far enough to enable the larvæ to come forth and obtain their own nutriment, are now continued at the expense of the food which they have collected and stored up within their bodies; so that the passage into the pupa state in such cases may be fairly likened to a re-entrance into the egg. The pupa is inclosed in the last skin exuviated by the larva, which, instead of being thrown off, dries up, and remains to encase the proper skin of the pupa that is formed beneath it; and in addition to this, it is frequently protected by a silken cocoon, the construction of which was the last act of larval life. The duration of the pupa condition, and the rate at which the developmental changes take place, vary considerably in different cases—some insects remaining in this state for years, while others pass through it in a few days or hours; in both cases however we perceive that an important influence is exerted by external temperature. As the state of the pupa is one of rapid transition it cannot be said to have any characteristic organisation. The assumption of the imago, or perfect type of insect life, is always marked by an exuviation of the integument which covered the pupa; and with this are cast off all the vestiges of the organs peculiar to the larva state, while the wings, the true legs, the compound eyes, the antennæ, the complete masticating or suctorial apparatus, and many other organs are now revealed for the first time in all those whose pupa condition was inactive. The wings however are seldom ready for use at the time of the insect's emersion from the pupa-case, being usually soft and moist, hanging loosely at the sides of the body, and having none of that rigidity which is requisite to give them power of serving as organs of impulsion in the air. It is not until the insect has forcibly injected the trachea with air—by taking several full inspirations, and then making an expiratory effort whilst the spiracles are closed—that the wings are expanded; they then soon become dried up by exposure to the air, and by the cessation of the circulation which previously took place within them, and from that time they are the chief instruments of locomotion in all insects in which they are fully developed. The nutritive apparatus of the Imago is far less developed relatively to the muscular, nervous, and sexual organs than it is in the preceding conditions; and its subordination to the offices of these is shown by the fact that many insects take no food whatever after their last change, the sole purpose of their existence in their perfect state being the propagation of the race by the generative process. In many instances the duration of the imago state is very brief, even when that of the preparatory periods has been very long, as in the case of the *Ephemera* (Day-Fly), which usually dies in a few hours after its last change; although the term of its previous life as a larva and an active pupa has not been less than two or three years: and even when the length of the life of the perfect insect is much greater, as in bees, wasps, &c., it seems to have a special relation to the nurture of the offspring, which are tended and supplied with food during the whole of the larva state. In the Ant tribe the neuters do not acquire wings; and some of them, which are two or three times the size of the rest, and are somewhat differently formed, are characterised as 'soldiers,' their special office being the defence of the nest rather than the nurture of the young. Among the *Termites* (White Ants) however the soldiers appear to be pupæ arrested in their development, whilst the 'workers' have the characters of permanent larvæ. In the Apterous orders of insects we find some tribes undergoing a regular metamorphosis, which is complete in every respect save the non-development of the wings. Thus, the larvæ of the *Pulex* (Flea) are footless worms, which afterwards pass into the pupa state, spinning for themselves a silken cocoon; in this they remain inactive for about twelve days, after which the imago comes forth, having the rudiments of wings attached to the second and third segments of the body, though without any proper distinction of thorax and abdomen. The *Pediculus* (Louse), *Podura* (Spring-Tail), and some other *Aptera* however undergo no metamorphosis, coming forth from the egg in the condition in which they remain all their lives, and this being far from the type of the perfect insect. (Carpenter, 'Principles of Physiology.')

We now come to speak of the classification of Insects. As the various orders of insects are noticed under their respective headings, at present we shall confine ourselves to the arrangement of these orders.

The orders of insects have been so variously arranged by different authors, that to give an outline of the views even of the more celebrated would occupy much space; we will therefore select the most distinguished of these systems:—Firstly, that of Linnæus, whose subdivisions are founded upon the substance and position of the wings; next, that of Fabricius, where the parts of the mouth have been selected in the division of this class into orders; then that of Burmeister, where no particular part or character has been chosen, but where the orders are established upon an aggregate of characters; and lastly, that of Mr. Westwood.

The orders of insects are thus characterised by Linnæus:—

Superior wings crustaceous, with a straight suture	*Coleoptera.*
Superior wings semicrustaceous, incumbent .	*Hemiptera.*
All the wings with scales	*Lepidoptera.*
All the wings membranous, tail unarmed .	*Neuroptera.*
All the wings membranous, tail aculeate .	*Hymenoptera.*
Two poisers in the place of the posterior pair of wings	*Diptera.*
Without either wings or elytra . . .	*Aptera.*

Insects are divided by Fabricius into—

I.—Insects with Biting Mouths.

1. *Eleutherata.* — Maxilla free, uncovered, and palpigerous. (*Coleoptera.*)

2. *Ulonata.* — Maxilla covered by an obtuse galea or lobe. (*Orthoptera.*)

3. *Synistata.*—Maxilla geniculate at the base, and connate with the labium. (*Neuroptera*, &c.)

4. *Piezata.* — Maxilla corneous, compressed, often elongate. (*Hymenoptera.*)

5. *Odonata.*—Maxilla corneous, toothed; two palpi. (*Libellulæ.*)

6. *Mitosata.* — Maxilla corneous, vaulted, not palpigerous. (*Myriopoda.*)

7. *Unogata.*—Maxillæ resembling scissors. (*Arachnida*, part.)

8. *Polygonata.*—Palpi mostly six; many maxillæ within the labium. (*Isopoda.*)

9. *Kleistognatha.*—Many maxillæ without the labium, closing the mouth. (Brachyurous Decapod *Crustacea.*)

10. *Exochnata.*—Maxillæ many without the labium, covered by palpi. (Macrurous Decapod *Crustacea.*)

II.—Insects with Suctorial Mouths.

11. *Glossata.*—Mouth with a spiral tongue between reflexed palpi. (*Lepidoptera.*)

12. *Ryngota.*—Mouth with a rostrum having a jointed sheath. (*Hemiptera*, Latr.)

13. *Antliata.*—Mouth with a haustellum without joints. (*Diptera*, *Anoplura*, and Tracheau *Arachnida*, Latr.)

Burmeister's System.

I.—*Insecta Ametabola.*

The larva resembles the perfect insect, yet it wants wings, if the perfect insect be winged; the pupa in this case has its rudiments. It runs about and eats.

a. With sucking mouths, which consist of four fine setæ lying in a sheath; palpi are wanting; four biliary vessels, and generally a free prothorax.

Order 1.—*Hemiptera.*

b. With mandibulate mouths; mandibles and maxillæ distinct, the latter having palpi, and generally distinct large superior lip.

a. Four unequal wings; the anterior pair leathery, or like parchment, the posterior pair folded longitudinally, and also once transversely; prothorax always free; many biliary vessels.

Order 2.—*Orthoptera.*

β. Four generally equal and rarely unequal wings, never folded, or sometimes none at all. In the first the nervures are usually reticulated, and there are generally many biliary vessels; in the latter case there are four biliary vessels attached to the intestine; prothorax sometimes free, sometimes not.

Order 3.—*Dictyoptera.*

II.—*Insecta Metabola.*

The larva consists of thirteen segments, either with or without legs; the pupa is inactive, or, if it moves, it takes no food.

a. Four equally large or equally long wings with reticulated nervures; mandibulate mouths; few biliary vessels, rarely more than eight; prothorax always free.

Order 4.—*Neuroptera.*

b. Wings always unequal, the posterior pair sometimes wanting, rarely all.

a. Mouths adapted to sucking.

a a. Instead of posterior wings there are pediculated knobs; yet the wings are sometimes wholly wanting; four biliary vessels; larva without feet; a soft proboscis with several setæ and a pair of palpi; prothorax not free.

Order 5.—*Diptera.*

b b. Four wings generally covered with scales; six biliary vessels; larva with feet and a distinct head; maxillæ forming a spiral tongue; prothorax not free but small, and closely connected with the mesothorax.

Order 6.—*Lepidoptera.*

β. Mouths with distinct biting mandibles.

a a. Four naked wings traversed by ramose nervures; larvæ generally without head and feet, but sometimes with both; many biliary vessels; prothorax not free.

Order 7.—*Hymenoptera.*

b b. Anterior wings in the form of horny elytra; larvæ with head, with or without feet; four or six biliary vessels; prothorax always free.

Order 8.—*Coleoptera.*

The first and second of the above classifications are by no means natural, nor were they intended to be so by their respective authors.

The former was established when entomology was, comparatively speaking, in its infancy; and although Fabricius possessed a more intimate acquaintance with insects, yet he contended that an artificial classification should he adopted till further discoveries had cleared the way for their satisfactory development. We cannot feel surprised therefore that these systems should have been superseded by others more modern.

The system of Burmeister is founded upon philosophical principles; we are not however prepared to agree with him in all instances. We allude more particularly to his order *Dictyoptera*, the species of which ought, we think, to be incorporated with the *Orthoptera*.

The following arrangement is that given by Mr. Westwood in his 'Introduction to the Modern Classification of Insects:'—

Class of Hexapod Metamorphic Insects.

Sub-class, Mouth with Jaws.	Sub-class, Mouth with a Sucker.
(*Dacnostomata*, W.)	(*Antliostomata*, W.)
Order *Hymenoptera*.	Order, *Diptera*.
? Osculant order *Strepsiptera*.	? Osculant order, *Homaloptera*.
Order *Coleoptera*.	
Osculant order *Euplexoptera*.	? Osculant order, *Aphaniptera*.
Order, *Orthoptera*.	Order, *Heteroptera* (including the Water-Bugs).
? (*Thrips*?)	
Order, *Neuroptera*.	Order, *Homoptera*.
Order, *Trichoptera* (*Phryganea* alone).	Order *Lepidoptera*.

The mutual affinities and likewise the grade of perfection of the various orders, may be expressed by arranging them in the following succession:—

1. *Hymenoptera*.	5. *Hemiptera*.
2. *Coleoptera*.	6. *Homoptera*.
3. *Orthoptera*.	7. *Lepidoptera*.
4. *Neuroptera*.	8. *Diptera*.

The number of species of Insects is much greater than that of any other class, and they are probably as numerous as all other forms of animals put together. Although possessed of extraordinary locomotive powers, they are each and all distributed within as certain bounds as the most stationary animals or plants. Independent, then, of its great interest as a part of philosophical zoology, the study of the range and specific centres of the forms of insect life becomes of great importance as an aid in the definition of tribes, genera, and species.

Climate and the extension or form of land are the chief influences regulating the distribution of insect life. The constitution of the soil affects it also, but in a secondary manner, through its influence on the vegetation, on which many insects feed. When from the intervention of tracts of water, of mountain barriers, or other causes depending on ancient geological events anterior to the origin of the existing Fauna of the earth, tracts of land presenting exactly similar conditions of climate and soil are placed far apart, we then have, not a repetition of the same forms among their insect population, but a representation by similar forms. This we see also in the Fauna of the several zones of climate belting mountains at different heights. Man's agency and the transporting power of currents of wind modify the distribution of many species of insects. In the following brief glance at the distribution of the principal genera of insects, examples of all these influences will be met with.

Coleoptera.—From the facility with which insects of this division may be preserved and trasported from place to place, we have more detailed accounts of their distribution than of any of the species of other orders. The *Cincindelidæ* are dispersed over most parts of the globe, the typical genus being cosmopolitan, whilst other groups are more limited. Among the *Carabidæ* are many genera peculiar to Europe. *Chlænius*, *Agonum*, and *Amara*, are common to both hemispheres. *Harpalus* and *Brachinus* are cosmopolitan. *Cnemacanthus* occurs in Africa and Chili. The *Carabidæ* of Western Asia agree remarkably with those of Europe. Erichson has remarked that *Carabi* are very constant to certain soils: the vertical distribution of the species is also very constant. The water-beetles allied to *Dytiscus*, itself universal in the Old World, are mostly European: several of the species live in salt or brackish waters. *Gyrinus* ranges from Northern Europe to Australia. The *Brachelytra* have their chief centre in Europe. The typical genus *Staphylinus* appears however to be represented everywhere: many species occur in South America. A species of *Aleochara* is found in Van Diemen's Land. *Elater* and *Buprestis*, types of families, are both cosmopolitan: the species are often local, and their distribution depends, in many cases, on that of certain plants on which the larvæ prey. Among the Fire-Flies (*Lampyridæ*) the genus *Lampyris*, which is European, is represented in the tropics by *Photinus*, and in the New World by *Aspisoma*. The *Malachii* are found everywhere, except in South America. *Ptinus*, a genus chiefly European, has a single representative in Australasia. Of the *Necrophagi*, the genera *Cryptophagus*, *Strongylus*, and *Silpha* are found everywhere, ranging from Britain to China, and from Brazil to Lapland. *Hister*, the type of a family, is also a cosmopolitan genus. *Byrrhus* belongs to the northern hemisphere, and has its chief centre in Europe. Among the Coprophagous *Lamellicornes*, the genus *Aphodius*, though represented in most countries, is chiefly developed in temperate regions; whilst *Ateuchus*, on the other hand, is mainly tropical. *Geotrupes* is cosmopolitan. *Copris* ranges to Australia, where however it is confined to the north coast. *Scarabæus* is subtropical. *Pelidnota* is American. The beautiful *Cetoniæ* appear to be of universal distribution. The strange forms of *Goliathus* are South African. Of the cockchafers, *Melolontha* is cosmopolitan; *Macrotops* and *Anoplognathus*, confined to Australia; *Hoplia*, with one exception, European; *Amphicoma* is Mediterranean; *Anisoplea* and *Serica* are natives of the warm and temperate regions of both hemispheres, whilst *Euchlorus*, occupying the same range, extends beyond in a northern direction. Of the *Melasomæ*, *Blaps* and *Pimelia*, both extensive genera, have their chief development in the warmer regions of the Old World. Of the *Stenilytra*, *Helops* is cosmopolitan, *Œdenura* European. Of the *Anthicidæ* the numerous species of *Anthicus* are chiefly inhabitants of temperate regions. The Blistering Beetles of the genus *Melöe* are very generally distributed.

Of the ten thousand species of Weevils the great genera *Centorhynchus*, *Cryptorhynchus*, *Calandra*, *Otiorhynchus*, and *Clionus* are all cosmopolitan. *Platysomis* and *Cyphus* are South American; *Brachycerus*, South African and Mediterranean. *Brentus*, mainly confined to the tropical regions of both hemispheres; *Apion* and *Rhynchites*, chiefly European. The distribution of the species of weevils depends in a great measure on that of plants.

The most beautiful and vividly coloured forms of Longicorn Beetles are mostly tropical. The presence of forests determines that of many of the genera. Of the seventy genera of *Cerambycidæ*, the typical one, *Cerambyx*, is cosmopolitan. Others have defined centres, as *Clytus* in Europe, *Trachyderes*, in South America.

Of the *Chrysomelinæ*, the typical genus *Chrysomela* is cosmopolitan. The presence of certain plants determines the distribution of the species. From this cause, species of limited distribution are sometimes multiplied far from their aboriginal centres. Thus *Galeruca calmariensis*, introduced from Europe into America, multiplied so at Baltimore in the years 1838 and 1839, that the elm-trees of the district were eaten bare by their larvæ, and probably they will henceforth become a constant annoyance in the New World. *Lema* and *Donacia* are instances of cosmopolitan genera having distinct centres in temperate climates. *Cassida*, on the other hand, has its centre in the tropics.

Of the *Trimera*, *Coccinellæ* are found everywhere. *Eumorphus* is Indian and Polynesian.

Orthoptera.—Though by no means an extensive order either as to genus or species, the *Orthoptera* are of very general distribution. Representatives of the genera *Gryllus* and *Acheta*, the grasshoppers and crickets, are found in most countries. The Locusts are mostly exotic. The strange *Phasmæ* are mostly tropical, as are also the greater number of *Mantidæ*, known popularly as 'walking leaves.' The Cockroaches, *Blattæ*, are very general, and have been greatly diffused from their original centres by unintentional human agency. The Earwig tribes, *Forficulidæ*, including more than fifty species, are in great part European, but range even to Van Diemen's Land.

Erichson notices the curious fact respecting the *Orthoptera* of Van Diemen's Land, that only one fourth of the species are completely winged and capable of flying.

Neuroptera.—The number of known species in this order is short of one thousand. The section of *Plicipennes* is almost entirely European; the genus *Macronoma*, including species from Madagascar and Brazil, is an exception. The *Planipennes*, a great part of the genera of which division are now considered by many naturalists Orthopterous, have a much more varied distribution. Thus the *Myrmelionidæ* are cosmopolitan, the *Perlæ* and *Nemouræ* chiefly European, the *Panorpæ* characteristic of the temperate regions of both the Old and and New World, the *Termites* of the tropics. In the section of *Subulicornes*, the *Ephemeridæ* are European; the *Æshnidæ*, cosmopolitan; as also the true Dragon-Flies, *Libellulæ*, of which near two hundred species are known. Other allied genera are more limited.

Hymenoptera.—Among the sting-bearing species, the true bees are characteristic of the ancient continent, those now dispersed in America having been transported from Europe. The genera *Centris* and *Euglossa* are exclusively American. *Nomia* is Asiatic. *Allodape* is south African. *Andrena*, *Xylocopa*, and several other extensive genera, are cosmopolitan. A great many genera of wasps are peculiar to South America. The ants are most developed in Europe. *Bembex* is a tropical genus. The terebrating *Hymenoptera* are both very numerous and widely distributed, especially the great genus *Ichneumon*. Certain genera forming the family *Oxyuræ* are exclusively European, as are also a great part of the numerous family of *Chalcididæ*. *Cynips* is European, and the greater number of *Tenthredinidæ*.

The distribution of the *Strepsiptera* depends on that of the insects on which they are parasitic.

Lepidoptera.—When the distribution of the butterflies shall have been worked out, it will doubtless prove very interesting. At present our knowledge of this subject is imperfect. The *Papilionidæ* are very numerous specifically, and for the most part tropical. Some of them possess great ranges. Thus certain species of *Pieris* are found over all Europe, and great part of Asia and Africa. Other forms are constant to mountainous regions. Of the *Nymphalidæ* the greater number and more gorgeous forms are tropical. In this family there are some remarkable instances of extensive distribution of species. Thus *Vanessa Cardui* (a common British butterfly) is found in every part of the world, and *Vanessa Atalanta* ranges over all Europe, part of Asia and Africa, and to North America. In the remaining tribes the typical genera are almost always cosmopolitan, whilst others have more limited areas.

The *Sphingidæ* and *Zygænidæ* are in great part European; the *Castnidæ* mostly tropical.

Among the Moths, the *Phalenidæ* are chiefly European, and the species are usually widely distributed. This appears to be the case also with the other families of Nocturnal *Lepidoptera*, probably rather in consequence of our imperfect knowledge of exotic forms, than because it is really so, for we find types and species in distant regions wherever they have been even casually explored, as in the instance of Asiatic Russia, where the researches of Eversmann among these insects have brought many new forms to light.

Diptera.—One half of the described species of two-winged flies (about eight thousand) belong to Europe. This disproportion arises from our comparative ignorance of the exotic forms. The small group of *Ornithomyzidæ*, parasites on quadrupeds and birds, has representatives of all its genera in Europe, the few remaining species being natives of eastern Asia, Western Africa, Australia, or Brazil. The flies forming the family of *Muscidæ* include a great number of genera, both European and exotic, the former being most prolific in species, some of which have wide ranges. The *Syrphidæ* are in the same category. The genus *Chrysops*, equally developed in Europe and America, and represented in a less degree in Africa and Asia, does not appear in Australia nor in the islands of the Pacific. *Tabanus* is more widely distributed. *Ommatius*, a genus of *Asilidæ*, has its members in all parts of the world. A great many genera are peculiar to South America, and several to Africa, hot, woody, and moist regions favouring their diffusion. *Tipula*, presenting numerous and varied forms in most parts of the world, is excluded from Australia and the Pacific, which region seems to be the least prolific in *Diptera*. The species of Gnats, *Culex*, are very generally distributed.

Hemiptera.—Of the two great divisions of this order, the *Homoptera* and the *Heteroptera*, the first is the smallest and also the most tropical. The distribution of the insects comprising them depends mainly on the Fauna and Flora of the countries they inhabit. Thus each species of *Coccus aphis* has a range correspondent to that of the plant upon which it feeds; and of the *Coræidæ* and *Lygæidæ* with the presence of their favourite animal food. Among the most interesting of the families of *Hemiptera* are the *Cicadeidæ*, of which the genus *Tettigonia* includes 200 species, centred in America, but having members also in the Old World; the *Fulgoridæ*, or Lantern-Flies, very generally distributed through warm climates; *Scutelleridæ*, remarkable for brilliancy, are mostly equatorial; and *Cimex*, of which the only true species is the common bed-bug, a pest spread over all Europe. Of the Aquatic *Hemiptera*, *Gerris* and *Nepa* are cosmopolitan; *Pelogonus* and the *Notonectidæ*, mostly European; *Galgulus* and *Mononyx*, American; and *Halobates*, equatorial.

Thysanura.—As yet the distribution of these minute insects has been scarcely attended to. The species of *Lepisma* range from Europe to China. *Podura* and *Smynthura* are European; a single species of the last-named genus occurs in North America.

Anoplura.—These disagreeable parasites have lately been honoured by the attention of some excellent naturalists, especially Denny and Gwilt. Their distribution corresponds with that of the animals upon which they are found. Of the equally annoying order *Aphaniptera* three-fourths of the known species are European. The Common Flea is a cosmopolite, and the *Chigo* is confined to South America.

Fossil Insects.

Until within a few years the occurrence of insects in a fossil state could only be substantiated by reference to a small number of localities, situated (as at Aix in Provence) among lacustrine tertiary strata, or (as at Stonesfield in Oxfordshire, and Solenhofen in Franconia) among marine Oolitic beds; but Mr. Prestwich has added traces of *Coleoptera* from the Coal Formation of Coalbrook Dale, and Mr. Strickland parts of *Neuroptera* from the Lias of Warwickshire; Dr. Buckland obtains *Neuroptera* from the Oolite of Stonesfield, and Mr. Brodie portions of insects belonging to various natural orders from the Lias of Somersetshire, Gloucestershire, and in the Wealden deposits of the Vale of Wardour in Wilts, and the Vale of Aylesbury.

Still the number of fossil insects, whether we estimate individuals or species, is very small compared to the probable number of anciently existing races; a circumstance quite explicable by reference to the phenomena which are now taking place in nature; for of upwards of 12,000 British species of insects there is reason to believe that but a very minute proportion is buried and preserved in lacustrine, estuary, or marine deposits now in progress. Only one elytron of a small beetle was observed in a deposit of the Elephantoidal era in Yorkshire, and one seed of some umbellate plant, along with hundreds of shells which inhabited the lake.

No doubt vast numbers of insects, wandering by caprice or drifted by winds, pass from the shore and fall into the sea—as we learn from the first voyage of Cook, who sailed through myriads of insects, some on the wing and others in the water, even thirty leagues from land off the coast of South America,—but few of these escape the watchful finny races, or ever reach the bottom of the sea.

In like manner we find land insects heaped in profusion by winds on certain tracts of fresh water, and borne down the course of rivers by inundations; and these cases, by the aid of particular suppositions, such as evaporation or slow draining off of the water, may offer the nearest analogy to the facts actually observed in the greater number of insect deposits.

The occurrence of fossil insects, especially in marine strata, is therefore to be regarded as an exceptional case, and this makes the circumstances brought to light concerning them remarkable and difficult of interpretation. We find however from Mr. Brodie that the insects lie in a certain bed or mass of thin beds in the Lias; similarly they occupy particular layers in the Oolite, the Wealden deposits, and in the tertiary accumulations of Aix, Oeningen, and Auvergne. In the latter region the calcareous incrustations gathering on the indusiæ, or larva-cases, of *Phryganidæ* have caused the formation of a peculiar limestone, called Indusial Limestone.

In the following summary of the groups of fossil insects in Great Britain the most recent stratifications come first. The catalogue commences with the Elephantoidal era. The authorities and localities are given for each case. (Morris's 'Catalogue of Fossils;' Brodie's 'Fossil Insects;' Lyell, in 'Geol. Proc.;' Phillips, 'Geol. Yorkshire;' Strickland, in 'Mag. of Nat. Hist.;' Buckland, in 'Bridgewater Treatise;' and 'Geol. Proc.')

1. Ossiferous Fresh-Water Deposits. (Pleistocene.)
Elytron of a *Chrysomela*. Bielbecks, in Yorkshire. (Phillips.)
Remains of *Copris lunaris*. Mundesley, Norfolk. (Lyell.)
Remains of *Donacia*. Mundesley, Norfolk. (Lyell.)
Remains of *Harpalus*. Mundesley, Norfolk. (Lyell.)
Remains of *Coleoptera*. Southwold, Suffolk. (Alexander.)

No truly aquatic beetle is mentioned among these. *Donacia* haunts aquatic plants. The others are strictly terrestrial. They must have been drifted into the lakes in which the *Planorbis*, &c., lived.

2. In the Cretaceous System, no insects have yet been found.

3. In the Wealden Strata of the Vale of Wardour. The specimens found by Mr. Brodie and examined by Mr. Westwood were:—

Land *Coleoptera*, of the families *Carabidæ* (?), *Harpalidæ* (?), *Staphylinidæ* (?), *Buprestidæ* (?), *Tenebrionidæ* (?), *Elateridæ* (?), *Curculionidæ* (?), *Cantharidæ* (?), and *Helophoridæ*.

Aquatic *Coleoptera*, of the families *Hydrophilidæ* (?) and *Dyticidæ* (?) (*Colymbetes*).

Orthoptera, of the genera *Acheta* and *Blatta*.

Hemiptera and *Homoptera*, including land-tribes, as *Cimicidæ*, *Cicada*, *Cercopis* (larva), *Aphides*, &c., and the aquatic races of *Velia* and *Hydrometra*.

Neuroptera.—In this water-hunting order occur *Libellula* and *Æshna*, *Corydalis*, *Libellulidæ*, *Termes* (?), and *Leptoceridæ*. *Trichoptera* (?), *Phryganidæ* (?).

Diptera.—*Simulium* (?), *Platyura* (?), *Tanypus* (?), *Chironomus* (?), *Culex* (?), *Tipulidæ* (?), &c. (Aquatic larva) *Empidæ* (?).

4. In the Oolitic Strata insects occur in the laminated probably littoral beds of Stonesfield and some other localities in Gloucestershire and near Bath. Dr. Buckland has described several species in the 'Geological Proceedings' and in his 'Bridgewater Treatise on Geology,' and Mr. Brodie has added others. The remains are chiefly elytra of *Coleoptera* and wings of *Neuroptera*. The following is abstracted from Mr. Brodie's list:—

Coleoptera, of the families *Prionidæ*, *Buprestidæ*, *Pimeliidæ* (?), *Chrysomelidæ* (?), and *Coccinellidæ*.

Neuroptera.—*Hemerobioides giganteus*. (Buckland.)

5. In the Upper Lias: at Dumbleton and Churchdown. (Brodie.)

In the Lower Lias: above the bone-bed of Aust Cliff, Waiulode Cliff, &c., on the Severn; Coombe Hill, Cracombe; Hasfield, Corsowood Hill, &c., in Gloucestershire. (Brodie.)

Mr. Westwood has examined 300 specimens of insects from the Lias beds.

Coleoptera, of the families *Buprestidæ* (?), *Elateridæ*, *Curculionidæ* or *Chrysomelidæ*, *Carabidæ*, *Telephoridæ*, *Melolonthidæ*, &c.; a species of *Gyrinus* (?).

Orthoptera, including *Gryllidæ* and *Blattidæ*.

Hemiptera and *Homoptera*. *Cicada* (?), *Cimicidæ* (?).

Neuroptera.—These are the best-determined of the fossil groups, owing to the structure of the wings being clear and characteristic:—

Libellula Brodiæi (Brodie), is found in Upper Lias, at Dumbleton, Gloucestershire.
L. Hopæi (Brodie). Strensham, Worcestershire.
Agrion Buckmanni (Brodie), in Upper Lias at Dumbleton.
Æshna liassina (Strickland). Bidford, Warwickshire.
Orthophlebia communis (Westwood). Waiulode, Forthampton, Strensham, Cracombe, Bidford.
Hemerobius (?) *Higginsii* (Brodie).
Chauliodes. Hasfield, Strensham, Bidford.
Ephemera. Strensham.
Diptera.
Asilus (?) *ignotus* (Brodie). Forthampton.

It is in the Lower Lias beds that the insects are most abundant. They occur in this part (between the ordinary lias limestones and the bone bed) so extensively as to justify the application to this genus of the term 'insect limestone' used by Mr. Brodie. As a whole the Lias insects appear to contain larger proportions of aquatic tribes than the Wealden. There is no decided evidence amongst them of the prevalence of a warm climate at the time and in the place of their existence. They are usually of small size, not so entire as to forbid the supposition of having been drifted (the *Neuroptera* may have been less drifted than the *Coleoptera*); and if there were islands or high coasts adjacent these might nourish, and in time of floods send down the small coleopterous insects to be imbedded with the fucoids, oysters, and *Modiolæ* of the coasts, and ferns and other plants of the land and streams.

6. In the ironstone nodules lying in the Carboniferous deposits of Coalbrook Dale Mr. Prestwick has discovered *Coleoptera*, *Curculioides Ansticii* (Buckl.), *C. Prestvicii* (Buckl.); and Sir R. Murchison ('Sil. Syst.' p. 105) mentions an insect to which the name of *Corydalis Brongniarti* is assigned. It is very possible that the laminated limestone deposits of Burdie House, near Edinburgh, and Ashford, in Derbyshire, may yield insect remains older than any yet mentioned; and seeing the frequent connection or proximity of fossil insects to fossil fishes it may be worth while to search the lower beds of the mountain limestone, where the rich fish-beds occur in it, on the Avon, in Caldy Island, and in Fermanagh. The fish-beds of the magnesian limestone (marl slate) may also be indicated for further research. A very interesting addition to the fossil insects of Aix has been made known by M. Coquand. It is a butterfly, and has been carefully examined by M. Boisduval, who has been able to recognise perfectly its generic and specific characters. It belongs to one of those genera the species of which are not numerous, and are at present confined to the islands of the Indian Archipelago, or the warmest countries of the Asiatic continent. It belongs to the genus *Cyllo*—it is an extinct species—and is named *C. sepulta*. M. Boisduval has examined the other fossil insects of Aix, and differing both from Curtis and Marcel de Serres, refers them to the extra-European genera, and to extinct species.

INSECTIVORA. [CARNIVORA.]

INSECTS. [INSECTA.]

INSECTS, FOSSIL. [INSECTA.]

INSESSO'RES, the name given by Mr. Vigors to the Perchers, the second order of Birds in his system, and, as the families of which it is composed are very numerous, he classes them in comprehensive sections or tribes, which he thus denominates:—*Fissirostres* (Cuvier), *Dentirostres* (Cuv.), *Conirostres* (Cuv.), *Scansores* (Auct.), *Tenuirostres* (Cuv.).

The FISSIROSTRES, according to Mr. Vigors, include the *Meropidæ*, the *Hirundinidæ*, the *Caprimulgidæ*, the *Todidæ*, and the *Halcyonidæ*.

The DENTIROSTRES include the *Muscicapidæ*, the *Laniadæ*, the *Merulidæ*, the *Sylviadæ*, and the *Pipridæ*.

The CONIROSTRES comprise the *Fringillidæ*, the *Sturnidæ*, the *Corvidæ*, the *Buceridæ*, the *Loxiadæ*.

The SCANSORES consist of the *Ramphastidæ*, the *Psittacidæ*, the *Picidæ*, the *Certhiadæ*, and the *Cuculidæ*.

The TENUIROSTRES are composed of the *Nectariniadæ* (?), *Cinnyridæ*, *Trochilidæ*, *Promeropidæ* (?), and *Meliphagidæ* (?).

Mr. Vigors finds the following parallel analogies by which the tribes of the *Insessores* represent the different orders of the class.

Dentirostres	*Raptores.*
Conirostres	*Insessores.*
Scansores	*Rasores.*
Tenuirostres	*Grallatores.*
Fissirostres	*Natatores.*

Of these the *Conirostres* are considered by Mr. Vigors the typical group. ('Linn. Trans.,' xiv.)

Mr. M'Leay conceives it to be demonstrated that, so far as relates to the analogies existing in nature between the orders of *Mammalia* and *Aves*, the *Primates* ought to be placed as analogous to the *Insessores*. Both are omnivorous. ('On the Comparative Anatomy of Certain Birds of Cuba,' by W. S. M'Leay, in 'Linn. Trans.,' xvi.)

Mr. Swainson, in accordance with his opinion that the primary divisions of every circular group are five apparently, but three actually, gives the following table as illustrating the

Circle of the order *Insessores*, or Perchers:—

1. Typical Circle.	Bill more or less conic, strong, slightly or not at all notched; mouth without bristles; feet robust, formed both for perching and walking. Omnivorous.		*Conirostres.*
2. Subtypical Circle.	Bill shorter and more compressed, with a distinct tooth-like notch; mouth generally defended by bristles. Insectivorous.		*Dentirostres.*
3. Aberrant Circle.	Bill entire; feet very short, not adapted for walking; position of the toes various.		*Curtipedes.*
	1. Feet formed for climbing.	*Scansores.*	
	2. Bill long; tongue extensile. Suctorial.	*Tenuirostres.*	
	3. Bill broad at the base. Feed upon the wing.	*Fissirostres.*	

The table of analogies set out by the same author is the same in substance with that of Mr. Vigors, differing only in the order in which the tribes and orders are placed. Mr. Swainson, who excludes Man from the Zoological circle, considers the *Insessores* to be analogous to the *Quadrumana*.

The *Dentirostres*, according to the last-named author, include the families *Laniadæ* [LANIADÆ], *Merulidæ* [MERULIDÆ], *Sylviadæ* [SYLVIADÆ], *Ampulidæ* and *Muscicapidæ* [MUSCICAPIDÆ], with their sub-families.

His families of the *Conirostres* are *Corvidæ* [CORVIDÆ], *Sturnidæ* [STURNIDÆ], *Fringillidæ* [FRINGILLIDÆ], *Musophagidæ* [MUSOPHAGIDÆ], and *Buceridæ* [HORNBILLS], with their sub-families.

Under the *Scansores* he comprises the *Rhamphastidæ* [RHAMPHASTIDÆ], the *Psittacidæ* [PSITTACIDÆ], the *Picidæ* [PICIDÆ], the *Certhiadæ* [CERTHIADÆ], and the *Cuculidæ* [CUCULIDÆ], with their sub-families.

The *Tenuirostres* are made to contain the *Meliphagidæ* [MELIPHAGIDÆ], the *Cinnyridæ* [CINNYRIDÆ], the *Trochilidæ* [TROCHILIDÆ], the *Promeropidæ* [PROMEROPIDÆ], and the *Paradisiadæ* [BIRDS OF PARADISE], with their sub-families.

The *Fissirostres* comprise the *Meropidæ* [MEROPIDÆ], the *Halcyonidæ* [HALCYONIDÆ], the *Trogonidæ* [TROGONIDÆ], the *Caprimulgidæ* [GOATSUCKERS], and the *Hirundinidæ* [SWALLOWS], with their sub-families.

INSPIRATION. [RESPIRATION.]

INTESTI'NA (Intestinaux), the second class of the *Radiata*, or fourth division of the animal kingdom, according to the classification of Cuvier. In the 'Règne Animal' this class is divided into two orders, *Cavitaria* and *Parenchymata*, which include all the *Entozoa* of Rudolphi; but the term *Intestina*, if retained at all, should be applied only to the true Intestinal Worms, or those parasites which live in the intestines of other animals, and should exclude the *Entoza* which are found in the cellular tissue and substance of the different viscera of the body.

The order *Cavitaria* ('vers intestinaux cavitaires') of Cuvier corresponds to the fifth order *Nematoidea* of Rudolphi, and the group *Cœlelmintha* of Owen. The *Parenchymata* ('vers intestinaux parenchymateux') includes the other four orders of Rudolphi, *Acanthocephala*, *Trematoda*, *Cestoidea*, and *Cystica*, and corresponds to Mr. Owen's group of *Sterelmintha*. [ENTOZOA.]

INTESTINAL WORMS. [ENTOZOA.]

INTESTINES are that portion of the digestive canal into which the food is received after it has been partially digested in the stomach, and in which its further assimilation, the separation and absorption of the nutritive matter, and the removal of that which is excrementitious, take place. In an adult the intestines consist of a convoluted tube of from 30 to 40 feet in length, and are, from the difference of their diameters in different parts, divided into *Small Intestines*, which comprise about the first four-fifths, and *Large Intestines*, which constitute the other fifth of their length. The former again are divided into the Duodenum [DUODENUM], into which the ducts from the liver and pancreas open, and in which the chyme from the stomach is converted into chyle [DIGESTION; CHYLE]; the Jejunum, in which the absorption of the nutritive matter of the food is principally effected; and the Ileum. The large intestines are divided into the Cœcum, Colon, and Rectum.

The walls of the intestinal canal are composed of three principal coats or membranes. The exterior, which is smooth and polished, is called the peritoneal, and its principal use is to permit the free motions of the intestines within the abdomen, and of their several convolutions against each other, by rendering the effect of friction as slight as possible. [PERITONEUM.] Next to and within the peritoneal coat is the muscular, which is composed of two layers of fibres; an external, in which they are directed longitudinally, and an internal, of which the fibres encircle the intestine. By these the motions of the intestines and the propulsion of their contents are effected; the longitudinal fibres tending to shorten each portion of the canal, while the circular contract its diameter; and the two sets together producing a motion of the tube somewhat like that of a worm, whence it has received the name of vermicular motion. Beneath these layers, and separated from them by a stratum of cellular tissue, which has been sometimes called the fourth or nervous coat, is the mucous membrane, which is the most important part of the intestinal canal.

The structure of these coats of the intestines has been most carefully observed by means of the microscope. The minute structure of the intestines corresponds to a considerable extent with what is met with in the stomach. There are however differences of structure especially in the mucous coat of the intestines. We shall describe first the muscular structure, and in doing this we shall follow Professor Kolliker in his 'Manual of Human Histology.'

The muscular coat of the smaller intestines is somewhat thicker in the duodenum and the upper portions, than in the lower; it has in general a thickness of ¼'''—⅓''', and is composed only of longitudinal and transverse fibres. The former are always less developed, and do not form a continuous layer, since they are very few or entirely absent along the attachment of the mesentery; they are usually most distinct upon the free border, though even here they may be readily torn away with the serous membrane, so as at once to leave the second layer exposed. The latter is complete and continuous, consisting of circular bundles, which not uncommonly anastomose at very acute angles.

In the large intestines the longitudinal fibres are reduced to the three ligamenta coli, muscular bands of 4'''—6''', or even 8''' broad, and ⅓'''—¼''' thick, which commencing upon the cœcum are united upon the sigmoid flexure into a single longitudinally fibrous layer, thinner than in the small intestines, and more especially developed in the duplicatures, which are known under the name of the plicæ sigmoideæ. All the fibres belong to the smooth or non-striated system of muscular fibres. Many of them present knot-like enlargements and frequently zigzag flexures, which produce the transversely striated appearance of the entire bundles of such muscles so frequently met with in spirit preparations. The arrangement of the fibre-cells in the different strata is simply this, mutually applied in their length and breadth, and coherent:—They are united into thin muscular bands, which when invested with a coating of connective tissue, and frequently also united into secondary bundles, constitute the thicker or thinner muscular tunics of the different regions; which, again are surrounded and separated from the contiguous parts by considerable layers of connective tissue.

Blood-vessels are very abundant in the smooth muscles; and their capillaries, of 0·003'''—0·004''', constitute a characteristic network with rectangular meshes. Nothing is known about the lymphatics; nor are the relations of the nerves yet ascertained, except that Ecker has observed the division of fine nervous tubules in the muscular tunics of the stomach of the frog and rabbit.

The mucous membrane of the small intestines is thinner than that of the stomach, but more complex in its structure, inasmuch as besides the tubular, or Lieberkühnian glands it presents a great number of permanent folds and villi, also imbedded in its substance, peculiar closed follicles, the so-called solitary and Peyer's glands, and, in the submucous tissue of the duodenum, Brunner's glands. The mucous membrane consists of connective tissue which is internally homogeneous, or indistinctly fibrillated; except where certain glands exist there is but little submucous tissue, so that it is pretty closely connected with the muscular tunic. Upon the inner surface of the mucous membrane there rests a cylinder-epithelium, whilst externally towards the submucous tissue it is bounded by a layer of smooth muscles discovered by Brücke, which measures at most 0·0177'''. They are disposed longitudinally and transversely, but in man their slight development renders it often very difficult to discover them.

The villi of the small intestines are small whitish elevations of the innermost portion of the mucous membrane, readily distinguishable with the naked eye, and which distributed upon and between the valvulæ conniventes through the whole extent of the small intestines, from the pylorus to the sharp edge of the ileocœcal valve, are set so close together as to give the mucous membrane its well-known velvety appearance. They are most numerous (50 to 90 upon a square line) in the duodenum and jejunum, less so in the ileum (40 to 70 upon a square line). In the duodenum they are broader and less elevated, resembling folds and laminæ $\frac{1}{10}$'''—¼''' in height, ¼'''—⅙''' or even ⅓''' in breadth. In the jejunum they appear for the most part to be conical and flattened; frequently they are even foliated or cylindrical, clavate, or filiform, the three latter forms predominating in the jejunum. The length of the villi is from ¼'''—⅓''', the breadth from ⅙'''—$\frac{1}{10}$''', or even $\frac{1}{12}$''', the thickness in the flattened forms $\frac{1}{30}$'''.

The villi are composed of two portions, a deeper coat belonging to the mucous membrane, and an epithelial superficial coat. The contour of the former, or villus proper, is similar to that of the entire villus; it is simply a solid process of the mucous membrane containing blood-vessels, lymphatics, and smooth muscles, whose matrix, through which a variable number of roundish nuclei are scattered, in general exhibits no morphological peculiarity more decided than that of the mucous membrane itself, yet must most undoubtedly be regarded as a metamorphosed connective tissue without any intermixture of elastic tissue. The bloodvessels of the villi are so numerous that when well injected those whose epithelium has been detached become coloured throughout; and in living animals, or in those which have just been killed, each villus if viewed from above appears as a red dot surrounded by a clear ring. In man every villus contains a close network of capillaries of 0·003'''—0·005''', with rounded or elongated nuclei, which lies immediately beneath the homogeneous external layer of the matrix, and is supplied by one, two, or three small arteries of 0·01'''—0·016'''. The blood is usually carried back directly into the larger trunks of the submucous tissue by a vein of 0·022''', which does not arise as in animals, by the arching round of the artery, but proceeds from the gradual confluence of the finest capillaries. The relations of the lacteals in the villi of man, have not hitherto been perfectly made out; for although the majority of investigators are inclined, like the older observers, to suppose that they commence by one or two cœcal branches, yet recently several observers have contended for the view that they originate in a filiform manner. On this subject Professor Kölliker remarks that in the human subject he has never succeeded in meeting with villi distended with chyle, and in empty ones, he has been unable to obtain any decisive evidence; on the other hand, in animals, he feels certain that in many cases only a single lacteal which has a cœcal and frequently enlarged end, and whose diameter is much greater than that of the capillaries, traverses the axis of the villus. He says he believes that all the narrow cylindrical and filiform villi will be found to present this condition, but that, on the other hand, the number and mode of origin of the lacteals may possibly be different in the broad and foliaceous forms.

In addition to these organs the villi also contain, as Brücke discovered a short time ago, a thin layer of longitudinal smooth muscles, situated more centrally round the lacteals; these however are not always distinct in man, they produce contractions of the villi, which are very evident immediately after death, and which, according to Brücke, are also perceptible in the living animal. They have in all probability an important influence over the propulsion of the chyle, and of the venous blood in the villi—always supposing that there is no objection to the assumption that they perform repeated contractions during life. Nothing is known of nerves in the villi. The epithelium of the villi and of the rest of the surface of the mucous membrane, although it is very intimately united with the deeper-seated parts during life, only becoming detached accidentally or by disease, separates very readily in the dead subject, and can only be observed in perfectly fresh portions of intestine. It consists everywhere of a simple layer of cylindrical cells slightly narrowed below of 0·01'''—0·012''' in length and 0·003'''—0·004''' in breadth, whose contents are usually nothing but fine granules, and an oval, clear, vesicular nucleus, provided with one or two nucleoli. During life, these cells, which agree in all their chemical characters with the deeper cells of the oral epithelium, are so intimately united, that even after death their contours in a longitudinal view, are at first either not at all or only indistinctly distinguishable, though on the surface they have the appearance of a beautiful mosaic. The cylinders only become quite distinct when they are either spontaneously or artificially detached, a process which usually takes place in such a manner that they hang together in continuous portions, all the cells covering a villus, sometimes coming off together like the calyptra of a moss.

The addition of water to these cells produces a separation of the cell-contents from the broad end, giving rise, in separate cells, to the appearance of a membrane thickened upon one side, and, in series of cells or entire villi, to that of a peculiar structureless coat, like the cuticle of plants; by its longer action, however, or by that of the intestinal fluids, the bursting of the cells produces apertures in them, or they become distended into large pyriform clear vesicles.

We may here refer to the changes which the epithelial cells and the villi in general undergo during digestion. The most striking circumstance is the occurrence of fat-globules in different parts of the villi, which may always be observed during the formation of a fatty milk-white chyle. The succession of the morphological steps is as follows:—The fat contained in the chyme at first enters only isolated epithelial cells in different regions of the villi, so that in each we soon observe a large ovate shining drop.

The number of these fat-cells rapidly increases, and then the villi acquire a very peculiar appearance, often as if beset with pearls, from the irregular alternation of cells filled with fat, and consequently bright and shining, with those which are empty and pale. In the end all the cells become filled with these drops, and the epithelium appears quite dark by transmitted, but whitish by reflected light, giving its aspect to the whole villus.

With the repletion of the entire epithelial covering of the villus, absorption commences, but up to this time nothing has entered the lacteals. This however soon takes place, and the first indication we observe is the breaking up of the large drops of fat in the cells into many tolerably minute fatty molecules. When this has occurred, these drops penetrate by degrees from all sides into the parenchyma of the villus itself, fill it more and more, and at last enter the central lacteal, whose whole length they eventually occupy. In the meanwhile, fresh fat has been continually passing in from the intestinal canal, not in the form of large drops however, but henceforward in small molecules or drops of the same kind as those which were at first developed secondarily in the cells. On the other hand, at a subsequent period, we not uncommonly meet in the interior of the villi with large round drops, which appear especially inclined to form considerable accumulations at their apex. In man the process is probably the same as in animals. These observations demonstrate that fatty matters are absorbed as such, and are not saponified; on the other hand, it cannot at present be certainly stated how it is possible that they penetrate the membrane of the epithelial cells, the parenchyma of the villi, and the walls of the lacteals.

The whole process may be compared to the imbibition of an emulsive fluid, such as milk, by a porous body; and the fatty molecules of the chyme are probably absorbed simply in consequence of their being carried along with its fluid part. While digestion is going on, we frequently find the whole parenchyma of the villi densely filled with small nuclei, here and there surrounded by cell-membranes—elements which are never entirely absent in a villus, but are at other times far fewer, and particularly are not to be distinguished in its interior.

The small intestines contain two kinds of true glands; 1, tubular glands, which are disposed over the whole mucous membrane; 2, racemose glands, in the submucous tissue of the duodenum.

The Racemose Glands, or as they are commonly named, after their discoverer, Brunner's Glands, form, at the commencement of the duodenum, upon the outer side of the mucous membrane, a continuous layer, which is best developed and thickest close to the pylorus, where it constitutes a considerable glandular ring, and extends about as far as the aperture of the biliary ducts. If the two layers of the muscular tissue be dissected off a stretched or distended duodenum, the glands may readily be recognised as yellowish flattened bodies of $\frac{1}{10}'''$—$1\frac{1}{2}'''$ (on the average $\frac{1}{4}'''$—$\frac{1}{2}'''$), with their angles rounded off, which inclosed within a little connective tissue, lie close to the mucous membrane, and send short excretory ducts into it. In their minute structure, Brunner's glands, the terminal vesicles of which measure 0·03'''—0·06''', even 0·08''', agree perfectly with the racemose glands of the mouth and œsophagus. Their secretion is an alkaline mucus, in which no formed elements are contained, having no digestive action upon coagulated protein compounds, and probably merely subservient to mechanical ends.

The Tubular, or Lieberkühnian Glands (cryptæ mucosæ), are distributed over the whole small intestines including the duodedum as innumerable straight narrow cœca, which occupy the entire thickness of the mucous membrane, and are frequently slightly enlarged at their extremities, though hardly ever dichotomously divided. The best idea of their number is obtained by viewing the mucous membrane either from above or in vertical section, under a low power. In the latter case we see the cœca standing close together, almost like palisades; in the former we observe that the glands do not occupy the whole surface, but only the interspace between the villi; here however they exist in such numbers as to leave no intervals of any width, the mucous surface between the villi appearing pierced like a sieve. Even on Peyer's patches, and over the solitary follicles, these glands are to be met with; but in man they leave those portions of the mucous membrane which lie immediately over the centre of the follicles free, and therefore are arranged like wings around the follicles.

The length of the Lieberkühnian glands equals the thickness of the mucous membrane and varies from $\frac{1}{5}'''$—$\frac{1}{3}'''$; their breadth is 0·028'''—0·036''', that of their aperture, 0·02'''—0·03'''. They are composed of a delicate homogeneous membrana propria, and of a cylindrical epithelium, which even during chylification never, like that of the intestine, contains fat; their cavity is filled during life by a clear fluid secretion, the so-called intestinal juice, which however becomes rapidly changed after death, or on the addition of water, so that the glands appear to be filled with cells, or with a granular mass.

The most important of the Closed Follicles are Peyer's patches (glandulæ agminatæ). They are rounded flattened organs, invariably situated along that surface of the intestine which is opposite the mesentery; they are most distinct upon the inner surface, where they appear as rather depressed smooth spots, without any very sharp definition, but they are also recognisable from the exterior by the slight elevation to which they give rise; by transmitted light they look like mere opaque portions of the membrane. These patches are usually the most abundant in the ileum, but they are not uncommonly to be met with in the lower part of the jejunum; occasionally they exist in the upper portion close to the duodenum, and even in the inferior horizontal portion of the duodenum itself. Ordinarily there are 20 to 30 of them; but when they are found higher up there may be as many as 50 to 60; but they are always most closely set in the lowest portion of the ileum. The dimensions of the separate patches are in general the larger the closer they are to the cœcum; their length is usually 5'''—$1\frac{1}{2}''$, but may diminish to 3''', and increase to 3'''—5''', or even 1'; their breadth varies from 3''' to 5''', or 9'''. Where the patches lie the valvulæ conniventes are usually interrupted; in the jejunum however these folds are also to be met with upon the Peyer's patches and in the ileum; rows of closely-set villi often take their place. More minutely examined, every Peyer's patch is seen to be an aggregation of closed follicles of $\frac{1}{4}'''$—$\frac{1}{2}'''$—1''' in diameter, either rounded or slightly conical towards the intestinal cavity, which lie partly in the mucous membrane itself, partly in the submucous tissue; and are on the one side not more than 0·02'''—0·03''' distant from the mucous surface, while on the other they are in immediate contact with the muscular tunic, which is here somewhat more closely united with the mucous membrane.

Viewed from the interior of the intestine their most striking feature in man is the presence of many small rounded depressions $\frac{1}{3}'''$—$\frac{1}{2}'''$—1''' apart, which corresponds with the separate follicles, and whose floor is indeed rendered slightly convex by the latter, but which present no villi whatever. The remainder of the patch is occupied by common villi, or by reticulated folds, and by the apertures of the Lieberkühnian glands; the latter are disposed around the slight elevations produced by the follicles in circlets of 6 to 10 and more apertures, the coronæ tubulorum of authors.

The Solitary Follicles (glandulæ solitariæ) resemble the separate elements of Peyer's patches so closely in size, contents, and general structure, that there is no reason for considering them as distinct, particularly as the number of follicles is subject to all possible varieties, and since, in animals at least, we find Peyer's patches with 2—3—5 follicles. In man, as all writers justly agree, their number is exceedingly inconstant; sometimes not one can be found, whilst in other cases the whole intestines, as far as the margins of the ileocœcal valve, is thickly beset with them; or, lastly, they may occur in the ileum and jejunum, but in no very great number. Their entire absence must probably be considered abnormal, since they are constant in newly-born children, being more abundant in the jejunum than in the ileum. The miliary vesicles however, which are often met with in immense quantities in the small intestines and stomach in catarrhal affections of the alimentary tract, may very probably be entirely or partially pathological, since the occurrence of such follicles has been demonstrated in other organs also (in the liver, according to Vorhow). The solitary follicles have the same structure as the elements of the patches, only they occur also in the mesenteric border, and support villi upon their intestinal surface, which is usually somewhat convex.

Professor Kölliker expresses himself as decidedly opposed to the notion that the follicles of Peyer's patches have any apertures. Of their functions he says:—"They and the follicles of the intestine in general appear to me to be closed glandular organs, analogous to the splenic follicles, the tonsils, and the lymphatic glands, which contain peculiar elements and a vascular network. In these a constant development of cells takes place, and at the same time substances are elaborated from the plasma, supplied by the bloodvessels, and perhaps also from matters not of a fatty nature, absorbed from the intestine, a part of which in all probability is at once taken up by the internal bloodvessels, while the larger proportion is excreted, and absorbed by the lymphatics."

The structure of the mucous membrane of the large intestines agrees so closely with that of the small intestines, that it need not be described separately. With the exception of the rectum it has no proper folds, for the transversely fibrous muscular layer also enters into the plicæ sigmoideæ. The villi are absent from the edge of the ileocœcal valve. The glandular organs are Lieberkühn's glands and solitary follicles. The latter are arranged close together in the processus vermicularis, and are very frequent in the rectum and cœcum, and are also usually more abundant in the colon than in the small intestines. [DIGESTION; FOOD; STOMACH; BILE; LIVER.]

INTESTINES, SMALL. [INTESTINES.]

INTRICA'RIA, a small Polypifer from the Oolitic rocks of France, allied to *Cellaria*.

INULA, a genus of Plants belonging to the natural order *Compositæ* and the sub-order *Asteraceæ*. It has a many-flowered heterogamous head. Florets of the ray female in one row, sometimes by abortion sterile, usually ligulate, sometimes somewhat tubular and trifid; those of the disc hemaphrodite, tubular, 5-toothed; involucre imbricated in several rows; receptacle flat or somewhat convex, naked; anthers with 2 setæ at the base; achenium without a beak, tapering, or in *I. Helenium* 4-cornered; pappus uniform in one row, composed of capillary roughish setæ.

I. Helenium, Elecampano, is found in pastures in various parts of Europe. It is a native of Great Britain. It has a thick branching root, which is aromatic, bitter, and mucilaginous. The stem is 3 feet high, leafy, round, furrowed, solid, branched, and most downy in the upper part. The leaves are large, ovate, serrated, and veiny; downy and hoary at the back, radical, 1-stalked; the rest sessile, clasping the stem. Flower-heads solitary at the downy summits of the branches, 2 inches broad, of a bright yellow colour; the scales of the involucre broad, recurved, leafy, finely downy on both sides; rays very numerous, long, and narrow, each terminating in three unequal teeth; achenia quadrangular, smooth; pappus roughish; receptacle reticulated, not quite smooth or naked. Various preparations of the boiled root have been recommended mixed with sugar to promote expectoration and to strengthen the stomach. Some think a spirituous extract contains most of its aromatic and tonic properties. The plant is generally contained in rustic gardens on account of its many reputed virtues. *Inulin*, the peculiar property contained in the root, is a white powder, like starch, is insoluble in cold, and soluble in hot water, from which it is deposited on cooling; and this distinguishes it from starch. With iodine it gives a greenish-yellow compound, which is not permanent. Inulin is distinguished from gum by its insolubility in cold water, and by not giving saccholactic acid when digested in nitric acid.

I. Conyza has the leaflets of the involucre all linear. Leaves ovate-lanceolate, downy, denticulate; lower leaves narrowed into a footstalk; florets of the ray subligulate; fruit terete. It is the *Conyza squarrosa* of Smith. The stem is from one to two feet high, leafy; heads corymbose. The flowers yellow, those of the circumference between tubular and ligulate, deeply divided on the inner side. It is found on calcareous soils in Great Britain, and is known by the name of Ploughman's Spikenard.

I. crithmoides has the leaflets of the involucre linear, taper pointed; leaves fleshy, linear, obtuse, or with three points. The stem about a foot high, slightly branched near the top, each branch terminating in a solitary head with an orange-coloured disc and yellow rays. It is found on rocks and in muddy salt marshes by the sea. It is called Golden Sampline.

INULIN. [INULA.]

INUUS, a genus of Monkeys. [QUADRUMANA.]

INVOLU'CRUM, in Botany, is any collection of bracts round a cluster of flowers. In umbelliferous plants it consists of separate narrow bracts placed in a single whorl; in many composite plants these organs are imbricated in several rows. If the bracts belong to a secondary series of the inflorescence, as in the partial umbels of an apiaceous plant, or in the solitary florets of *Echinops*, they form an involucel. The most singular state of the involucrum is that which is found in the genera *Castanea*, *Fagus*, *Quercus*, &c., where it forms a cup, or closed cover, remarkable in the European species of those genera, but much more so in the species of India.

IOLITE, a Mineral, also called *Dichroite* and *Cordierite*. It belongs to the group of anhydrous silicates of alumina. It crystallises in rhombic and hexagonal prisms, and usually occurs in 6- or 12-sided prisms, or disseminated in masses without distinct form. The cleavage is indistinct; but the crystals are often separable into layers parallel to the base. The colour is of various shades of blue—often deep blue in the direction of the axis, and yellowish-gray transversely. The streak is uncoloured. Lustre and appearance much like that of glass. Transparent to translucent. It is brittle, and has a hardness of 7 to 7·5. Its specific gravity is 2·6 to 2·7. A specimen from Connecticut, United States, had the following composition:—

Silica	48·3
Alumina	32·5
Magnesia	10·0
Protoxide of Iron	6·0
Protoxide of Manganese	0·1
Water	3·1
	——100

Before the blow-pipe it fuses with difficulty to a blue glass resembling the mineral. It is distinguished by this property from blue quartz, for which alone it could be mistaken.

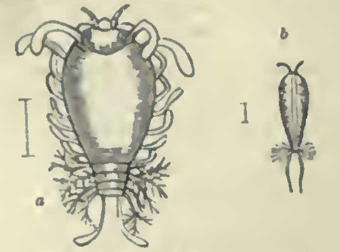
Iolite is found at Bodenmais in Bavaria, Arendal in Norway, Cabo de Gata in Spain, Tunaberg in Finland, also in Greenland, Ceylon, and the United States. It is occasionally employed as an ornamental stone, and when cut it presents different shades of colour, hence one of its names, Dichroite (δίχροια). Iolite refers to its violet colour (ἴδεις).

When Iolite is exposed to the air and moisture it undergoes a gradual alteration. It absorbs water, and becomes converted into a hydrate. It then assumes a foliated micaceous structure resembling talc. Hydrous *Iolite*, *Chlorophyllite*, and *Esmarkite* are names that have been given to altered Iolite, and *Fahlunite* and *Gigantholite* have probably the same origin.

(Dana, *Mineralogy*.)

IONE, or, as it is sometimes written, JONE, a parasitic genus of Crustaceans, placed by Desmarest under the *Isopoda*, but by Latreille, who established the sub-genus, under the *Amphipoda*. The latter founded his separation on the figure given by Montagu under the denomination of *Oniscus thoracicus* ('Linn. Trans.,' ix. iii. 3, 4); and observes that it presents particular characters which place it at a distance from all the other forms of the order. The body is composed of about fifteen joints, which are only to be distinguished by lateral incisions in the form of teeth. The four antennæ are very short: the external ones, longer than the two others, are only visible when the animal is seen on the back. The first two segments of the body in the female are each provided with two elongated fleshy flattened oar-like cirrhi. The feet are short, hidden under the body, and hooked. The last six segments are furnished with lateral fleshy elongated fasciculated appendages, which are simple in the males, but in the form of oars in the other sex. At the posterior extremity of the body are six other appendages, which are simple and curved, two of them being longer than the others. The abdominal valves are very large, cover all the lower part of the body, and form a species of receptacle for the eggs.

This parasite hides itself under the shell of *Callianassa subterranea* [CALLIANASSA], and there forms a tumor on one of its sides. Montagu extracted it, and kept it alive for some days. The females are always accompanied by their males, which are very inferior in size, and fix themselves firmly upon the abdominal appendages of the former by means of their claws. Latreille, whose account we have given, speaks of it as rare, and remarks that in its habits it approaches to *Bopyrus*. [ISOPODA.] (Montagu, 'Linn. Trans.')



Ione thoracica. *a*, female; *b*, male.

IONIDIUM, a genus of Plants belonging to the natural order *Violaceæ*. It has 5 sepals not prolonged at the base; corolla unequal, 2-lipped, consisting of 5 petals, the lowest of which is very large and unguiculate; stamens 5, hypogynous, unequal, the two anterior having anthers that are often appendiculate; capsule protected by the permanent sepals; petals and stamens few, or many-seeded. The species are herbaceous plants or shrubs.

I. Ipecacuanha is a native of the forests of Brazil. It has alternate lanceolate ovate leaves, serrated, acute at each end; stipules ovate-lanceolate, acute, membranous, ribbed in the middle; sepals semi-pinnatifid; lower petal very large, transversely elliptical. The roots are emetic, and are often collected as a substitute for the true Ipecacuanha.

I. Poaya is found in fields in the western parts of Minas Geraës, and elsewhere in Brazil. It is a very shaggy plant. The stem suffruticose, usually simple; leaves alternate, subsessile, ovate, somewhat cordate at the base, rather acute, obsoletely toothed; stipules linear, scarious, quite entire, hardly perceptible; lower petal very large, broadly obcordate; filaments bearded on the outside at the apex; membranous process of the anthers very small. Roots emetic, and like the last species substituted for true Ipecacuanha.

I. microphyllum is found at Quito near the foot of Chimborazo. The stems are somewhat quadrangular, smooth on the angles, downy on the sides, filiform, erect, apparently not above one foot high, if so much. The leaves are all opposite, ovate, wedge-shaped, and entire at the base, with two or three coarse serratures on each side towards the point, covered sparingly on each side with short fine down; the stipules are membranous, linear-ovate, acuminate, longer than the very short petioles; flowers small, axillary, solitary, and erect; peduncles filiform, slightly downy, twice as long as the leaves; sepals ovate-acute, with a little fine down along the middle of the back; lip panduriform, that is, unguiculate, roundish, emarginate, with the claw almost rhomboidal from the projection of its sides at opposite points. It is stated to be a specific in Elephantiasis tuberculata, the 'Mal de San Lazaro' of the Spanish Americans, and 'Cocobay' of Jamaica. Dr. Bancroft speaks most favourably of its effects in this disease. It is known by the name of 'Cuchunchully' in its native country. There is some difference of opinion as to the exact species which furnishes this preparation.

I. parviflorum has roots extremely like Ipecacuanha in appearance and properties.

I. brevicaule is a Brazilian plant. It is emetic, and a powder of the root rubbed up with sugar and milk furnishes an agreeably sweet medicine.

I. urticæfolium is also an emetic of the same country.

IÖRA, or JORA, a genus of Birds established by Dr. Horsfield, and placed by Mr. Swainson among his *Brachypodinæ*, or Short-Legged Thrushes. [MERULIDÆ.]

IPECACUANHA. [CEPHAELIS.]

IPHÆROCERA. [BORBORUS.]

IPOMÆA, a genus of Plants of the natural family of *Convolvulaceæ*, which is very closely allied to *Convolvulus*, or Bindweed, whence has been derived its name. From the more minute investigations of modern botanists considerable changes have taken place in the nomenclature of the species sometimes referred to this genus and sometimes to other nearly allied genera. M. Choisy, who has most recently examined the Oriental *Convolvulaceæ*, excludes many species usually referred here, and forms the genus of the species of *Ipomæa* and *Convolvulus* of authors. *Ipomæa* has a 5-sepaled calyx, a campanulate corolla, with five stamens included within it; style single; stigma bilobed; lobes capitate; ovary 2-celled; cells 2-seeded; capsule 2-celled. The species are very numerous, and found in the tropical parts of Asia, Africa, and America. A few ascend the mountains in such latitudes.

Most of the species are ornamental; others have been removed to *Quamoclit*, *Argyreia*, *Pharbitis*, &c., and one of the most useful as an article of diet in tropical countries, to *Batatas*. *B. edulis* produces the tubers so well known by the name of Sweet Potatoes. [BATATAS.]

I. Turpethum is found in the East Indies, Malayan Archipelago, Australia, Timor, Otaheite, Friendly Islands, Marianne Islands, Tinian, &c. Its root is perennial. The stems twining, several fathoms long, from 3- to 4-sided, a little downy, with winged angles; leaves stalked, varying in form from cordate to linear, all pointed and lobed, or angular and downy; peduncles axillary, downy, many-flowered; flowers large and white; bracts oval, concave, velvety, deciduous; ovary seated on a large glandular disc; stigma 2-lobed; capsules involved in the dry calyx, absolutely 4-sided, 2-celled, opening at the apex by a kind of operculum; seeds round, black, one in each cell. The root has been long employed in India as a common purgative. The bark of the roots is the part employed by the natives, as it contains all the active properties; they use it fresh, rubbed up with milk. About six iuches in length of a root as thick as the littlo finger they reckon a common dose. (Roxb.) It is reckoned an excellent substitute for jalap, and is free from the nauseous taste aud smell of that drug. The plant is a native of all parts of coutinental and probably of insular India also, as it is said to be found in the Society and Friendly Isles and the New Hebrides.

I. macrorhiza is supposed to be the *Convolvulus Jalapa* of Linnæus. It is a plant inhabiting the sandy soil of Georgia and the Carolinas, with white insipid farinaceous roots, weighing from 40 to 50 lbs. It is said to possess no purgative properties, but, liko *Batatas*, consists chiefly of saccharine and farinaceous matter.

I. pandurata is common in North America, in sandy fields and by fences, from Canada to Florida. It is the Mechameck of the Indians. It has a very large root, 2 or 3 feet long and as thick as the arm, of a yellow-ochre colour. The stem is downy; leaves on long stalks, broadly cordate, entire, acuminate, slightly repand; peduncles many flowered, cymose longer than the petioles; corolla large, campanulate, white, dull purple towards tho base; stamens white, the length of the tube. The powdered root acts like rhuburb; it requires to be giveu iu larger doses than jalap. It has an American reputation as a remedy for calculous affections, and in cases of gravel.

I. Purga (*I. Jalapa* of Nuttall) is found on the eastern declivity of the Mexican Andes near Chiconquiaco, and near San Salvador on the eastern face of the Côfre de Perote, at an elevation of about 6000 feet above the sea; and on the mountains near Orizaba. It has a tuberons fleshy root, with numerous roundish tubercles. Stem smooth, brownish, very slightly rough; leaves stalked, the first hastate, the succeeding ones cordate, acuminate, mucronate, smooth; peduncles axillary, 2-flowered, twisted, the length of the corolla;

Ipomœa Purga.

sepals obtuso, mucronate, smooth; corolla purple, with a long somewhat clavato tube, and an undulated limb with 5 plaits; filaments smooth, unequal, longer than the tube of the corolla; anthers linear, projecting; stigma capitate, deeply furrowed; capsule 2-celled; cells 2-seeded. It has long been employed as a modicinal agent, and

is considered by the traders in jalap to be extremely similar in quality to the true plant; and as it is the more abundant and larger of the two, at least in some districts, the probability is that it also forms a part of the imported samples of this drug.

I. Orizabensis is native of the temperate parts of the state of Oaxaca. It has a tuberous fleshy root, with numerous oblong tubercles; stem twining, green and hairy; leaves cordate, acumiuate, mucronate, hairy, the earliest oues hastate; peduncles 2-3-flowered, twisted, three times as long as the corolla; sepals oblong-obtuse, mucronate, hairy; corolla purple, campanulate, with a regular tube inflated in the middle, and a wavy limb with 5 plaits; stamens shorter than the tube, hairy at the base; capsule 2-celled; cells 2-seeded. Tho Spanish name of this plaut is Jalapa Macho.

I. tuberosa is found in Jamaica, where it is called Seven-Eared or Spanish Arbour-Vine. The root is tuberous, as large as a man's head; stems 200 or 300 feet long, purplish at the extremities; leaves smooth, downy beneath, palmate, or 7-lobed; the lobes much smaller at the side than in the middle, narrow, lanceolate, acuminate; peduncles many-flowered; flowers pale yellow, sweet scented; capsule as large as a waluut, membranous, shining, brown, 2-celled, with two black or dark-brown shaggy triaugular seeds in each cell. All the parts are purgative. Dr. Barham thinks scammony might be obtained from it.

I. cathartica is fonnd in moist places iu St. Domingo. The stems are twining, smooth, and herbaceous; leaves large, distinct, long-stalked, broad, oval, cordate, smooth, and 3-lobed; the two lateral lobes oval, shorter, acute; the terminal oval lanceolate, acuminate; peduncles axillary, usually 1-flowered; flowers large, deep bright-red; tube of the corolla thick, inflated, contracted and cylindrical at the base, an inch and more long, pale green; the limb broad, 5-lobed; stamens shorter than the corolla; stigma capitate. The roots furnish a resinous substance used as a purgative in St. Domingo. Its use is not however very safe, as it is apt to produce excessive purgation.

(Lindley, *Flora Medica;* Royle, *Materia Medica.*)

IPS, a genus of Insects belonging to the order *Coleoptera*, to the section *Pentamera*, aud the family *Empidæ*. The body is of an oblong-oval form and depressed, with the third joint of the antennæ longer than the second, and the club large aud rounded. The species are generally found under the bark of decayed trees. They are chiefly confined to Europe. The British species, of which there are four or five, are rare.

IRIDA'CEÆ, *Irids*, a natural order of Endogenous Plants, usually with equitant leaves, and a rhizoma or cormus for their stem, but

Leaves and flowers of *Sisyrinchium striatum*. 1, the stamens; 2, the ripe fruit.

more particularly characterised by having three stamens, the anthers of which are turned outwards, and an inferior ovary. The genera are numerous, and some not well defined; they inhabit the temperate parts of the world in preference to the hottest, where they are comparatively rare. The *Iris* and *Crocus* are representatives of the predominant northern form of the order, as *Gladiolus* and *Ixia* are of the genera prevalent in the southern hemisphere. All the species are sufficiently ornamental to deserve cultivation, and many are of striking beauty. They are principally natives of the Cape of Good Hope, or of the middle parts of North America and Europe. A few only are found within the tropics. Acrid, purgative, and emetic properties are met with in some plants of this order. Some are fragrant and aromatic, others supply starch and materials for dyeing. The position of the order is between *Hæmodoraceæ* and *Amaryllidaceæ*. It has 53 genera and 550 species. [IRIS.]

IRIDEA. [ALGÆ.]

IRIDINA. [CONCHACEA.]

IRIDIUM. [PLATINUM.]

IRIDOSMINE. This name is given to a compound of the metals Iridium and Osmium, found in the platinum mines of Russia, South America, and the East Indies. The crystals are hexagonal prisms of a pale steel-gray. It occurs in flat grains. Their composition varies. One variety contains rhodium. They are distinguished by the odour of osmium.

IRIS. [EYE.]

IRIS, a genus of Plants, the type of the natural order *Iridaceæ*. It has a tubular perianth with a petaloid membranous limb, the segments of the sepals revolute, often bearded, those of the petals erect and converging; 3 stamens, concealed beneath the lobes of the style; the style 3-parted near the upper end with petaloid segments overarching the anthers, and bearing a 2-lipped transverse stigma below their ends; the capsule 3-celled, bursting through the cells into three valves, coriaceous, with numerous flat or round and fleshy seeds.

I. versicolor, Blue Flag, has sword-shaped striated leaves, sheathing at the base, a stem 2 or 3 feet high, round on one side and acute on the other, and bearing from 2 to 6 flowers. This plant is a native of swamps and wet meadows in the United States. The rootstock has a nauseous acrid taste. It acts as a cathartic, and its action is attended with great depression of the nervous system and prostration of strength. It also acts upon the kidneys, and is useful in cases where diuretics are indicated.

I. pseud-acorus, Yellow Flag, has sword-shaped leaves; the stem round; perianth beardless, its inner segments narrower and shorter than the stigmas. It is a native of wet places in Great Britain, France, Germany, and most countries of Europe. The rootstock is acrid, and possesses an emetic and purgative action. The seeds when roasted are said to form a good substitute for coffee.

I. Florentina, Florentine Iris, has broad and somewhat falcate leaves, shorter than the stem, the petals two inches long and one inch broad, reflexed at the edge and rather plaited towards the base. The dried rootstock is known in the shops under the name of orris-root. The plant is a native of the southern parts of Europe and the islands of the Mediterranean. The rootstock has an aromatic odour and subacrid taste, and is employed as a dentifrice. It enters into the composition of Ruspini's tincture and tooth-powder, and other popular dentifrices. It was at one time used in medicine and admitted into the British pharmacopœias. The fresh rootstock acts as a purgative, and was also employed as an expectorant in diseases of the chest. When dried and turned into small balls it is used for issue-peas. According to Sibthorp this plant is found in Greece at the present day. It is the Ἶρις of Hippocrates ('Morb. Mul.,' 2, 673) and the Ἶρις ἰλλυρική of Theophrastus ('Hist. Plant.,' 7, 12).

I. fœtidissima, Stinking Flag, has sword-shaped leaves, the stem compressed, the perianth beardless, its inner segments about as long as the stigmas. This plant is a native of Great Britain and other parts of Europe. It has a peculiar smell, which some have compared to roast beef, but which to others suggests much less pleasant associations. It is the Ἶρις ἀγρία of Theophrastus ('Hist. Plant.,' 9, 8) and Ξυρὶς of Dioscorides (4, 12).

I. tuberosa has tetragonal leaves, the segments of the perianth acute, the roots tuberose. It is not a common plant in Europe, but has been naturalised at Penzance in Cornwall, and near Cork in Ireland.

Many other species of *Iris* have been described. *I. Germanica* has been used for the same purposes as *I. Florentina*, and they are considered by some botanists as identical. The roots of many of them contain starch, and Pallas says that the roots of *I. dichotoma* are eaten in Siberia. *I. edulis* is eaten by the Hottentots of Africa, where it is called Oenkjes. All these species are cultivated in gardens on account of handsome showy flowers.

(Fraas, *Synopsis Floræ Classicæ*; Lindley, *Flora Medica*; Sibthorp, *Flora Græca*; Babington, *Manual of British Botany*; Burnett, *Outlines of Botany*.)

IRON. Of all the metals iron is the most widely diffused, the most abundant, and the most useful. It is found not only intermixed with soils, and contained in rocks and minerals, but it is found in animal and vegetable bodies, and also in mineral waters.

Iron occurs rarely, if indeed at all, in nature in the metallic state, for almost the whole of it that has been found occurs as meteoric iron containing nickel, or in meteoric stones. It has however been stated that it has been discovered in situ near Canaan in the United States; it there occurs in a vein two inches thick in chlorite schist, filled with native iron. It appears that this iron is traversed by graphite. Its specific gravity is 5·95 to 6·71. The Uralian Mountains yield a kind of native iron which is accompanied with platinum.

The greatest quantity of iron is found either combined with oxygen, oxygen and carbonic acid, or with sulphur; the last mentioned is not however worked as an ore. The best iron-ores are oxides, which occur in primitive countries, where they generally form very large beds, such as those of Sweden; but the greater part of the iron-ore of Britain is an impure carbonate.

The properties of iron are, that it is grayish-white with a tint of blue; it is extremely ductile, so that it may be drawn into wire finer than the human hair, but it cannot be beaten into very thin leaves. It is of all metals the most tenacious, for a wire 0·787 of a line in diameter is capable of supporting a weight of about 550 lbs.

Iron is susceptible of a high polish. It is combustible when minutely divided, as in the state of filings, which is shown by sprinkling them in the flame of a spirit lamp. It is very hard at common temperatures, and this property may be increased by its being heated and then suddenly cooled; it then however becomes brittle. It requires a most intense heat to melt it, but when heated to redness it becomes soft and pliable, and possesses the valuable property of 'welding,' that is, two pieces of red-hot iron may be made to unite by hammering. Its texture is fibrous. Its specific gravity is about 7·77, but this varies in some degree according to the extent to which it has been drawn, rolled, or hammered, and it is increased by fusion. Iron, or rather steel, is capable of being rendered permanently magnetic, a property which no other metal possesses but nickel: when heated to redness this property is lost, and a loadstone suffers the same loss just below visible ignition; while a steel magnet loses its polarity when subjected to the temperature of boiling almond-oil. Iron has great affinity for oxygen and sulphur, and some other elementary bodies, and combines with them in various proportions.

Meteoric Iron.—There have been found in different parts of the earth large masses of native or metallic iron, of the history and origin of which nothing very accurate is known; but they are regarded as being of meteoric origin, for it is invariably found that, like the iron which occurs in meteoric stones, this metallic iron contains nickel, and no such compound or mixture is found in the earth in veins or beds; and in point of fact two masses of such iron were seen to fall at Hradschina, near Agram in Croatia, in 1751. They contained 3·5 per cent. of nickel. Similar masses have been found in Africa, America, and Siberia. That in the last-mentioned part of the world was discovered by Professor Pallas: it weighed 1600 lbs., had a cellular structure, and contained crystals and grains of a green substance of a vitreous appearance, which have been stated to be *Olivine* or *Chrysolite*. This iron contains only 1·5 per cent. of nickel. One of the largest masses is that found in Peru by Don Rubin de Celis; it weighed 15 tons, and contained nickel. This was also the case with the knives which Captain Parry obtained from the Esquimaux. The largest quantity of nickel contained in any specimen was about 10 per cent.

Meteoric Iron sometimes occurs crystallised; the primary form is the cube, and it is stated to have been found in regular octohedrons. It has no apparent cleavage. Fracture hackly. Hardness 4·5. Specific gravity 6·48 to 7·768. Opaque. Lustre metallic. Colour pale steel-gray.

Oxides of Iron.—The protoxide of iron does not occur in nature except in combination, and usually with carbonic acid; in this form it is found in mineral waters. The ore which most nearly approaches it is Magnetic Iron, sometimes called Oxydulous Iron and Octohedral Iron. This ore is found crystalline, massive, and arenaceous. The crystals occur attached and imbedded. The primary form is a cube, but it is generally met with in the form of the regular octohedron. Cleavage parallel to the planes of the octohedron, but not obtainable in some varieties. Fracture uneven or conchoidal. Hardness 5·5 to 6·5. Scratches fluor-spar, and is scratched by quartz. Specific gravity variously stated from 4·4 to 5·094. Opaque. Lustre metallic, occasionally bright. Colour iron- or steel-gray. Streak black. Obeys the magnet.

The massive varieties are amorphous; structure granular to compact. It is of this variety of iron-ore that native loadstones consist. This ore occurs in various parts of the world, especially in the north of Europe, and it is of it that the best Swedish iron is made, and so also is the iron which yields the wootz steel of the East Indies. It is generally found in primitive countries. This ore frequently contains titanium; but the varieties have not been well distinguished. By the blow-pipe it becomes brown, and loses its magnetic property, but does not fuse.

It consists of 28·4 of oxygen and 71·6 of iron, which are equal to—

Two equivalents of Sesquioxide of Iron . .	80
One equivalent of Protoxide of Iron . . .	36

There are several ores, which possess very different appearances, that are altogether composed of the sesquioxide or peroxide of iron, and which are principally the *Oligiste Iron Ore* and the *Hematite*.

Oligiste Iron; Specular or *Micaceous Iron.*—This occurs crystallised and massive. The crystals are attached; the primary form is a rhomboid. Cleavage parallel to the primary planes, and perpendicular to the axis in some varieties. Fracture uneven, conchoidal. Hardness 5·5 to 6·5; scratches phosphate of lime; is scratched by quartz. Specific gravity 5·0 to 5·25. Lustre metallic. Colour steel- and iron-gray; the surface frequently iridescent. Obeys the magnet slightly. Streak red and reddish-brown. It is found in the island of Elba and in many other parts of Europe. It also occurs in the lava of Auvergne in France, and in that of Vesuvius.

Göthite, Pyrosiderite occurs in very thin transparent crystalline plates in the cavities of black Hematite. Colour brownish-red, by reflection yellowish, in a strong light of a brilliant red. Lustre adamantine. It occurs in England and in Germany. The former yielded by analysis—

Peroxide of Iron	89·2
Water	10·8
	—100

Iron Froth consists of very thin brownish-red scaly particles, which have a greasy feel, and stain the fingers. It is found plentifully in Devonshire and Lancashire, and was ascertained by Dr. Henry to be pure Peroxide of Iron. The massive varieties are amorphous; structure foliated.

Red Hematite occurs in globular and botryoidal masses. Structure fibrous, radiating, opaque. Specific gravity 4·7 to 5. Lustre externally sometimes metallic, sometimes dull; internally, nearly dull. Colour externally red; grayish-red, &c., internally, and streak red. It occurs in large quantity at Ulverstone in Lancashire, and in other parts of Great Britain and Europe. According to D'Aubuisson it consists of—

Peroxide of Iron	94
Silica	2
Lime	1
Water	3
	—100

Brown Hematite; Hydrous Oxide of Iron; Brown Iron Ore, occurs in attached crystals and massive prisms. Primary form a right rhombic prism. Cleavage parallel to the short diagonal; fracture uncertain. Hardness 5·0 to 5·5. Specific gravity 3·93. Lustre adamantine; nearly opaque; translucent. Colour brown of various shades. Streak yellowish-brown. Occurs in Cornwall.

Massive varieties globular, reniform, and some of the varieties of brown and yellow clay iron-stone. Stalactitic, structure fibrous, or fibro-laminar. Sometimes occurs in pseudomorphous crystals. It occurs in most parts of the world Analysis by D'Aubuisson:—

	Fibrous.	Compact.
Peroxide of Iron	82	84
Water	14	1
Oxide of Manganese	2	2
Silica	1	2
	—99	—89

Franklinite is a mixture of the peroxide with oxide of zinc. [FRANKLINITE.] *Ilmenite* contains iron and titanium. [TITANIUM.]

Carbonate of Iron; Brown Spar; Spathose Iron Ore.—This occurs in attached crystals and massive. Primary form a rhomboid. Cleavage parallel to the primary planes, distinct. Fracture imperfect conchoidal. Hardness 3·5 to 4·5. Specific gravity 3·6 to 3·829. Transparent, translucent, opaque; lustre vitreous, inclining to pearly; colour white, yellow, red, and brown of different shades.

Massive varieties tabular, structure fibrous; botryoidal and globular (these being called *Sphærosiderite*), structure fibrous, diverging; amorphous, structure foliated, granular, compact. Found in Cornwall, Scotland, and Ireland, and in other parts of Europe; and also in America.

Before the blow-pipe it blackens and becomes magnetic, but does not fuse; in the reducing flame it colours borax bottle-green, and in the oxidating yellow; dissolves in acids with effervescence. Analysis, by Beudant, of the hexahedral variety:—

Carbonic Acid	38·72
Protoxide of Iron	59·97
Oxide of Manganese	0·39
Lime	0·92
	—100

Clay Iron-Stone, or *Argillaceous Iron-Ore*, consists essentially of carbonate of iron mixed with various proportions of earthy matter; on an average carbonate of iron forms about one-third of the abundant clay iron-stone of England, Wales, and Scotland. It occurs in beds and in coal deposits; it is found sometimes in globular masses, and also columnar.

Thomaite is a carbonate of iron from the Siebengebirge. *Junkerite* is common spathic iron. *Mesitine Spar* is a carbonate of iron and manganese; so also is *Oligon Spar*.

Sulphur and *Iron* exist in combination in enormous quantities; the compounds which it forms are called *Magnetic Iron Pyrites, Iron Pyrites*, and *White Iron Pyrites*.

Magnetic Iron Pyrites, Protosulphuret of Iron, occurs in imbedded hexagonal crystals and massive. Primary form a rhomboid. Cleavage parallel to all the planes, of a regular hexagonal prism; fracture uneven, sometimes conchoidal. Hardness 3·5 to 4·5; scratches calcareous spar, and is scratched by felspar. Specific gravity 4·63. Opaque; lustre metallic; colour bronze yellow mixed with red; streak grayish black. Obeys the magnet but feebly. Soluble in dilute sulphuric acid; when exposed to the blow-pipe on charcoal is converted into oxide of iron. Occurs at Kongsberg in Norway and Andreasberg in the Harz. Analysis by Hatchett:—

Sulphur	36·5
Iron	63·5
	—100

Massive varieties amorphous, structure foliated, granular, compact. Found in Cornwall, Wales, Germany, North America, &c.

Iron Pyrites; Martial Pyrites; Persulphuret, or *Bisulphuret of Iron*, occurs in attached and imbedded crystals, and massive. Primary form a cube. Cleavage parallel to the primary planes, distinct. less so parallel to the planes of the octohedron. Fracture uneven, sometimes conchoidal. Hardness 6·0 to 6·5; scratches felspar, and is scratched by quartz. Colour brass-yellow; streak brownish-black; lustre metallic opaque.

Massive varieties amorphous, structure granular, compact; globular and stalactitic, structure fibrous or columnar, radiating; surface frequently reddish brown, owing to the loss of sulphur and acquisition of oxygen. It sometimes contains gold; the pyrites of Anglesey, Sweden, and Bohemia contains selenium.

By the blow-pipe sulphur is expelled, and magnetic oxide of iron remains. It is scarcely acted upon by dilute sulphuric acid, but nitric acid dissolves iron and deposits sulphur. Analysis by Hatchett:—

Sulphur	52·15
Iron	47·85
	—100

Iron pyrites occurs abundantly in every part of the world. It is frequently found in the form of various fruits. The amorphous occurs sometimes to a great extent in coal-beds. Very large crystals occur in Cornwall and South America. The massive varieties in general more readily become oxidised and converted into sulphate of iron than the crystallised, and hence it is largely employed in preparing copperas. The sulphurets are not used for obtaining iron on account of the difficulty of separating the sulphur. The bisulphuret is principally used for procuring sulphate of iron, sulphuric acid, and sulphur. It is also used in preparing alum.

White Iron Pyrites occurs in attached crystals and massive. Primary form a right rhombic prism. Cleavage parallel to the planes of the primary form. Fracture uneven, granular. Hardness 6·0 to 6·5; scratches felspar, is scratched by quartz. Colour various shades of yellowish, greenish, and grayish-white; streak grayish-black; opaque; lustre metallic.

Massive varieties botryoidal, reniform, stalactitic, and amorphous. Structure diverging, fibrous, or columnar. It is found in Cornwall, Derbyshire, Bohemia, and various other mining districts. According to Berzelius it consists of—

Sulphur	53·35
Iron	45·07
Manganese	0·70
Silica	0·80
	—99·92

Arsenical Iron Pyrites, or *Mispickel*, consists of a mixture of iron, arsenic, and sulphur. It occurs in rhombic prisms, with cleavage parallel to the faces. The colour is silver-white; streak dark grayish-black; lustre shining. A cobaltic variety contains 4 to 9 per cent. of cobalt in place of a part of the iron. Mispickel is found mostly amongst primitive rocks, and is commonly associated with ores of lead, silver, iron, or copper. It is abundant at Freiburg and Munzig, on the continent of Europe, and in Cornwall in England. It is also found in the United States in many places. *Leucopyrite* is an arsenical iron without sulphur, found in Styria, Silesia, Carinthia, and the United States.

Chromate of Iron is a compound of chromic acid, protoxide of iron, and alumina and magnesia. [CHROMIUM.] It occurs usually in serpentine rocks, in imbedded masses or veins.

Columbite is a native columbate of the oxide of iron. [COLUMBITE.]

Wolfram is a combination of iron, tungsten, and manganese. [TUNGSTEN.]

Green Copperas, or *Green Vitriol*, is a sulphate of iron. It crystallises in the form of acute oblique rhombic prisms, but generally occurs pulverulent or massive. The colour is greenish to white; lustre vitreous. Taste astringent, sweetish, and metallic. It is brittle, and has a hardness of 2. The specific gravity is 1·83. It becomes magnetic before the blow-pipe. It yields a green glass when fused, and gives a black colour with gallic acid. By exposure it becomes covered with a yellowish powder, which is a persalt of iron. Green vitriol occurs as the result of the decomposition of iron pyrites. The old mine of Rammelsberg in the Harz near Goslar is its most noted locality, but it is found wherever pyrites is exposed to the air.

Coquimbite, or *White Copperas*, and *Yellow Copperas*, are names of two sulphates of the peroxide of iron. *Pittzite* and *Fibro-ferrite* are allied compounds. *Apatelite* is another containing but 4 per cent. of water.

Voltaite is a double sulphate of iron, alumina, potash, and water, crystallising like alum in octahedrons. It occurs at the Salfatara near Naples.

Phosphate of Iron—Vivianite. It occurs in modified oblique prisms, with cleavage in one direction highly perfect. It is also found radiated, reniform, and globular, or as coatings. The colour is deep blue to green. The crystals are usually green at right angles with the vertical axis, and blue parallel to it. The streak is bluish; lustre pearly to vitreous; transparent to translucent; opaque on exposure. The thin laminæ are flexible. It has a hardness 1·5 to 2; and a specific gravity of 2·66. It has the following composition:—

Protoxide of Iron	42·4
Phosphoric Acid	28·7
Water	28·9
	——100

It loses its colour before the blow-pipe, dissolves in nitric acid, and affords water in a glass tube. It is found with iron, copper, and tin ores, and sometimes in clay or with bog iron-ore, at St. Agnes in Cornwall, Bodenmais, the gold mines of Vöröspatak in Transylvania, and in the United States.

Blue Iron-Earth is an earthy variety. It contains 30 per cent. of phosphoric acid. *Anglarite* is a variety from Anglar in France.

Triphyline is an anhydrous phosphate of iron and manganese, with some lithia. It occurs at Bodenmais in Bayern in cleavable masses of a greenish gray or bluish colour.

Cacoxene is a handsome mineral. It is a phosphate of iron and alumina, and occurs in radiated silky tufts of a yellow or yellowish-brown colour. It is found on brown iron-ore in Bohemia, and with specular iron in the United States.

Carphosiderite is another yellow phosphate of iron from Greenland. It occurs in reniform masses.

Green Iron-Stone (*Kraurite*), *Alluandite*, *Melanchlor*, and *Beraunite* are names of phosphates of the peroxide of iron.

Oxalate of Iron occurs native. It is a soft yellow earthy mineral of rare occurrence. It blackens instantly in the flame of a candle. It is found in Bohemia, and is supposed to have resulted from the decomposition of those orders of such plants, such as *Cactaceæ*, which naturally contain oxalic acid.

Silicates of Iron.—There are several compounds of silica and oxide of iron, none of which are of special interest in an economical point of view.

Hedenbergite is a variety of Augite. [AUGITE.]

Iron Chrysolite differs from ordinary chrysolite in containing oxide of iron in place of magnesia.

Isopyre is a black glassy amorphous mineral found in granite. [ISOPYRE.] Its hardness is 6 to 6·5.

Yenite (called also *Lievrite* and *Ilvaite*) occurs in rhombic prisms, often with the sides much striated or fluted; its colour is black or brownish-black, streaked with greenish or brownish-black. Its hardness is 5·5 to 6. Its specific gravity, 3·8 to 4·1. It contains from 50 to 55 per cent. of oxide of iron, with 14 per cent. of lime, and 29 per cent. of silica. It fuses to a black globule. It is found in the island of Elba in large crystallisations, also in Norway, Siberia, and Silesia.

At Cumberland, in Rhode Island, *Yenite* occurs in slender black or brownish-black crystals in quartz; also in Essex county, New York.

The following are hydrous species, giving off water when heated in a tube before the blowpipe:—

Nontronite and *Pinguite* are earthy, almost like clay, of a yellowish or greenish colour.

Chloropal is a much harder species, of a greenish-yellow or pistachio-green coolour.

Grengesite, *Thuringite*, *Knebelite*, and *Kirwanite* are other allied species.

Green Earth includes different compounds of a green earthy appearance. The Green Earth occupying cavities in amygdaloid is near chlorite. It is a silicate of the peroxide of iron, with some potash, magnesia, and water; often with other ingredients.

The *Green Grains* of the *Greensand* of New Jersey consist of—

Silica	51·5
Alumina	6·4
Protoxide of Iron	24·3
Potash	9·96
Water	7·7
	——99·86

Hisingerite, *Cronstedtite*, *Anthosiderite*, *Polyhydrite*, *Sideroschisolite*, *Chamoisite*, *Stilpnomelane*, and *Xylite* are names of dark brown or black species.

Crocidolite has a fibrous structure much resembling Asbestus, and is frequently called *Blue Asbestus*. Colour lavender-blue or leek-green. Its hardness is 4, and its specific gravity is 3·2 to 3·3. It is found in Southern Africa.

Pyrosmalite occurs in hexagonal prisms, with a perfect basal cleavage and a pearly surface. Colour pale liver-brown, grayish, or greenish. Its hardness is 4 to 4·5; and its specific gravity 3·8. It contains 14 per cent. of chloride of iron, and gives off fumes of muriatic acid before the blow-pipe.

Iron Zeolite is a hydrous silicate of the oxides of iron and manganese, forming incrustations at a mine near Freyberg.

Arsenates of Iron.—*Cube Ore* occurs in cubes of dark green to brown and red colours. It is of an adamantine lustre, not very distinct, with a greenish or brownish streak. Its hardness is 2·5; and its specific gravity 3. It is a hydrous arsenate of the peroxide of iron, containing 38 per cent. of arsenic acid. It is found in the mines of Cornwall; also in France and Saxony.

Scorodite crystallises in rhombic prisms, modified. It is of a pale leek-green or liver-brown colour, with a colourless streak, of a vitreous lustre inclining to subadamantine; subtransparent, or nearly opaque. Its hardness is 3·5 to 4·8. Specific gravity, 3·1 to 3·3. Scorodite is a hydrous arsenate of the peroxides of iron, containing 50 per cent. of arsenic acid. It comes from Saxony, Carinthia, Cornwall, and Brazil. It occurs in minute crystals near Edenville, New York, with arsenical pyrites. The name of this species is from the Greek, σκόροδον (garlic), alluding to the odour before the blow-pipe.

Iron Sinter is a yellowish or brownish hydrous arsenate of the peroxide of iron, containing but 30 per cent. of arsenic acid.

Arseno-Siderite is another fibrous arsenate, containing 34 per cent. of arsenic acid.

Symplesite is a blue or green mineral, supposed to be an arsenate of the protoxide of iron. Its crystals are right rhomboidal, with a perfect cleavage. It hardness is 2·5; and its specific gravity is 2·96. It is found in Voigtland.

(Dana, *Mineralogy*.)

IRON-BARK-TREE. [EUCALYPTUS.]

ISARIA, a genus of *Fungi*, belonging to the division *Trichosporei*, and the tribe *Isareii* of Léveillé. It is characterised by a compound, solid, capitulated, or elongated receptacle. The species are found parasitic upon caterpillars and the larvæ of various insects. Robin enumerates the following species:—

I. Eleuteratorum has been found upon the *Carabidæ* in the autumn of the year.

I. floccosa, upon the larvæ and chrysalides of *Bombyx Jacobæa*.

I. strigosa, upon the chrysalides of *Noctua Upsilon*.

I. arachnophila, upon small spiders belonging to the genus *Geometra*, in the autumn.

I. leprosa, on the chrysalides of *Noctua instabilis*.

I. Tartarica, observed by Robin upon an unknown spider, in the autumn.

I. crassa, upon decaying chrysalides.

I. sphecophila, upon a dead hornet.

I. exoleta, upon the larva of a moth.

I. Aranearum, an American species, found on spiders in Carolina.

I. Sphingum, also found in America, upon the caterpillars of the silk-worm moths.

I. gigantea, found upon a Mygale in the island of Cuba.

(Robin, *Histoire Naturelles des Végétaux Parasites*.)

ISATIS, a genus of Plants belonging to the natural order *Cruciferæ* and the tribe *Isatideæ*. It has a laterally compressed pouch, 1-celled, 1-seeded, valves keeled, eventually separating.

I. tinctoria, Dyer's-Woad, has the radical leaves oblong, crenate; pouch abrupt, smooth, thrice as long as broad. It is a rare plant in cultivated and waste land in Great Britain. It yields a blue dye, long known and used in this country. It was before the introduction of indigo a plant of considerable importance commercially, and it was extensively cultivated in Somersetshire, especially about Glastoubury, which town received its name from the Celtic word 'Glas,' signifying 'Blue.' The ancient Britons are said to have painted their bodies with the blue colour obtained from this plant.

(Babington, *Manual of British Botany*.)

ISCHY'ODUS, a genus of Fossil Fishes included in *Chimæra* by Agassiz.

ISERINE. [TITANIUM.]

ISINGLASS. [GELATIN.]

ISNARDIA, a genus of Plants named by Linnæus in memory of M. Antoine Dante Isnard, member of the Academy of Sciences. It belongs to the natural order *Onagraceæ*, and has a 4-cleft calyx, 4 petals, 8 stamens, and a filiform style, with a clavate or cruciform stigma. There is one British species of this genus. *I. palustris* has a procumbent rooting glabrous stem, opposite ovate acute leaves, terminating in a petiole, axillary solitary sessile flowers, with the petals absent. It is found in pools and marshes in Europe, Siberia, and Persia, and in Sussex in England.

I. alternifolia has an erect branched stem, alternate leaves, rather scabrous on the margins, and hoary beneath. It is a native of Virginia and Carolina, in marshy places, and has oval yellow petals. The root is used as an emetic, and is called Bowman's Root.

None of the species of this genus possess qualities which entitle them to cultivation except in botanical gardens. They may however be reared in a hot-bed, and then planted in an open border in a moist situation.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*.)

ISOCA'RDIA, a genus of Conchiferous *Mollusca*. Linnæus placed the form under *Chama*; Bruguière arranged it among the *Carditæ*. Lamarck, who made it the last of the genera of his Cardiacées, separated it from the last-mentioned genus, giving it the generic name at the head of this article. Mr. G. B. Sowerby ('Genera of Recent and Fossil Shells') thinks that this separation was effected with good reason, because the involute divaricate umbones of *Isocardia*, and its consequently dichotomous ligament running in each valve to the point of the umbo, serve to distinguish it from the other *Carditæ* of Bruguière. M. De Blainville, under the name of *Isocardium*, inserts it between *Tridacna* and *Trigonia* among his Camacées. M. Rang retains it in the same family, but restores Lamarck's original termination of the name, and places it between *Caprina* and *Tridacna*.

M. Deshayes, in his edition of Lamarck, remarks that the *Isocardiæ* have in truth large and contorted umbones like *Chama* and *Diceras*, but that they are regular and always free, while the true *Chamæ* are adherent and irregular. From the *Carditæ*, he observes, they are to be distinguished, both as respects the shell and the animal. In *Cardita* the lobes of the mantle are separated throughout their length, and are without siphons. In *Isocardia* the lobes of the mantle are united posteriorly, and provided with two short siphons, or rather perforations, which may be compared with those of the *Cardia*. Here doubtless, says M. Deshayes, the *Isocardiæ* approach the *Cardiæ;* but when the foot and the form of the branchiæ in these two genera are compared, the distinction is obvious. In the *Cardia* [CONCHACEA], the foot is cylindraceous, very long, and bent in an elbow-like form in the middle; in the *Isocardiæ*, on the contrary, it is flat, subquadrangular, and rather short.

Isocardia has the following characters:—Animal more or less globular, having the borders of the mantle fringed with very fine tentacular papillæ, leaving a rather large opening between them at the lower part, and united posteriorly by a transverse delicate band, pierced with two orifices surrounded by papillæ, one for the vent, and the other, lower, for respiration; foot of moderate size and trenchant.

Shell sometimes with an epidermis, very convex, globulose, heart-shaped, equivalve, inequilateral; umbones divaricated, and widely divergent, curved forwards and outwards, and slightly spiral; hinge composed of two flattened hinge-teeth; ligament external, forked at one of its extremities; muscular impressions very distant.

I. Cor, the Heart-Shell, has been taken on the British coasts.

The Rev. James Bulwer, from whose figure in the 'Zoological Journal,' vol. ii., the two figures below are taken, saw the animal when in sea-water, and in the position represented at No. 1. The feelers, or ciliated fringe of the upper orifice (the largest) of the mantle, moved slowly, as if in search of food. Having remained in this situation about ten minutes, water was ejected with considerable force from the lower orifice, which had till then remained motionless. The expulsion of the water appeared to be effected by a sudden contraction of the muscles, because this was never done without the valves nearly closing at the same instant. After a few seconds the valves gradually returned to their open position, and remained quiescent as before, till the water was again ejected with a jerk; this alternating process was repeated during the whole time his specimens (which were trawled up in very deep water on the east coast of Ireland) were under his examination, but at shorter intervals on receiving fresh supplies of sea-water. The animal appeared to Mr. Bulwer to be insensible both to sound and light, as the presence or absence of either did not at all interrupt its movements; but its sense of feeling appeared to be very delicate. Minute substances

Heart-Shell (*Isocardia Cor*).

1, valves open, to show the animal and the feelers or ciliated fringe of the upper and lower orifices; 2, one of the valves, showing the animal with its sharp-edged foot and the muscular impressions.

dropped into the orifice of the mantle instantly excited the animal, and a column of water strongly directed expelled them from the shell; with so much strength was the water in some instances ejected, that it rose above the surface of three inches of superincumbent fluid. ('Zool. Jour.,' vol. ii.)

Shell of *Isocardia Cor*, valves closed.

Lamarck recorded four species, including *Isocardia semisulcata*. M. Deshayes, in his edition of that author, adds four others, reckoning that species: making eight in all, recent and fossil.

The species are found in the European and East Indian seas, and those of Australia. They have been dredged up from mud and sand at depths ranging from 10 to 20 fathoms.

Fossil Isocardiæ.

Mr. G. B. Sowerby remarks ('Genera of Recent and Fossil Shells') that several fossil species are given in plate 295 of Sowerby's 'Mineral Conchology,' one of which is from the London Clay, and the other from Kelloway's. Mr. G. B. Sowerby, in a note, states that a fossil species also occurs in the Crag, which so nearly resembles the *I. Cor* that he knows not wherein the specific difference consists; and, in the text, goes on to state that according to Brocchi ('Conch. Foss. Subap.,' ii. 520), two varieties of *I. Cor* are found in a fossil state in several parts of Italy; but as a subject upon which much diversity of opinion exists is here brought into question, he would recommend an attentive and comparative re-examination of the fossil with recent specimens, before the inquirer comes to an absolute decision upon this point. Another fossil species, he observes, is found at Piacenza, namely, *I. arietina*, Lam.; and he has figured *I. Basochiana* (Defr., 'Dict. des Sciences Naturelles'), a new species found by M. De Basoches de Falaise, in the district of Coutances. He thus concludes his remarks upon the fossil species of this genus:—"We think we may venture to express our opinion that all the fossil specimens published in various books, and existing in various collections, are not distinctly characterised *Isocardiæ*, but only the casts of the insides of other bivalves: the best distinguishing character is in the groove formed for the extension of the ligament from the hinge to the umbo. It is incumbent on us to mention that in *Isocardia* the line to which the mantle is attached, passing from one muscular impression to the other, is entire."

M. Deshayes, in his Tables, records two living species and three fossil (tertiary); and *I. Cor* as both living and fossil (tertiary).

Mr. Lea places his genus *Hippagus* (of which he gives an engraving) under the family *Cardiacea*. ('Contributions to Geology,' 8vo., Philadelphia, 1833.) He states that he has in vain endeavoured to place this shell in one of the established genera. In its general character he says that it approaches most closely to the *I. Cor*, but that it cannot be placed in that genus, being destitute of teeth. It bears, he adds, some resemblance to the genus *Inoceramus;* but, he continues, the hinge in that genus "closes by a series of oblong fossets," and besides it is very inequivalve. In its natural order he thinks that it seems to follow the genus *Isocardia*, and he proposes to place it in that position. *Hippagus* occurs in the Claiborne beds (tertiary of Alabama—Eocene of Lyell).

Other species of *Isocardia* have been found from the Oolitic beds upwards, but they resemble more closely tropical species than *I. Cor*.

ISOCRINITES, a genus of *Crinoidea*. (Goldfuss.)

I'SOETES (from ἴσος, equal, and ἔτος, year), a Cryptogamic genus of Plants belonging to the natural order *Lycopodiaceæ*. The capsule of the plant does not open, and the fructification is inclosed within the swollen base of the leaves; it has sporules of two kinds, which are attached to filiform receptacles. The organs of fructification in this plant are small cases, which are situated in the angles formed by the union of the leaves and the contracted stem; those seated in the axillæ of the outer or inferior leaves are divided into three cavities, containing about fifty spherical bodies (granules); the cases in the axillæ of the internal or superior leaves are divided by numerous transverse partitions into many cavities, all of which are filled with an impalpably fine powder, in the early stages of its development white, but subsequently becoming black.

The species of *Isoetes* grow at the bottoms of ponds and lakes, and are said to afford excellent food for fish. They are called Quillworts from the rush or quill-like appearance of the leaves.

I. lacustris, Quillwort, has subulate roundish-quadrangular leaves with four longitudinal jointed tubes. The rhizoma of this plant is a blunt tuber; the leaves are slender, broad, and flat at the base, but elsewhere between cylindrical and quadrangular. It is found in Great Britain at the bottom of lakes and ponds in hilly districts. The structure of the fructification of this plant, and other species of the genus, is only imperfectly understood. It is on this account referred to *Marsileaceæ* by some authors, and made to form an independent order by others. Lindley refers it to *Lycopodiaceæ*, and observes, "I follow De Candolle and Brongniart in referring it here." Delile has published an account of the germination of *Isoetes setacea*, from which it appears that its sporules sprout upwards and downwards, forming an intermediate solid body, which ultimately becomes the stem or cormus, but it is not stated whether the points from which the ascending and descending axes take their rise are uniform; as no analogy in structure is discoverable between these sporules and seeds, it is probable that they are not. Delile points out the great affinity that exists between *Isoetes* and *Lycopodium*, particularly in the relative position of the two kinds of reproductive matter. "In *Lycopodium*," he says, "the pulverulent thecæ occupy the upper ends of the shoots, and the granular thecæ the lower parts; while in *Isoetes* the former are found in the centre and the latter at the circumference. If this comparison is good, it will afford some evidence of the identity of nature of those thecæ, and that the pulverulent ones are at least not anthers, as has been supposed; for in *Isoetes* the pulverulent inner thecæ have the same organisation, even to the presence of what has been called their stigma, as the outer granular ones; so that if *Isoetes* has sexes, it will offer the singular fact of its anther having a stigma."

(Babington, *Manual of British Botany*; Newman, *History of British Ferns*; Lindley, *Natural System*; Burnett, *Outlines of Botany*.)

ISONANDRA, a genus of Plants belonging to the natural order *Sapotaceæ*. It is distinguished by the stamens being all fertile, and twice as numerous as the lobes of the corolla.

I. Gutta (Hooker), the Gutta-Percha Tree, has its leaves on long stalks, obovate-oblong, with a short point golden beneath; flowers axillary, fascicled; stamens 12. This tree is a native of the Malayan Archipelago.

The substance yielded by this tree, and designated by the name of Gutta-Percha (pronounced 'Pertsha'), is, like Caoutchouc, a carburet of hydrogen, and isomeric with that substance, and possesses a great number of the properties which characterise India-Rubber [INDIA-RUBBER], but exhibits certain special properties which admit of its being applied to particular uses to which caoutchouc is not adapted. Gutta-Percha possesses as great an indestructibility by means of chemical agents as caoutchouc. It has an intermediate consistence between that of leather and wood; it is capable of being softened by heat, and of regaining its primitive consistence on cooling. It is therefore at the same time capable of taking and of retaining the most delicate impressions. The important uses to which it has been latterly applied are only the forerunners of those to which it will be adapted hereafter, provided the lack of this precious material (which unfortunately is produced in much less quantities than India-Rubber, and in localities much more circumscribed) does not present an obstacle to it.

Whilst the plants which furnish caoutchouc abound in the whole of the territorial zone which extends between the tropics, the *Isonandra Gutta* is the only tree which yields Gutta-Percha. It grows scarcely anywhere except in certain parts of the Malayan Archipelago, and up to the present time has been almost exclusively obtained from Singapore. It was brought for the first time into England in the days of Tradescant, as a curious product, under the name of Mazer-Wood; and subsequently it was frequently brought from China and other parts of the East, under the name of India-Rubber, in the form of elastic whips, sticks, &c. In 1843 Doctors D'Almeida and W. Montgomery drew particular attention to it, together with its various singular properties, its easy manipulation, and the uses for which the Malays employed it. The most common employment of it was for whips; and it was by the introduction of a horse-whip made of this substance that its existence was for the first time known in Europe. The specimens of the products of the East Indies, shown in the Great Exhibition of 1851, proved that the natives of the country in which the *I. Gutta* grows know also how to appropriate it to the manufacture of different kinds of vases, and that European industry has little more to do than to imitate their processes.

The importation of Gutta-Percha into England, where the employment of this substance first drew attention, was in 1845 only 20,600 lbs.; but in 1848 it had increased to above 3,000,000 lbs.; and during the last five years the importation has amounted to a much larger quantity, and one which begins to cause some apprehension as to the possibility of the supply sufficing for the requirements of the novel uses in store for it in the future. It is true that during its use Gutta-Percha is but little consumed, and the waste from the articles in this material, submitted to a proper softening, can be made to serve new uses; nevertheless its constantly increasing consumption, added to the barbarous manner in which the product has hitherto been extracted, may well justify some apprehension.

During the first few years of the employment of Gutta-Percha it was the custom to cut down the tree for the purpose of obtaining the juice, which, left to itself, very soon allowed the Gutta-Percha to separate and coagulate of its own accord. There is reason to hope that European industry will soon be embarked in the cultivation of this product, and that the Niato (which is the name that the Malays give to the tree which produces Gutta-Percha), multiplied by means of a regular culture, naturalised in other countries than those to which it is indigenous, and worked by regular incisions, which will only take from the tree a portion of its juice without hindering its development, will be the means of furnishing at a low price a substance which is destined to render notable services to industrial and domestic economy.

The Gutta-Percha which arrives in Europe in the form of lumps of some pounds weight is far from being pure. The natives of the Malayan Archipelago make no scruple of introducing into it stones, earth, &c.; the presence of which in the interior of these blocks renders a purification indispensable, which purification however is capable of being attained without much manipulation.

Indestructible by water, and at the same time a bad conductor of electricity, Gutta-Percha has been found available for inclosing the metallic wires employed in the electric telegraph; and the use of this substance may certainly claim its share in the success of the submarine telegraph, by means of which London and Paris and the other great cities of Europe are now brought within a few minutes of each other.

It may be conceived to what a variety of forms a substance can be turned which, becoming soft without adhering at the temperature of boiling water, regains at the ordinary temperature the slight elasticity and the consistence of leather. [GUTTA-PERCHA, in ARTS AND SC. DIV.]

ISO'PODA, Latreille's name for the fifth order of the class *Crustacea*. The *Isopoda*, according to that zoologist, approach the *Læmodipoda* by the absence of mandibular palpi, though they are removed from them by several points; the two anterior feet are not annexed to the head, and, like the succeeding ones, depend upon their particular segment. The feet are always fourteen in number, unguiculated, and without any vesicular appendage at their base. The under part of the tail is furnished with appendages which are very apparent, and in the form of leaflets or vesicular purses. Of these the two first, or external ones, ordinarily cover the others, either totally or in great part. The body is generally flattened, and wider than it is thick. The mouth is composed of the same pieces as in the *Crustacea*, which precede it in M. Latreille's system, but in the order before us those which answer to the two superior jaw-feet in the *Decapoda* present more the appearance of a lower lip terminated by two palpi. Two of the antennæ, the mesial ones, are almost obliterated in the last genera of this order, which are all terrestrial, and differ besides from the other by their respiratory organs. The male sexual organs are indicated most frequently by the presence of linear or filiform appendages, and sometimes by hooks placed at the internal origin of the first subcaudal laminæ. The females carry their eggs under the breast, either between the scales or in a membranous pouch or sac that opens to afford a passage for their young, which are hatched with the form and parts proper to the species, and only cast their skin as they increase in size. The greater number live in the water. Those which are terrestrial have need, like other *Crustacea* that live out of water, of a certain degree of atmospheric humidity, in order that respiration may be carried on, and that their branchiæ may be in a fit state for performing this function.

Messrs. Victor Audouin and Milne-Edwards have studied very carefully the organisation of the *Isopoda*, the *Ligiæ* especially. It appears from their observations that the heart has the form of a long vessel extended above the dorsal surface of the intestine. Its anterior extremity gives off three arteries, as in the *Decapoda*. The lateral branchiæ may also be seen directed from the heart towards the feet. At the edge of the two first articulations of the abdomen, or tail, this organ receives, both right and left, small canals (the branchio-cardiac vessels), which seem to come from the branchiæ. According to the demonstrations of these zoologists in the case of the *Ligiæ*, it would appear that the venous system is less complete than in the Macrurous *Decapoda*; and that the blood driven from the heart to the different parts of the body passes into lacunæ, which the organs leave between them at the lower surface of the body, and which have a free communication with the different vessels of the branchiæ. The blood, after having traversed the respiratory apparatus, returns to the heart in traversing the branchio-cardiacal vessels. This disposition would establish the passage from the circulating system of the Decapodous *Crustacea* to that of the *Branchiopoda*. According to

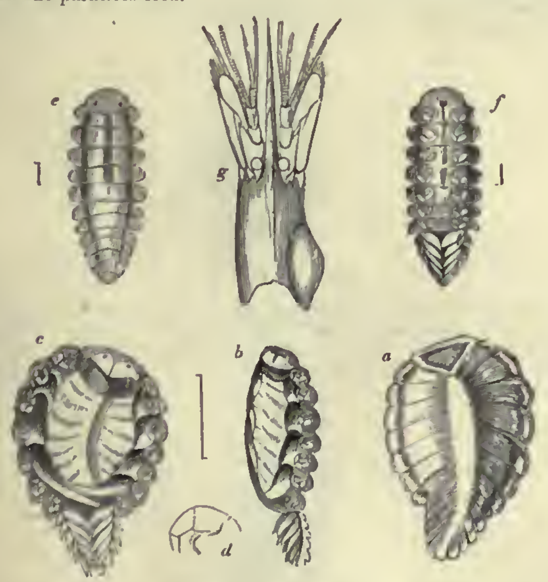
Cuvier, the two anomalous chords composing the mesial part of the nervous system of the *Onisci* (and probably of the other *Isopoda*, and even of the *Amphipoda*) are not entirely approximated, and may be well distinguished throughout their length. There are nine ganglions, without counting the brain; but the first two and the last two are so approximated that they may be reduced to seven. The second and the six following furnish the nerves to the seven pairs of feet; the four anterior feet, although analogous in the order of succession of the parts to the last four jaw-feet of the *Decapoda*, are really feet, properly so called. The segments which immediately succeed, or those that form the tail, receive their nerves from the last ganglion. These segments may be considered as simple divisions of a single segment, represented by that ganglion; and we accordingly see that the number of these posterior segments varies.

The following is the arrangement of M. Latreille:—

The order consists of six sections.

1. Epicarides (Latreille).—These are parasitical *Isopoda*, which, according to M. Latreille, are without either eyes or antennæ; the males however have eyes, though the females are blind. The body is flat, very small and oblong in the males, but much larger in the females, taking in their case the form of an oval, which is narrowed and a little curved posteriorly, hollow below, with a thoracic border, divided on each side into five membranous lobes. On this border the feet, which are very small and unfit either for walking or swimming, are situated. The under part of the tail is furnished with five pairs of small ciliated imbricated leaflets, answering to as many segments, and disposed in two longitudinal rows; but the posterior extremity is deprived of appendages. The mouth presents distinctly only two membranous leaflets applied one upon the other, of the same consistence, and quadrilateral. The lower concavity, forming a sort of flat basket, is filled with eggs. Near the place of their issue is constantly found an individual, which is presumed to be the male; but M. Latreille adds, that the extreme smallness of its size seems to forbid the possibility of copulation. According to M. Desmarest, this individual is furnished with two eyes; its body is straight and nearly linear. One sub-genus only belongs to this section.

Bopyrus (Latreille).—The most common species is *B. Crangorum*. Those who are in the habit of eating prawns will probably have observed a tumour occasionally presenting itself under the carapace on one of the sides, which is bulged out. On lifting this part of the shell, the parasite will, in such cases, be discovered immediately under it and upon the branchiæ. We have frequently detected the *Bopyrus*, but on whatever species of prawn it has been found, we have never remarked that the animal to which it adhered was more meagre than its fellows, though this perhaps may have arisen from the prawn not having been long subject to the visitation of the parasite. But there is another reason why the prawn should not suffer much from the adhesion of the parasite. The author of 'Horæ Entomologicæ' informs us that he has lately found three specimens of *Bopyrus* (females) with their backs turned to the branchiæ of the prawns; and he is of opinion that they and other crustaceous parasites which adhere to the anterior parts of fishes and *Crustacea*, fix themselves there for the sake of the currents (produced by the branchiæ in respiration), which bring with them the animalcules on which the parasites feed.



Bopyrus Crangorum.

a, the upper side; *b*, the animal seen in profile; *c*, the under side; *d*, one of the feet, much magnified (female); *e*, small individual, considered as the male, upper side; *f*, the same, lower side; *g*, carapace of a Prawn deformed on the right side by the presence of *Bopyrus*. (Desmarest.)

B. Crangorum is found on *Palemon serratus* and *Palemon squilla*, but most frequently on the former.

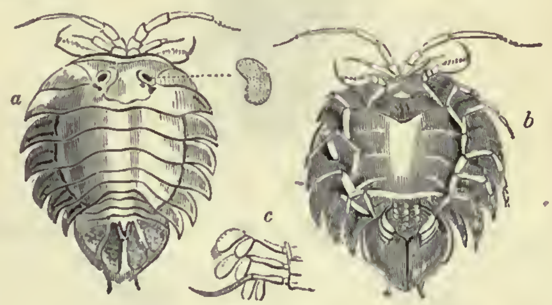
M. Risso has described another species, under the female of which he states that he found 800 or 900 living young ones.

2. Cymothoada (Latreille).—This section comprises those *Isopodæ* which have four very apparent antennæ; these are setaceous, and nearly always terminated by a pluriarticulate stem. These crustaceans have eyes, a mouth of the ordinary formation, vesicular branchiæ, disposed longitudinally in pairs, a tail consisting of from four to six segments, with a fin on each side, and the anterior feet most frequently terminated by a strong but small nail or hook. These *Isopodæ* are all parasitic according to Latreille; but *Serolis* appears not to be a parasite. Sometimes the eyes are mounted on tubercles at the summit of the head. The tail is composed of only four segments.

Serolis (Leach). One species only known, *S. Fabricii* (*Cymothoa paradoxa* of Fabricius).—Antennæ placed on two lines, and terminated by a pluriarticulate stem. Under the first three segments of the tail there are between the ordinary appendage three others, which are transverse, and terminated posteriorly in a point.

M. Desmarest describes the animal thus:—Superior antennæ formed of four joints, larger than the first three of the inferior antennæ; the last joint composed of many others, and smaller. Inferior antennæ with five joints, the first two small; the third and fourth (principally this last) elongated; the fifth composed of many others, smaller. Second pair of feet having the penultimate joint enlarged and the nail or claw much elongated; the sixth pair ambulatory, rather spiny, and having the nail slightly curved. Anterior appendages of the belly, or branchial laminæ, formed of two equal parts, which are foliaceous, rounded at their extremity, furnished with hairs at their base, placed upon a common peduncle; the two posterior and lateral appendages small and narrow, especially the interior one, which hardly projects.

This is a very interesting animal, and has been considered to offer some resemblance at first sight to the extinct form of the *Trilobites*. [Trilobites.]

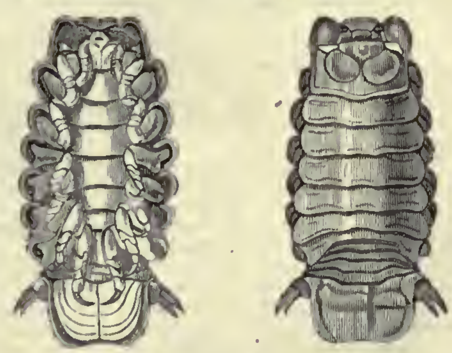


Serolis Fabricii.

a, back; *b*, under surface, showing the union of crustaceous legs with the membranous branchiæ; *c*, magnified view of branchiæ.

This creature has been found at Tierra del Fuego, Straits of Magalhaens (Banks), and Senegal (Dufresne). Captain Phillip Parker King, R.N., collected many specimens on the east coast of Patagonia, and also at Port Famine, in the Straits, where Captain King saw the beach covered with dead specimens. He also observed them alive swimming close to the bottom among the sea-weed. They moved slowly and gradually, unlike a shrimp. He never saw them swimming near the surface: their legs seemed adapted for swimming and crawling on the bottom.

Cymothoa (Fabr.)—Antennæ nearly equal in length; eyes but little apparent; last segment of the tail squared, and the two pieces terminating the lateral fins linear, equal, and styliform.



Cymothoa œstrum.

a, upper side; *b*, lower side.

Ichthyophilus (Latreille; *Nerocila*, *Lironeca*, Leach).—Antennæ of equal length, and eyes not very visible; last segment of the body nearly triangular, with two pieces terminating the lateral fins, in form of leaflets or blades: the exterior of these is greatest in *Nerocila*, and of the same size as the others in *Lironeca*.

M. Latreille observes that in the four following sub-genera the superior antennæ are manifestly shorter than the inferior.

Many, as well as the *Cymothoæ*, have all the feet terminated by a powerful and strongly-arched nail (onglet); the last eight are not spiny; the eyes are always distant and convex. These, in the method of Dr. Leach, form three genera, but M. Latreille is of opinion that they may be united under one sub-genus, namely:—

Canolira (Leach; *Anilocra*, *Olencira*, of the same).—In those *Canoliræ*, designated by Dr. Leach as *Olenciræ*, the blades of the fins are narrow and armed with points. In those named by the same zoologist *Anilocræ* the external blade of the fins is longer than the internal one; the inverse of which is the case with the *Canoliræ*, in which, besides, the eyes are but very little granulated, while they are very sensibly granulated in *Anilocra*.

M. Latreille remarks that in the three following sub-genera the second, third, and fourth feet only are terminated by a very strongly-curved nail (onglet), and the last eight are spiny. The eyes ordinarily have but little convexity, and are large and converging anteriorly.

Canolira (Anilocra) Capensis.

Æga (Leach).—Two first joints of the superior antennæ very large and compressed.

Æga emarginata.

a, upper side; *b*, anterior foot; *c*, posterior foot; *d*, under side.

Rocinella (Leach).—Two first joints of the superior antennæ nearly cylindrical, but approaching the *Ægæ* in their large and anteriorly approximated eyes.

Conilira (Leach).—Antennæ as in *Rocinella*; but the eyes are small and distant; and the edges of the segments are nearly straight, and not falciform and prominent.

Synodus (Latr.).—Antennæ upon two lines, lower antennæ always short, tail of six segments; distinguished from all the preceding by their great and projecting jaws. Only one species.

Cirolana (Leach).—Length of the lower antennæ surpassing the half of that of the body. Six segments in the tail.

Nelocira (Leach).—Length of lower antennæ as in *Cirolana*. Five segments only in the tail. Cornea of the eyes smooth.

Eurydice (Leach).—Resembling *Nelocira* in the number of the caudal segments, but differing from that form in its granulous eyes.

M. Latreille is of opinion that this sub-genus conducts us to those whose eyes are formed of small grains, or which have those organs smooth, and which have besides the four antennæ inserted upon the

Nelocira Swainsonii.

same horizontal line, consisting of four joints at most, all the feet ambulatory, and the tail composed of six segments. Such a form is—

Limnoria (Leach).—The only living species known is *L. terebrans*, which, although only two lines in length, is nevertheless highly injurious in consequence of its multiplication and its habits. The rapidity with which this little crustacean pierces the timber of ships makes its attacks not only mischievous but alarming. The pier at Southampton and also that at Herne Bay, have suffered from the attacks of this crustacean. It rolls itself up like a wood-louse when it is seized. It is a native of all the European seas.

3. SPHÆROMIDES (Latr.).—The *Isopoda* composing this section have four very distinct antennæ, which are either setaceous or conical; and, with the exception of *Anthura*, they are always terminated by a stem divided into many small joints, and short. The lower antennæ, which are always the longest, are inserted under the lower part of the first joint, which is large and thick. The mouth has the usual form. The branchiæ are vesicular or soft, naked, and disposed longitudinally in pairs. The tail has only two complete and moveable segments, but has often impressed transverse lines upon it, indicating the vestiges of other segments. On each side of its posterior extremity is a fin terminated by two leaflets, the lower of which is moveable, while the upper one is formed by an internal prolongation of the common support. The branchial appendages are curved internally; the internal side of the first is accompanied in the males by a small linear and elongated piece. The anterior part of the head, situated below the antennæ, is triangular, and in the form of a reversed heart. Some have an oval or oblong body, contracting ordinarily into the form of a bowl. The antennæ are terminated by a pluriarticulate joint, and the lower ones at least are sensibly longer than the head. The lateral and posterior fins are formed of a peduncle and two blades, composing, together with the last segment, a fan-like fin. In these the impressed and transverse lines of the anterior segment of the tail, always shorter than its successor, or the last, do not reach the lateral borders. The first joint of the superior antennæ is in the shape of a triangular battledore (palette). The head seen from above forms a transversal square. The leaflets of the fins are very much flattened, and the intermediate piece, or last segment, is enlarged and rounded laterally.

Zuzara (Leach).—Leaflets of the fins very large, the upper of which is shortest, separated from the other to form a border to the last segment.

Sphæroma (Latr.).—Leaflets of moderate size, equal, and applied one over the other.

Sphæroma dentata.

In others the impressed lines, or transverse sutures of the anterior segment of the tail, attain the lateral border and cut it. The first joint of the superior antennæ forms an elongated palette, which is square or linear. The leaflets of the fins are ordinarily narrower

Næsa bidentata.

and thicker than in the preceding; the exterior sometimes (as in *Cymodocea*) envelops the other: their point of junction resembles a kuot or joint. Sometimes the sixth segment of the body is sensibly longer than the preceding segments and the succeding one. One of the leaflets of the fins only is projecting.

Næsa (*Campecopæa*, Leach).—Sometimes the sixth segment of the body is of the length of the preceding segments, and of the succeeding one, as in *Cilicæa*, where one of the leaflets of the fins only is projecting, the other leaning against the posterior border of the last segment.

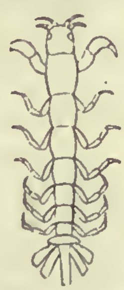
Cilicæa Latreilli.

Cymodocea (Leach).—In this form the leaflets of the fins are projecting and directed backwards. The sixth segment is not prolonged posteriorly, aud the extremity of the last segment has a small blade in a notch.

Cymodocea Lamarckii.

Dynamene.—Resembling *Cymodocea* in the projection and direction of the leaflets of the fins, but having the sixth segment prolonged backwards, and the last with a simple slit only, there beiug no blade.

Others again, as *Anthura*, have a vermiform body, and the antennæ, hardly so long as the head, consisting of four joints. The leaflets of the posterior fins form by their disposition and approximation a sort of capsule. The anterior feet are terminated by a monodactyle claw.



Anthura gracilis, magnified.

4. Idoteidæ (Leach). — This section consist of *Isopoda* whose antennæ are four in uumber, but upon the same horizontal and trans-

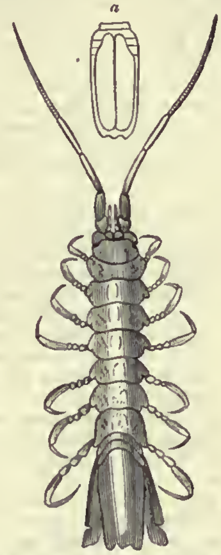
Idotea tricuspidata.

verse line; the lateral ones are terminated by a stem ending in a point, gradually decreasing and pluriarticulate; the intermediate antennæ are short, filiform, or a little the largest towards the eud, and 4-jointed, none of the joints beiug divided. The conformation of the mouth is the same as iu the preceding sections. The branchiæ are in the form of bladders, white in the greater part, susceptible of being blown up, capable of aiding in swimming, and covered by two blades or valvules of the last segment, adhering laterally to its borders, longitudinal, biarticulate, and opening in the middle by a straight line, like a folding door. The tail is formed of three segmeuts, the last of which is much the largest, without appendages at the end or lateral fins. These Crustaceans are all marine.

Idotea (Fabr.).—All the feet strongly unguiculated and identical; the body oval or simply oblong, and the lateral antennæ shorter than the half of the body.

Stenosoma (Leach).—Differing from *Idotea* iu the linear form of the body and the length of the antennæ, which surpasses the half of that of the body.

a



Stenosoma lineare, natural size.
a, laminæ of the under part of the abdomen.

Arcturus (Latreille).—Very remarkable for the form of the second and third feet, which are directed forwards, and terminated by a long bearded joint, unarmed or feebly unguiculate; the two anterior feet are applied upon the mouth and unguiculated; the last six are strong, ambulatory, thrown backwards, and bidentated at their extremity. In the length of the antennæ and form of the body *Arcturus* approaches *Stenosoma.* M. Latreille (1829) says that he never saw but one species, *A. tuberculatus*, brought home from the North Seas by oue of the last English expeditions to the North Pole.

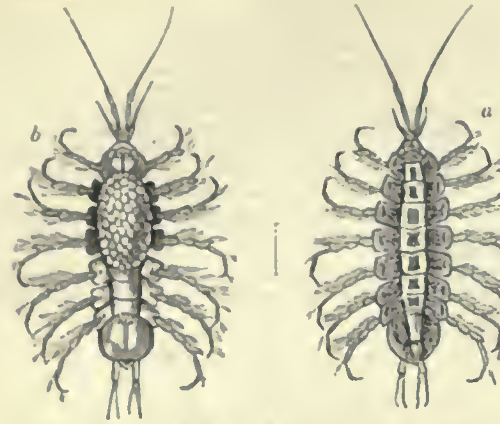
5. Asellota (Latreille). — The fifth section consists of *Isopoda* with four very apparent antennæ which are disposed on two lines, and are setaceous and terminated by a pluriarticulate stem. There are two mandibles, four jaws, ordinarily covered by a species of lip formed by the first jaw-feet. The branchiæ are vesicular, disposed in pairs, aud covered by two longitudinal and biarticulate but free leaflets. The tail is formed of a single segment, without lateral fins, but with two bifid needle-like processes, or two very short appendages in the form of tubercles at the middle of its posterior border. Thero are other lamellar appendages situated on its inferior base, more numerous in the males than in the females, and these serve to distinguish the sexes.

Asellus (Geoffroy).—Two bifid needle-like processes at the posterior extremity of the body; eyes distaut; superior antennæ at least as loug as the peduncle of the inferior antennæ. Hooks at the end of the feet entire.

A. aquaticus is very abuudant in fresh stagnant waters, as in the pools about Paris. It moves slowly when not terrified. In the spring it comes forth from the mud, in which it has passed the winter. The male, which is much larger than the female, carries her about for a space of eight days, holding her by means of his fourth pair of feet. When he quits her she is pregnant with a great number of eggs, inclosed in a membranous sac placed under her breast, aud opening by a longitudinal slit to give passage to the young.

Oniscoda (Latreille).—These, the *Janiræ* of Dr. Leach, differ from the *Aselli* in the approximation of their eyes, in having their superior antennæ shorter than the peduncle of the inferior ones, and iu the hooks of the tarsi, which are not bifid. M. Latreille remarks that the only species known (*Janira maculosa* of Leach) has been found on the coasts of England among the sea-weeds and *Ulvæ*.

Jæra (Leach).—This form, in the place of the needle-like processes (stylets) at the end of the tail, has only two tubercles. M. Latreille remarks that only a single species (*J. albifrons*, Leach) has been fouud,



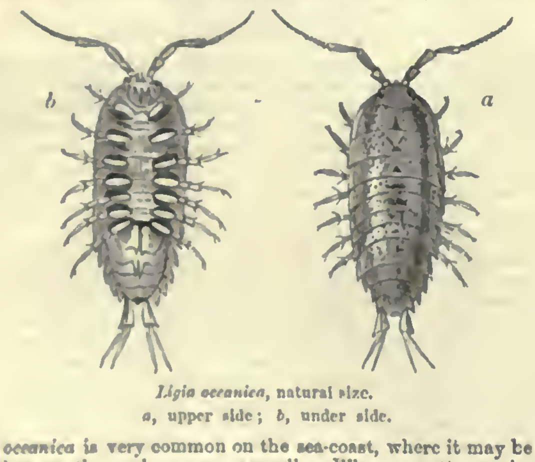
Asellus aquaticus (*Idotea aquatica*, Fabr.), female, magnified.
a, upper side; *b*, under side.

and that it is very common on the English coast, under stones and among the sea-weed.

6. CLOPORTIDES (*Oniscidæ*, Latreille).—This, the last section of *Isopoda*, according to the arrangement of M. Latreille, consists of those forms which have indeed four antennæ, but the two intermediate ones are very small, little apparent, and consist of two joints at most: the lateral antennæ are setaceous. The tail is composed of six segments, with either two or four needle-shaped appendages at the posterior border of the last segment, and without lateral fins. Some are aquatic, others terrestrial. In the latter the first leaflets below the tail exhibit a row of small holes, where the air penetrates to the organs of respiration there inclosed.

Some have the sixth joint of their antennæ, or their stem, so composed that in counting the small articulations of this part the total number of all the joints is nine at least. These are marine, and consist of two sub-genera.

Ligia (Fabr.).—Stem of the lateral antennæ composed of a great number of small joints, and two very projecting stylets, separated at the end into two branches, at the posterior extremity of the body.



Ligia oceanica, natural size.
a, upper side; *b*, under side.

L. oceanica is very common on the sea-coast, where it may be seen creeping on the rocks or on sea-walls. When an attempt is made to seize it, the animal quickly folds its feet and lets itself drop.

Tylos (Latreille).—These seem to have the faculty of rolling themselves up. The last segment of the body is demicircular, and exactly fills the notch formed by the preceding. The posterior appendages are very small and entirely inferior. The antennæ have only nine joints, the last four of which compose the stem. On each side is a tubercle representing one of the intermediate antennæ; the intermediate space is elevated. The branchiæ are vesicular, imbricated, and covered by laminæ.

T. Armadillo, an inhabitant of the Mediterranean, may be taken as an example.

Philoscia (Latreille).—Lateral antennæ divided into eight joints and exposed at their base. The four posterior appendages nearly equal. These occur in moist places. *Oniscus sylvestris* (Fabr.) is an example.

Cloportes, properly so called; *Oniscus*, Linn. (Wood-Lice).—Eight joints to the lateral antennæ, but their base is covered; and the two external appendages of the tail are much larger than the two internal ones. These animals frequent dark and retired places, such as caves, cellars, holes in walls, &c., and are also found under stones and old logs. Their food consists of decayed vegetable and animal substances; and they scarcely ever come forth from their retreats except in rainy or moist weather. They move slowly when not in danger. The eggs are inclosed in a pectoral pouch. The young at their birth have a thoracic segment, short, and consequently only twelve feet. These *Crustacea* were formerly used in medicine; but they no longer form part of the Materia Medica.

Wood-Louse (*Oniscus murarius*).

Porcellio (Latreille).—Distinguished from the true Wood-Lice by the number of joints of their lateral antennæ, which are only seven. In other respects *Porcellio* resembles *Oniscus*.

Armadillo (Latreille).—The posterior appendages of the body are not projecting; the last segment is triangular. A small blade, in form of a reversed triangle, or more large and truncated at the end, formed by the last joint of the lateral appendages, fills up on each side the void between the segment and the preceding. Lateral antennæ with only seven joints. The upper subcaudal scales are pierced with a row of small holes.

Armadillo pustulatus.
a, expanded; *b*, rolled up.

Such is the arrangement of M. Latreille.

Lamarck divided the *Isopoda* into two great sections: the first consisting of those which have the branchiæ situated under the tail, and comprising two subdivisions; the second composed of those which have their branchiæ placed under the anterior part of the abdomen, between the feet.

Under the first he arranged the genera *Armadillo, Oniscus, Philoscia, Ligia, Asellus, Idotea, Sphæroma, Cymothoa, Bopyrus, Typhis, Anceus, Praniza, Apseudes*, and *Ione*. Under the second he included the genera *Leptomera, Caprella*, and *Cyamus*.

M. Desmarest also divided the *Isopoda* into two great sections, with many subdivisions.

His first section, which he makes equivalent to the Phytibranchiate Isopods of Latreille, consists of the genera *Typhis, Anceus*, including *Gnathia* of Leach, *Praniza, Eupheus*, and *Ione*.

His second section, which he makes equivalent to the Ptérygibranches of Latreille, comprises the genera *Idotea, Stenosoma, Anthura, Serolis, Campecopea, Næsa, Cilicæa, Cymodocea, Dynamene, Zuzara, Sphæroma, Eurydice, Nelocira, Cirolana, Conilera, Rocinella, Æga, Canolira, Anilocra, Olencira, Nerocila, Livoneca, Cymothoa, Limnoria, Asellus, Janira, Jæra, Ligia, Philoscia, Oniscus, Porcellio, Armadillo*, and *Bopyrus*.

M. Milne-Edwards (edition of Lamarck, 1838) states, in a note to that part of Lamarck's definition of an Isopod Crustacean, 'mandibules sans palpes,' that Lamarck, Latreille, and most authors are in error when they assign this character to the *Isopoda*, for in a great number of these Crustaceans the mandibles are provided with a palpiform stem, entirely resembling that which may be seen in the greater part of the *Amphipoda*.

He further remarks that the respiratory lamellæ situated under the abdomen are hardly ever branchiæ, properly so called, but only one of the branches of the false feet become membranous and vascular, as in one of the appendages of the thoracic feet in the *Amphipoda*. The female of *Ione*, he observes, exhibits an exception, for she carries ramose branchiæ on each side of the abdomen.

M. Milne-Edwards, in his notes, further states that those *Crustacea* whose respiratory appendages are placed under the thorax (which Lamarck calls abdomen) ought not to remain in the order of *Isopoda*, but belong to the *Læmodipoda* of M. Latreille. The egg-pouch he describes as being formed of the flabelliform appendages, which have become foliaceous, and are raised against the sternum.

The same acute zoologist (loc. cit.) says that the *Isopoda*, properly so called, are Edriophthalmous Crustaceans, whose abdomen is never rudimentary, and carries below five pair of false branchial feet, having all nearly the same form and the same functions. The appendages of the penultimate ring (or the false feet of the sixth pair) have a form and use different from those of the preceding. The thorax, composed in general of seven rings, but sometimes having only five, carries nearly always seven pair of feet, which are often furnished with a foliaceous palp, serving to protect the eggs and young, but they hardly ever carry a vesicular appendage proper for respiration, as in the *Amphipoda* and *Lœmodipoda*. Finally, the conformation of their buccal apparatus varies, and the greater part of authors are in error when they assign to them as a character the possession of mandibles deprived of palpiform appendages.

M. Milne-Edwards is of opinion that the *Isopoda* form three natural families, namely, the Idoteidians, the Cymothoadians, and the Cloportidians, and he thus distinguishes them:—

A. Jaw-feet operculiform, and deprived of a palpiform stem, or only showing the vestiges of it.

* Thoracic feet ambulatory; last segment of the abdomen smaller than the preceding segments; internal antennæ rudimentary.

These form the family of—

Cloportidians.

** Thoracic feet anchor-like (ancreuses), last segment of the abdomen nearly always much larger than the preceding segments; internal antennæ in general well developed.

These form the family of—

Cymothoadians.

AA. Jaw-feet palpiform. Last abdominal ring much more developed than the preceding ones; all or nearly all the feet ambulatory.

These form the family of—

Idoteidians.

In this classification, says the author, the family of the Cloportidians has the same limits as in the method adopted by Lamarck, and comprises the Terrestrial Isopods.

The family of Cymothoadians is composed of the Parasitic Isopods, and comprehends *Cymothoa* of Lamarck, *Ione*, *Anceus*, and *Typhis*.

The family of Idoteidians consists of Marine Isopods not parasitic, and embraces the genera *Idotea*, *Sphæroma*, *Anthura*, *Asellus*, &c. [CRUSTACEA.]

Fossil Isopoda.—M. Latreille states that Professor Germar had sent to M. le Comte Dejean the figure and description of a small Fossil Crustacean which appeared to him (M. Latreille) to be referrible to the sub-genus *Limnoria*; and he further remarks that *Oniscus prægustator*, figured in Parkinson's work, comes near to that species, or at least appears to belong to the same section.

M. Desmarest ('Histoire Naturelle des Crustacés Fossiles') enumerates two fossil species of the genus *Sphæroma*: one, *S. antiqua*, found in a fragment of white fine-grained calcareous stone, analogous in that respect to the Pappeheim stone, but of which he knows not the origin; the other, *S. Margarum*, from the horizontal beds of green fissile marl (marne verte fissile) at Montmartre, above the gypseous beds, mingled with Spirorbes.

ISOPYRE, a Mineral which occurs amorphous in granite. The fracture is flat and conchoidal. It is brittle, with a hardness of 5·5 to 6. The colour is velvet- or grayish-black, occasionally dotted with red. The colour of the streak is greenish-gray. It slightly obeys the magnet. Lustre vitreous; opaque or slightly translucent. The specific gravity is 2·9 to 3. It is with difficulty acted upon by acids, and fuses before the blow-pipe. It occurs in the granite of St. Just, near Penzance, in Cornwall. According to Turner's analysis, it consists of—

Silica	47·09
Alumina	13·91
Lime	15·43
Peroxide of Iron	20·07
Oxide of Copper	1·94
	98·44

ISO'TELUS, a genus of Fossil *Crustacea* (*Trilobites*) from the Silurian strata, especially of North America. (Green.)

ISOTOMA. [LOBELIACEÆ.]

ISPIDA. [HALCYONIDÆ.]

ISTIO'PHORI, a family of Bats. [CHEIROPTERA.]

ISTIU'RUS, a genus of Saurians. [IGUANIDÆ.]

ITABALLI. [VOCHYACEÆ.]

ITACOLUMITE, a Micaceous Granular Quartz with which gold and topaz are associated. It is found in Brazil. [DIAMOND.]

ITCH-MITE, [ACARIDÆ.]

ITTNERITE. This Mineral occurs crystallised in rhombic dodecahedrons and massive. It has a compact structure. The fracture is imperfect, conchoidal, passing into uneven. Hardness 5·0 to 6·0. The colour is bluish or ash-gray. The lustre resinous to vitreous. Specific gravity 2·3. It forms a jelly when put into acids, and fuses per se before the blow-pipe, with effervescence of sulphurous acid, into an opaque blebby glass. It yields by analysis—

Soda	11·29
Potash	1·57
Silica	30·17
Alumina	28·40
Lime	5·24
Oxide of Iron	0·62
Sulphate of Lime	4·89
Common Salt	1·62
Sulphuretted Hydrogen and Water	10·76
	94·56

IU'LUS, a genus established by Linnæus for such *Insecta Myriapoda* as now form the order *Chilognatha* (χεῖλος, γνάθος), the first division of *Myriapoda* in the arrangements of Leach and Latreille. The *Chilognatha* have crustaceous and usually cylindrical bodies, formed of numerous unequal segments, very short feet, each terminating in a single hook; a vertical rounded head, furnished with two mandibles, which are either thick and robust or united with the labium and elongated. They have no palpi. The antennæ are two, very short, either slightly thickened towards their extremities, or filiform throughout, and composed usually of seven, more rarely (as in the genus *Sphæropœus*) of six joints. Their eyes are smooth and vary greatly in number. These animals move slowly and with a gliding motion. When disturbed, they roll themselves up spirally, or into a ball. They feed on decomposing animal and vegetable matter.

The position assigned to the *Chilognatha*, at the head of the *Myriopoda*, by Latreille and others, has been disputed by Professor Brandt and by Mr. Newport. The following remarks on this subject by the latter naturalist, of all living zoologists the most competent to decide in questions affecting this difficult class, are taken from his catalogue of *Chilognatha* in the British Museum, published in the 'Annals of Natural History for April, 1844,' and afford in a brief compass much information respecting these curious animals.

"The *Chilognatha*, have usually been regarded by naturalists as the first order of *Myriapoda*, partly in consequence of the more compact form of the head, and its similarity to that of the larva state of hexapod insects, and partly from the general form of their bodies being similar to that of the larvæ. This was the view taken of these animals by Latreille, Leach, Gervais, and some others, and very recently by Lucas. But a different and, as I believe, more correct view and arrangement have been followed by Professor Brandt, who regards the *Chilopoda* as the first, and the *Chilognatha* as the second division of the class. Although I cannot entirely agree with Brandt in his division of the *Chilognatha* into masticating and sucking species, because, as Lucas has recently remarked, there are species even among the *Chilopoda* which have the external organs of nutrition fitted only for taking liquid food, as in the little *Scolopendrella*, I fully agree with him in the superiority of the *Chilopoda*, as an order, over the *Chilognatha*, notwithstanding the less compact structure of the head in the former. The general characters of the *Chilopoda* certainly point them out as the most perfect animals of the osculant class of *Articulata*. The more compact frame of body, the reduced number of the organs of locomotion, the greater activity, and the predaceous habits of the higher species, approximate the *Chilopoda* to the predaceous insects on the one hand, and to the *Arachnida* on the other. The form of the head, in the two divisions of *Myriapoda*, seems to have reference chiefly to the particular habits of the species. Thus, in those which seize their prey and subsist like the Arachnidans on living objects, those segments which in reality compose the whole head are not all anchylosed together, but are in part freely moveable on each other, and thus allow of a more prehensile function to the large forcipated foot-jaws, the true mandibles of the *Articulata*. Some naturalists have believed that these foot-jaws in the *Chilopoda* are not the true analogues of insects and of *Chilognatha*; but I am satisfied, by recent examinations, that this is truly the case. In the *Chilognatha* the foot-jaws have the form of true mandibles, because the habits of the species require that compact form of the organ which alone can be subservient, not to the seizing and piercing of living prey, but to the grinding or comminuting of more or less solid vegetable matter, on which most of the genera of *Chilognatha* entirely subsist. In all other respects, both in their internal as well as their external anatomy, and in their physiology and mode of growth, the *Chilognatha* are decidedly inferior to the *Chilopoda*. They seem to conduct us down to the *Annelida* from the vegetable-feeding *Crustacea*, as the *Chilopoda* do from the Arachnidans to the same class."

The Chilognathous *Myriapoda* are found in all parts of the world, certain genera however affecting certain geographical divisions. Thus the species of *Glomeris* are European; those of *Spirastreptus* and *Sphæropœus* African and eastern. The genus *Iulus*, in its most limited sense, includes European, Asiatic, and North American species. *Iulus terrestris* is a familiar British example.

A synopsis of the genera of *Chilognatha* will be found in the third part of the nineteenth volume of the 'Linnæan Transactions,' appended to a valuable memoir on the *Myriapoda* by Mr. Newport. Professor Brandt's papers on these animals are published in the

'Transactions and Proceedings of the Imperial Academy of St. Petersburg.' [MYRIAPODA.]

IVORY. [TEETH.]

IVORY, VEGETABLE. [PHYTELEPHAS.]

IVY. [HEDERA.]

IVY, GROUND. [NEPETA.]

I'XALUS, a form of herbivorous Mammifers, placed by Mr. Ogilby under his family *Moschidæ*.

IXODES. [ACARIDÆ.]

IXOLYTE, a Mineral Resin found with others in brown coal.

IXO'RA, a genus of Plants belonging to the tribe *Cinchonaceæ* and the genus *Rubiaceæ*, so named, it is supposed, from the Indian god Iswara. The genus is characterised by having a small 4-toothed calyx; corolla 1-petaled, funnel-shaped; tube long, with the four stamens in its mouth; ovary 2-celled, 1-seeded; style single; berry drupaceous, inferior, 2-seeded. The species are numerous, and chiefly confined to India and the Oriental Archipelago. They form shrubs or small trees, with opposite leaves, and stipules arising from a broad base, but acute at the apex. The flowers are in terminal corymbs, and are usually red, but sometimes white, and are generally highly ornamental, whence several are cultivated in our hot-houses, where they require to be kept in a moist heat to thrive well. Some of the species are used medicinally, but not to any extent. Dr. Horsfield mentions *I. coccinea* as employed in Java as a stimulant, and Rheede two or three other species; but none appear to be possessed of any very active properties.

IXOS, a genus of Birds established by M. Temminck, for those Thrushes which have the bill shorter than usual, and embracing the greatest part of the *Brachypodinæ* and nearly the whole of the *Crateropodinæ* of Swainson.

J

JABIRU, the name or a genus of Grallatorial or Wading Birds, called *Mycteria* by Linnæus. It is thus characterised:—

Bill long, conical, smooth, robust, compressed, and pointed; upper mandible trigonal and straight, the lower thicker and turned up. Head and neck more or less bare of feathers. Anterior toes united at the base by a membrane. Size gigantic.

The species are found in South America, Western Africa, and Australasia. Its habits are almost entirely the same with those of the Storks. There are three species known, distributed geographically as above.

M. Americana may be taken as an example.

This bird is very large in size, white; the head and neck (excepting the occiput) without feathers, and covered with a black skin, which becomes reddish towards the lower part. On the occiput are a few white feathers. Bill and feet black.

It is found in South America, where it frequents the borders of lakes and marshes, preying on reptiles and fish.

Mycteria Americana.

JACARANDA, a genus of Monopetalous Exogenous Plants belonging to the natural order *Bignoniaceæ*. It has a 5-toothed calyx, sometimes entire; corolla with a short tube or campanulate throat, and a 5-lobed bilabiate limb; stamens 4, didynamous, with the rudiment of a fifth; lobes of anthers divaricate; capsule ovate, rather ligneous. The species are trees, natives of South America. They have showy panicled terminal flowers. They have very much the habit of the fine-leaved Acacias.

Several species, as *J. Bahamensis, J, Braziliens, J. tomentosa*, are cultivated in stoves in this country.

JACARANDA, a wood known in commerce, and which is said by Prince Maximilian to be the timber of a Brazilian *Mimosa*. (Burnett, *Outlines of Botany*.)

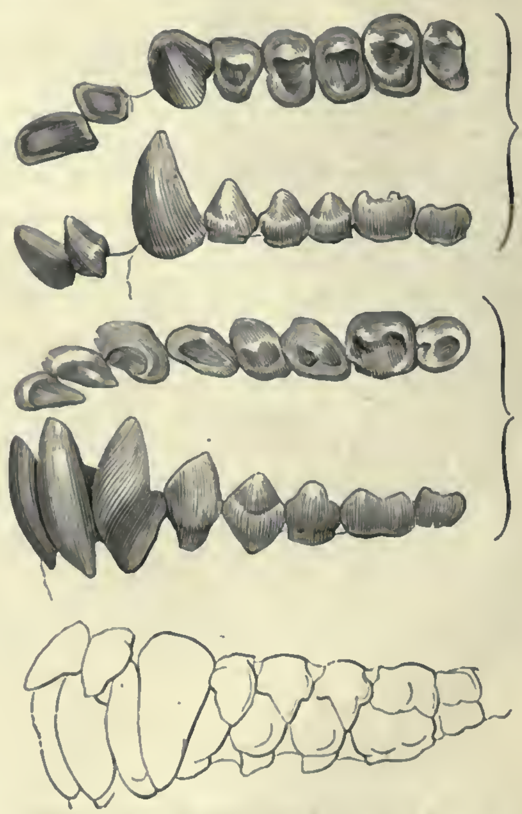
JACARÉ. [ALLIGATOR.]

JACCHUS, or IACCHUS, the name of a genus of Monkeys applied by Geoffroy, Desmarest, and others to the form denominated *Hapale* by Illiger, *Ouistitis* of the French, the type of which may be considered to be the *Simia Jacchus* of Linnæus.

M. Geoffroy treats them as a family divided into two sub-genera (Hapale and Midas), under the name of *Arctopitheci*; but the term *Arctopithecus* has been applied by Gesner to another animal, probably the Three-Toed Sloth, whilst the latter uses *Galeopithecus* to designate the Sagoin.

The characters of Jacchus are:—Upper intermediate incisors larger than the lateral ones, which are isolated on each side; lower incisors elongated, narrow, and vertical, the lateral ones longest; upper canine teeth conical and of moderate size; two lower ones very small.

Dental Formula:—Incisors, $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{6-6}{6-6} = 36$.



Teeth of *Jacchus*, four times larger than nature. F. Cuvier.

Size small, muzzle short, facial angle about 50°. Head round, prominent at the occiput; the five fingers armed with claws, with the exception of the thumbs of the posterior extremities, which are furnished with nails; thumb of the anterior extremities in the same direction as the fingers; fur very soft; tail full and handsome.

The species are natives of South America. How Ludolph, who figures two in his 'History of Ethiopia,' could have been so far misled as to place the form in that part of the world, does not appear.

The species, which are not few, have been separated into two sections: the first consisting of those which have an annulated tail, as

J. vulgaris; and the second of those whose tail is not annulated, as *J. melanurus.*

J. vulgaris appears to be the *Simia Jacchus* of Linnæus and others; *Callithrix Jacchus* of Erxleben; *Hapale Jacchus* of Illiger and Kuhl; *Cercopithecus Jacchus* of Blumenbach; Cagui, Sagouin, Sagoin, Sanglain, and Sanglin, of Edwards and various authors, the latter terms being probably derived from Sahuim, the name by which it is said to be known near Bahia; Ouistiti of Buffon and the French; Striated Monkey of Pennant.

Length of body about 8 inches; tail rather more than 11 inches; colour olive-gray, darkest on the head and shoulders, where it becomes nearly black; tail and lower part of the back barred or annulated with pale-gray; lower parts of extremities brownish-gray. Face of a flesh-colour; two tufts of pale hair spring round the ears; front claws hooked and thick.

Jacchus vulgaris.

It is a native of Guyana and Brazil. The habits of the genus generally are squirrel-like, though they are, occasionally at least, carnivorous. *J. vulgaris*, in a wild state, is omnivorous, feeding on fruits, roots, seeds, insects, and little birds or nestlings. The individual (in captivity) from which Edwards took his drawing fed upon biscuits, fruit, greens, insects, snails, &c., and once, when loose, it suddenly snatched a Chinese gold-fish from a basin of water and devoured it: Mrs. Kennon, to whom it belonged, after this gave it live eels, which frightened it at first by twisting round its neck, but it soon mastered and ate them. Mrs. Moore, of Rio Janeiro, sent a living specimen of *J. penicillatus*, which was said to have been obtained from Bahia, to the Zoological Society of London, with the following note:—"Like most monkeys, it will eat almost anything; but its chief and favourite food, in its wild state, is the banana. It is a very delicate animal, and requires great warmth; and its very beautiful tail is in this respect eminently conducive to the comfort of the little creature, who, on all occasions when he requires warmth, rolls himself up in the natural boa with which Providence has in its wisdom endowed him."

The Ouistitis, or Sanglins, not unfrequently breed in confinement. Edwards notices a pair that bred in Portugal, and F. Cuvier possessed two which had young. Three little ones were born, and the female soon ate off the head of one; but the others beginning to suck, she became careful of them and affectionate to them. The male seemed more fond of them than the mother, and assisted her in her care of them. Lady Rolle addressed a letter to the secretary of the Zoological Society of London (February, 1835), giving an account of the birth of two young ones, the produce of a pair of Ouistitis (*J. penicillatus*, Geoff.) in her ladyship's possession. The parents were obtained in London during the preceding summer, and the young were brought forth on the 1st January. One was born dead, but the other was surviving at the date of the letter, being then about six weeks old, and appearing likely to live. It was every day put on the table at the dessert, and fed upon sweet cake. Lady Rolle stated that the mother took great care of it, exactly in the manner described by Edwards in his 'Gleanings.' It was observed that young of the same species had been born at the Society's Gardens, but not living, and that a female in the collection of the president, the Earl of Derby, at Knowsley, had produced, about the same time as Lady Rolle's, two living and healthy young ones, which were then still thriving. ('Zool. Proc.')

Dr. Gray places the form among the Anthropomorphous *Primates*, in the family *Sariguidæ*, and in its last sub-family (the 5th) *Harpalina* (*Hapalina?*), which is immediately preceded by *Saguinina*.

Mr. Swainson, who arranges it under his family *Cebidæ*, gives the group the appellation of Mouse-Monkeys, because the large cutting teeth in the lower jaw strongly indicate, in his opinion, "a representation of the order *Glires*."

JACK. [ESOX.]

JACK-IN-A-BOX, a name given to a species of *Hernandia*, in which the seeds make a noise when shaken in their pericarps. [HERNANDIACEÆ.]

JACK-OF-THE-HEDGE. [ERYSIMUM.]

JACK-SNIPE. [SCOLOPACIDÆ.]

JACK-TREE. [ARTOCARPUS.]

JACKAL. [CANIS.]

JACKDAW, the well-known English name for *Corvus Monedula* of Linnæus. [CORVIDÆ.]

JACKSAW, one of the provincial English names for the Dun Diver. [DUCKS.]

JACOB'S-LADDER. [POLEMONIUM.]

JADE, a name which has been given to several Minerals which resemble each other but little, except in colour, and therefore it is one which it would be well should fall into disuse.

Serpentine, *Nephrite*, and *Saussurite* have all been described under the name of *Jade*. *Yu*, or Chinese Jade, is supposed to be *Prehnite*.

JÆRA. [ISOPODA.]

JAGER. [LARIDÆ.]

JAGUAR. [FELIDÆ.]

JALAP. [IPOMÆA.]

JAMESONITE, a Mineral which occurs crystallised and massive. Its specific gravity is 5·564. It consists of—

Sulphur	22·5
Lead	38·7
Antimony	34·9
Iron	2·6
	98·7

JANIA. [CORALLINACEÆ.]

JANIPHA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has monœcious flowers; calyx campanulate, 5-parted; petals wanting; stamens 10 in the male flowers, filaments unequal, distinct, arranged round a disc. In the female flowers the style is one; stigmas 3, consolidated into a rugose mass; capsule 3-coccous.

J. Manihot (*Jatropha Manihot* of Linnæus) is a native of Brazil. It has an oblong tuberous root, as big as a child's head, full of a wheyish venomous juice. The stems are white, brittle, having a very large pith, and several knobs sticking out on every side like warts, being the remains of the foot-stalks of the leaves, which have dropped off, usually 6 to 7 feet high, with a smooth white bark; branches crooked, and have on every side near their tops leaves irregularly placed on long terete petioles, broadly-cordate in their outline, divided nearly to their base into 5 spreading lanceolate entire segments, alternate at both extremities, dark-green above, pale-glaucous beneath; the midrib strong, prominent below, and there yellowish-red: from it there branch off several oblique veins, connected by lesser transverse ones; stipules small, lanceolate, acuminate, caducous; panicles, or compound racemes, axillary and terminal, 4 to 5 inches long, bearing sometimes all male or female flowers, at other times these are mixed on the same peduncle; pedicels with small subulate bracts at their base. Male flowers smaller than the female. Calyx purplish on the outside, fulvous-brown within, cut about half-way down into five spreading segments; disc orange-coloured, fleshy, annular, 10-rayed; stamens 10, alternate with the lobes of the disc; filaments shorter than the calyx, white, filiform, free; anthers linear, oblong, yellow. Female flowers of the same colour as the male, deeply 5-parted; the segments lanceolate, ovate, spreading; disc an annular orange-coloured ring, in which the purple ovate furrowed ovary is imbedded; style short; stigmas 3, reflexed, furrowed and plaited, white; capsule ovate, 3-cornered, 3-coccous; seeds elliptical, black, shining, with a thick fleshy funiculus. The expressed juice is dangerously poisonous. Fecula of the root harmless when separated from the juice and exposed to heat. It is called Cassava—a principal article of diet in South America. The nutritious substance known as Tapioca is the Cassava differently prepared and granulated. [FOOD.] These preparations are obtained by crushing the roots after the bark has been removed, and straining off the water, when the mass is gradually dried in pans over the fire.

(Lindley, *Flora Medica.*)

JANI'RA (Oken), a genus of *Acalephæ*, apparently nearly allied to the *Callianiræ*.

JA'NTHINA, or IANTHINA, Lamarck's name for a genus of Turbinated Testaceous Mollusks of remarkable habits.

Linnæus placed the form among the *Helices*, under the name of *Helix Janthina*, between *H. perversa* and *H. vivipara;* and he was aware of its pelagic distribution.

Lamarck arranges it next to *Natica* the last genus of his

Neritaceans, between which family and the Macrostomes it appears in his list of Phytophagous (Plant-Eating) Trachelipoda.

Cuvier assigns to the *Janthinæ* a place among his Pectinibranchiate Gastropoda, between the *Pyramidellæ* and the *Neritæ*.

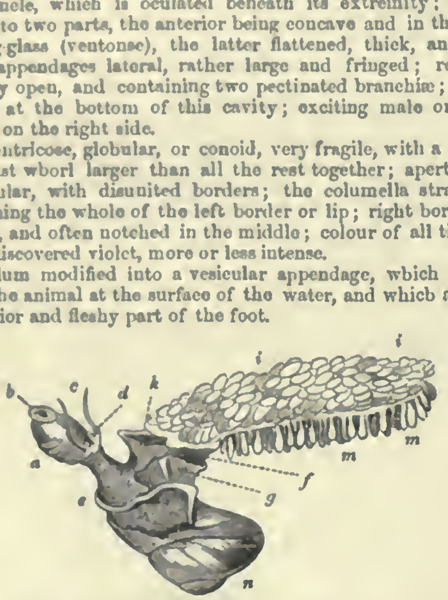
De Blainville elevates the group into a family, under the name of Oxystomes, being the fifth and last of his order *Asiphonobranchiata*. This family comes next to the Hemicyclostomes, which comprise the Nerita, &c.

M. Rang makes *Janthina* a genus of the Trochoids of Cuvier, giving it a position between *Ampullaria*, Lam., and *Litiopa*, Rang.

This genus has the following characters:—Animal with a very large head and a proboscidiform muzzle, at the extremity whereof is the mouth, furnished with two vertical subcartilaginous lips (which are armed with long and very sharp points curved inwards), and with a lingual enlargement (renflement); tentacles two, conical, pointed, not very contractile, and very distant, each bearing at its base a rather long peduncle, which is oculated beneath its extremity; foot oval, divided into two parts, the anterior being concave and in the form of a cupping-glass (ventouse), the latter flattened, thick, and fleshy; natatory appendages lateral, rather large and fringed; respiratory cavity very open, and containing two pectinated branchiæ; orifice of the ovary at the bottom of this cavity; exciting male organ very small and on the right side.

Shell ventricose, globular, or conoid, very fragile, with a low spire, and the last whorl larger than all the rest together; aperture large, subtriangular, with disunited borders; the columella straight and long, forming the whole of the left border or lip; right border or lip trenchant, and often notched in the middle; colour of all the species hitherto discovered violet, more or less intense.

Operculum modified into a vesicular appendage, which serves to suspend the animal at the surface of the water, and which adheres to the posterior and fleshy part of the foot.



Common Oceanic Shell (*Janthina fragilis*). Shell with the animal, the float expanded.

a, head; *b*, mouth; *c*, tentacles; *d*, eyes; *e*, border of the mantle at the entrance of the branchial cavity; *f*, foot, the posterior part, which is flat; *g*, lateral expansion of the mantle, provided for swimming; *k*, foot, anterior part forming a sort of pouch; *i*, bunch of aerated vesicles, serving to suspend the mollusc at the surface of the water; *m*, eggs suspended under the vesicular bunch; *n*, shell. (Rang.)

The geographical distribution of this genus is very extensive, the form having been met with in the four quarters of the world floating on the ocean or driven on the shores by tempests. It has occurred on the coasts of our own islands, but there is reason for thinking that it is not to be found in very cold latitudes. In warm climates it is very plentiful.

Sir Everard Home published in the 'Philosophical Transactions' for 1817 a paper which is appended (Appendix. No. iii.) to Captain Tuckey's 'Narrative of the Expedition sent to explore the River Zaire, usually called the Congo,' wherein he describes and figures among other ova of Molluscs, or *Vermes testacea*, as he denominates them, the camerated nidus of *Helix Janthina* (pl. xiii., figs. 1, 2, 3, 4, 5, 6). "This animal," observes Sir Everard, "not living at the bottom of the sea, like the *Vermes testacea* in general, deposits its ova upon its own shell, if nothing else comes in its way. One of the specimens of the shell of the *Janthina* caught in the voyage to the Congo fortunately has the ova so deposited." And he then refers to the drawings of Mr. Bauer, engraved as above quoted.

In the 4th vol. of the 'Journal of the Philadelphia Academy' will be found 'Remarks on the Floating Apparatus and other peculiarities of the genus Janthina,' by Reynall Coates, M.D. This highly interesting paper, the result of the author's personal observations during a voyage to the East Indies, establishes the correctness of Cuvier's remark, that no anatomical connection exists between the animals and the air-cells of their float; but does not corroborate the views of Sir Everard as to the camerated nidus on the shell which he saw with so much satisfaction. Dr. Coates placed some *Janthinæ* in a tumbler of brine, and having removed a portion of the float of one with scissors, the animal soon set to work to supply the deficiency after the following manner:—The foot was advanced upon the remaining vesicles until about two-thirds of that part rose above the surface of the water; it was then expanded to the uttermost, and thrown back upon the water, like the foot of a *Lymnæa* when it begins to swim; it was then contracted at the edges, and formed into the shape of a hood, inclosing a globule of air, which was slowly applied to the extremity of the float. There was now a vibratory movement throughout the foot, and when it was again thrown back to renew the process the globule was found inclosed in its newly-made envelope. From this it results that the membrane inclosing the cells is secreted by the foot, and that there is no attachment between the float and the animal other than that arising from the nice adaptation and adjustment of proximate surfaces. Dr. Coates states that the float varies in different species. In *Janthina fragilis* he describes it as convex, subcarinate above and concave beneath, straight, and composed of large vesicles: in *J. globosa* he found the vesicles smaller, and the float flat both above and beneath, added to which it is formed by the reunion of one of the edges into a spiral and nearly circular disc. In *J. exigua* it was straight, narrow, and flattened, and the vesicles were small. Along the under surface of the float a little line of pearly fibres was remarked, to which are attached the eggs of the animal.

Although Dr. Coates had no opportunity of observing the eggs of *J. fragilis*, he is strongly inclined to believe that the eggs figured and described in 'Phil. Trans.,' as above alluded to, belong to some other marine animal; and he grounds his belief on the dissimilarity between those figures and the eggs of *J. globosa* and *J. exigua*. In these two species the eggs are contained in little membranous bags of some consistence, which are attached in rows to the pearly fibres of the under surface of the float by small filamentous pedicles similar in appearance to the fibres. These bags are covered with minute gelatinous conical eminences, and are partially divided by incomplete septa, as may be seen by the aid of a powerful lens. In *J. exigua*, the division is very partial; but in *J. globosa* it gives to the whole sac a chambered appearance. It would seem that the animal consumed considerable time in depositing its eggs, for the bags nearest to the extremity of the float were constantly found empty, while the central bags contained young shells fully formed: those towards the animal were filled with eggs. The probability is, that the young animals when hatched ascend the float of the mother, and thus gaining access to the surface, construct the elements of their future support.

M. Rang, who also notices Sir Everard's statement, mentions it as certain that *Janthina* deposits its eggs sometimes in considerable number, as he has had occasion to remark, under the float, where they are attached by means of small pedicles; and he goes on to say, that the animal abandons them, together with the float, which is then charged with their preservation. M. Rang adds, that it is possible that, at this epoch, the natatory appendages of the mantle, being sufficiently developed, permit the animal to use them for swimming, and thus supply the loss; or one must suppose that these animals have the faculty of replacing the float. That they have that faculty we have above seen.

Browne, in his 'Natural History of Jamaica,' gives by no means a bad account of the floats of these animals, many of which he encountered between the Bermudas and the Western Islands, in his voyage from Jamaica. He says, "I have observed many of the vesiculæ themselves swimming upon the surface of the water, which induced me to think that they were thrown off as the creatures retired." Sloane also saw these oceanic snails, and figures them.

In January, 1833, Dr. Grant exhibited to a meeting of the Zoological Society of London numerous specimens of *J. vulgaris*, Lam., and of *Velella limbosa*, Lam., both animals of rare occurrence on the English coast, and chiefly met with floating in tropical or warmer seas. They were obtained by him at the beginning of September, 1832, in Whitsand Bay, close to the point of the Land's End, Cornwall, where they were thrown in great numbers on the sands, after a storm of three days' continuance from the north-west: they must, he observed, consequently have been floating before they were directed to the coast by the storm, in latitudes at least as high as that in which they were found. Dr. Grant regards it as probable that neither of these animals is capable of discharging at will the gaseous fluid by which they are supported on the surface of the sea; otherwise, in such a violent and continued tempest as that which stranded them, they would have emptied their vesicles and have sunk to the stiller bottom. ('Zool. Proc.') Browne on the other hand says, speaking of the float, "This raises and sustains it while it pleases to continue on the surface; but when it wants to return, it throws off its bladder and sinks."

Lamarck places *Janthina* among the Plant-Eaters: but in the communication by Dr. Grant above noticed, it is suggested that *Janthina*, a predaceous Gastropod accompanying *Velella*, as there described, may prey upon it, and acquire from it the blue colouring matter of its shell.

Several authors speak of the beautiful purple liquor which the living animal diffuses when it is touched.

J. fragilis, Common Oceanic Snail, has the shell pale; body whorl angulated; the base flattened, striated, and deep violet; aperture broader than long; outer lip deeply emarginate. (Swainson.)

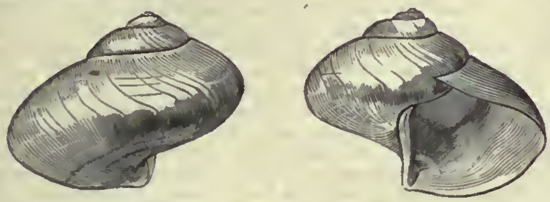
It occurs in warm and temperate climates; several instances are recorded of its capture on and near the British Islands.

J. exigua has been found on the English and Irish coasts.

J. pallida is a species nearly allied to *J. globosa*. This species is very rare, and has been obtained only twice from the coast of Ireland.

Mr. Swainson, who, in his 'Zoological Illustrations,' has given beautifully correct figures of *J. fragilis* and *J. globosa*, justly remarks that the shells are so brittle that it is rare to find them perfect.

M. De Blainville is inclined to think that those shells which are notched belong to females.



Shell of Common Oceanic Snail (*Janthina fragilis*).

Fossil Janthinæ.—Mr. G. B. Sowerby ('Genera') states that he has never seen any fossil species of this genus, nor is he aware that any exist, but he refers to a fossil engraved in 'Min. Con.,' pl. 10, which bears a very near resemblance to it. The fossil is named, in the valuable work alluded to, *Helix carinata*, and the solid gray limestone near Settle in Yorkshire is said to be the locality..

JASIONE, a genus of Plants belonging to the natural order *Campanulaceæ*. It has a 5-leaved rotate calyx, anthers cohering at the base, a hairy trifid style, 2-celled capsules, opening by a large and somewhat valvular pore at the base. There is but one British species of this genus—

J. montana, Sheep's Scabious, has a simple root, bluntish oblong wavy leaves, and stalked flowers. The stems are from 6 inches to 2 feet long, pilose, simple, or branched, leafy below, bare and glabrous above, and ascend from the crown of the root. The flowers are small, in terminal bracteated heads, having a light blue corolla.

(Babington, *Manual of British Botany.*)

JASMINA'CEÆ, *Jasminworts*, a natural order of Monopetalous Exogens, deriving its name from the *Jasminum*, which forms one of its genera. It is one of the very few orders of that class with regular diandrous flowers, and is only to be mistaken for *Oleaceæ*, which have a valvate corolla, and which otherwise are scarcely different. Only five genera of this order have yet been discovered, the principal being *Jasminum* itself, which consists of a large number of species, sometimes fragrant, sometimes scentless, erect or twining, inhabiting the hot or temperate regions of Europe, Africa, and Asia, including Australia, but hardly known in America. The order is characterised by having opposite or alternate, simple or compound exstipulate leaves; monopetalous flowers, the segments of whose corolla are imbricated, and seldom correspond with those of the calyx; two stamens, and a superior 2-celled few-seeded ovary. The species, about 100 in number, are chiefly valued for their fragrance; a few species have been regarded as bitter and astringent. [JASMINUM.]

Common Jasmine (*Jasminum officinale*).

1, a longitudinal section of the corolla; 2, a longitudinal section of the ovary and calyx.

JASMINUM, a genus of Plants belonging to the natural order *Jasminaceæ*. It has a tubular 5- or 8-cleft calyx; a 5- or 8-parted corolla; stigma 2-lobed or bifid; berry didymous, having one of the lobes usually abortive; seeds without albumen. The species are usually twining shrubs. Leaves simple or compound; petioles articulated; flowers white or yellow.

J. Sambac, Single-Flowered Arabian Jasmine, is a twining plant; the leaves almost sessile, membranous, from cordate to oblong, acute or obtuse, glabrous; berries globular; branches, petioles, and peduncles downy. It is a native of the East Indies. The flowers generally form small trichotomous umbellets, white and fragrant. The berries are black. A perfume, known as Oil of Jasmine, is obtained from this species.

J. angustifolium, Narrow-Leaved Jasmine, is a native of the Coromandel coast. It is a twining bright plant, with ovate or oblong leaves, smooth, of a shining deep-green colour. The flowers are large, white, with a faint tinge of red, star-shaped, having a peculiar but very pleasing fragrance. The bitter root of this species, ground small and mixed with powdered *Acorus Calamus* root, is considered in India as a valuable external application in cases of ringworm. The plant being constantly covered with leaves of a bright deep-green, sometimes as small as those of Box, render it always beautiful and well adapted for screening windows and covering arbours in warm climates.

J. officinale, Common Jasmine, is a native of the South of Europe. It has opposite leaves, pinnate; leaflets ovate-accuminate; buds erectish. The plant is glabrous, the branches angular. Calycine segments 5, subulate; corolla white, 4- or 5-cleft, sweet-scented; the terminal leaflet is the longest. The Common Jasmine has been a favourite wall-shrub from time immemorial. Its native country, as well as the date of its introduction, are unknown. Gerarde in 1597 says it was in common use for covering arbours. There are golden and silver-edged leaved varieties of the Common Jasmine, as well as a double flowered variety.

J. grandiflorum has opposite pinnate leaves, leaflets bluntish, the outer ones 3- to 5-confluent, buds horizontal. It is a native of the East Indies, and greatly resembles *J. officinale*, except in the size of the leaflets and in the exterior ones being confluent and the flowers larger and reddish underneath. Both this and the former species yield the true essential oil of jasmine of the shops.

The leaves of *J. undulatum* are slightly bitter. The root of *J. pubescens* is thought to be elexiteric.

(Lindley, *Vegetable Kingdom.*)

JASPER. [QUARTZ.]

JASSA, a genus of Amphipodous *Crustacea*, established by Dr. Leach.

The general characters resemble those of *Corophium*, Latr.; but differ from them as well as from those of *Podocerus*, Leach, in the considerable size of the bands of the first four feet, which are oval; those of the second pair being the greatest, and armed with teeth more or less numerous on the internal border. Eyes not projecting.

Dr. Leach records two species, one, *Jassa pulchella*, from the south coast of Cornwall, where it was found in the midst of sea-weed; the other, *Jassa Pelagica*, found near the Bell Rock, Scotland.

JATROPHA, a genus of Plants belonging to the natural order *Euphorbiaceæ*. It has monœcious flowers; a 5-parted or lobed calyx; corolla 5-parted or absent; stamens 8 or 10, with unequal monadelphous filaments; styles 2, bifid or dichotomous; capsule 3-coccous.

J. Curcas, Physic-Nut, is a very common small tree, or bush, on the coast of Coromandel. The bark is smooth and light ash-coloured; leaves scattered, stalked, broad, cordate, 5-angled, smooth, about 6 inches each way; petioles round, smooth, 4 to 6 inches long; stipules absent; panicles terminal or from the exterior axils cymose, bearing many small yellow flowers. The male flowers at the extremities of the ramifications on short articulated pedicels, and the female ones in their divisions with their pedicels not articulated. Bracts, a small one below each subdivision of the panicle, and generally one pressing on the calyx; calyx 5-leaved; corolla 5-petaled, campanulate, somewhat hairy; disc of 5 glandular bodies round the base of the filaments; filaments 6, the central one very thick, columnar, the 5 exterior ones filiform towards the base, adhering to the central one, all erect, and a little longer than the calyx; anthers 10, sagittate, equal: 5 supported by the large general filament, and 1 by each of the others. The leaves are rubefacient and discutient; warmed and rubbed with castor-oil, they are applied by the natives of India as poultices. The seeds are violently emetic and drastic; their expressed oil is reckoned a good application in itch and herpes, and also, a little diluted, in rheumatism. The milky juice is considered detergent and healing; it dyes linen black. The oil boiled with oxide of iron forms a varnish used by the Chinese for covering boxes. In large doses the seeds are energetic poisons.

J. glauca is found in Arabia Felix. It has leaves from 3-5-lobed, mucronate, serrate, toothed; petioles naked; stipules palmate, with setaceous branched divisions, glandular at the apex. The seeds yield a stimulating oil recommended by the Hindoos as an external application in cases of rheumatic and paralytic affections.

J. glandulifera is a native of the East Indies. The leaves about the extremities of the branchlets are alternate, petioled, and generally palmate; the lobes from 3 to 5, oblong, serrate, with each serrature ending in a short green glandular-beaded bristle; stipules bristly, many-cleft, each division ending in a glandular head; panicles terminal, about as long as the leaves. Male flowers most numerous and terminal, small, of a pale yellowish-green colour. The female flowers few, and subsessile in the divisions of the panicle. The pale or whey-coloured thin juice which exudes from a fresh wound is employed by the Hindoos as an escharotic to remove films from the eyes.

J. multifida is a native of tropical America. It has palmate 11-lobed smooth leaves, the segments wedge-shaped and pinnatifid; stipules setaceous, multifid; flowers corymbose, scarlet, with coloured pedicels. The seeds are one of the best of all emetics and purgatives, acting briskly, but without inconvenience: their effects are readily stayed by the administration of a glass of good white wine.

J. Manihot is now referred to the genus *Janipha*. [JANIPHA.]

(Lindley, *Flora Medica.*)

JAVELIN-SNAKE. [MELEAGRIS.]

JAY. [CORVIDÆ.]

JEFFERSONITE, a Mineral belonging to the varieties of *Augite*. [AUGITE.]

JEFFREYSIA, a genus of *Mollusca* belonging to the family *Littorinidæ*, established by Mr. Alder, and named after Mr. Jeffreys of Swansea. The species were originally referred to *Rissoa*. Forbes and Hanley give two species, *J. diaphana* and *J. opalina*, as inhabiting British seas.

JEJUNUM. [INTESTINES.]

JELLY. [FOOD.]

JERBOA. [MURIDÆ.]

JER-FALCON, or GYR-FALCON, the English name of the *Falco Islandicus* of Latham, Gerfaut of the French, Hebog Chwyldro of the Welsh. [FALCONIDÆ.]

JERICHO, ROSE OF, a name applied to the *Anastatica*, a genus of Plants belonging to the natural order *Cruciferæ*. This genus has the following characters:—Silicle ventricose, with the valves bearing each an appendage on the outside at the end; petals obovate. There is but one species—

A. Hierochuntina, the Rose of Jericho, or Holy Rose. The whole plant is small, the stem branched, dichotomous; the leaves oblong or ovate, narrowed at the base into the petiole; the pods somewhat pubescent. The leaves fall off from the plant after flowering, and the branches and branchlets become dry, hard, and ligneous, and rise upwards and bend inwards at their points; hence they become contracted into a globular form, and in this state the plant is with facility removed from the sand by the wind, and blown from the desert places where it grows into the sea. When the plant is immersed in water the branches gradually expand, and the pods open and let out the seeds, which are again thrown on the shore by the tide. This plant long preserves the power of expansion when immersed in water, hence many wonderful stories are told of its influence. It is called Kaf Maryan, or Mary's Flower, in Palestine, where it is believed that this plant opened at the time of the birth of our Saviour. It is a native of the arid wastes in Egypt near Cairo, also of Palestine and Barbary. It grows on the roofs of houses and on rubbish in Syria, and on the sandy coasts of the Red Sea.

(Don, *Dichlamydeous Plants.*)

JET, a variety of Coal, which occurs sometimes in elongated reniform masses, and sometimes in the form of branches, with a woody structure; fracture conchoidal; soft and brittle; specific gravity but little greater than that of water; lustre brilliant and resinous; colour velvet black; opaque. It is found in Saxony, and also in the Prussian amber-mines, in detached fragments. The finer sorts are used for the manufacture of ornaments and trinkets, and the coarser kinds as fuel; it burns with a greenish flame and a strong bituminous smell, and leaves a yellowish ash. [COAL.]

JOHANNITE. [URANIUM.]

JOHNSTONITE. [LEAD.]

JOINT-FIRS. [GNETACEÆ.]

JONE'SIA, a genus of Plants of the tribe *Cassieæ*, and of the natural family of *Leguminosæ*, which was named by Dr. Roxburgh in honour of Sir William Jones, who, in the midst of his numerous other avocations, found time to pay attention to Indian plants. The species are few in number, and indigenous in the islands of the Malayan Archipelago, as well as on the eastern frontier of Bengal, that is, in Silhet and lower Asam. They form trees which are highly ornamental from their handsome shining abruptly-pinnate leaves, and from the showy nature of their crowded racemes of flowers.

J. Asoca, the best known species, is often referred to by Hindoo poets by the name which has been adopted by botanists to distinguish it as a species. Dr. Roxburgh says, and we can in a great measure coincide with him in opinion, "When this tree is in full blossom, I do not think the whole vegetable kingdom affords a more beautiful object." ('Flora Indica,' ii. p. 220.)

JUDAS-TREE. [CERCIS.]

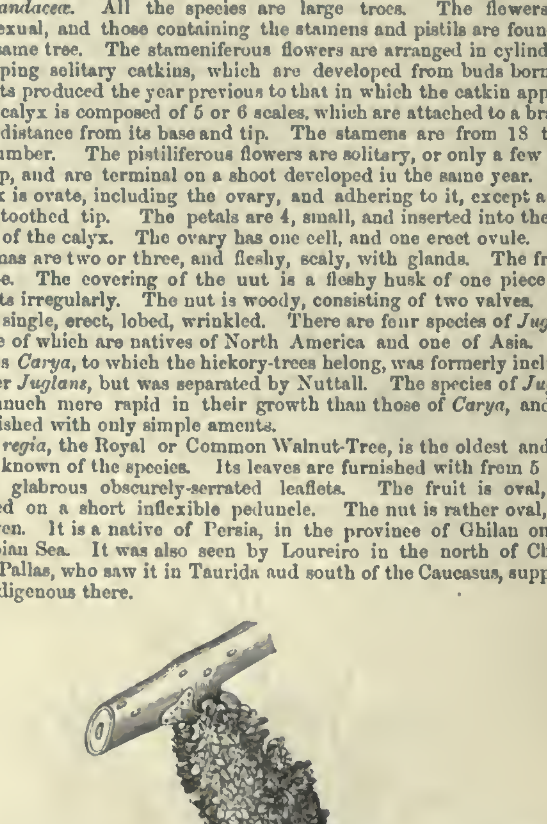
JUDCOCK. [SCOLOPACIDÆ.]

JUGLANDA'CEÆ, *Juglands*, are a natural order of Apetalous Exogenous Plants, consisting of trees or shrubs having eatable nuts and somewhat resinous leaves. The former are the walnuts and hickory nuts of the markets; the first produced by the genus *Juglans*, the latter by that called *Carya*. The leaves are alternate and pinnated; the flowers usually monœcious, those which are male collected in catkins. The calyx of the latter consists of a few scales attached obliquely to a single bract, and surrounding a variable number of stamens; that of the females is superior. The ovary is 1-celled, and has one solitary erect ovule, which changes into a 4-lobed seed, with crumpled cotyledons, inclosed in a 2-valved nut, clothed with a fleshy epicarp. The Common Walnut (*Juglans regia*), a native of Persia, is well known for its excellent timber, from which musket-stocks (and formerly cabinet-work) are manufactured, for its agreeable wholesome nuts, and the sweet drying oil which they furnish when pressed. *Carya alba*, the White Hickory, bears nuts like those of the walnut, only smaller, smoother, and with a thicker shell, and furnishes a valuable tough elastic white timber much employed in the construction of carriages and other vehicles. Other species of Hickory are also eaten, especially the Pecan Nut, the produce of *Carya olivæformis*, a small and delicate sort. Although the fruit of these plants is eaten, it contains a purgative principle, which renders some of the species cathartic, as is the case with *J. cathartica* and *J. nigra*, two North American species; and even the common walnut participates so much in this quality, when the fruit is young, that a laxative conserve well known in domestic medicine is prepared from it. *J. nigra*, the Black American Walnut, is a tree of remarkable size and beauty.

The species are chiefly found in North America, a few are East Indian, one species a native of Persia and Cashmere, another of Caucasus, and a third of the West India Islands. There are 4 genera and 27 species.

JUGLANS, a genus of Plants belonging to the natural order *Juglandaceæ*. All the species are large trees. The flowers are unisexual, and those containing the stamens and pistils are found on the same tree. The stameniferous flowers are arranged in cylindrical drooping solitary catkins, which are developed from buds borne by shoots produced the year previous to that in which the catkin appears. The calyx is composed of 5 or 6 scales, which are attached to a bractea at a distance from its base and tip. The stamens are from 18 to 36 in number. The pistiliferous flowers are solitary, or only a few in a group, and are terminal on a shoot developed in the same year. The calyx is ovate, including the ovary, and adhering to it, except at the four-toothed tip. The petals are 4, small, and inserted into the free part of the calyx. The ovary has one cell, and one erect ovule. The stigmas are two or three, and fleshy, scaly, with glands. The fruit a drupe. The covering of the nut is a fleshy husk of one piece that bursts irregularly. The nut is woody, consisting of two valves. The seed single, erect, lobed, wrinkled. There are four species of *Juglans*, three of which are natives of North America and one of Asia. The genus *Carya*, to which the hickory-trees belong, was formerly included under *Juglans*, but was separated by Nuttall. The species of *Juglans* are much more rapid in their growth than those of *Carya*, and are furnished with only simple aments.

J. regia, the Royal or Common Walnut-Tree, is the oldest and the best known of the species. Its leaves are furnished with from 5 to 9 oval glabrous obscurely-serrated leaflets. The fruit is oval, and seated on a short inflexible peduncle. The nut is rather oval, and uneven. It is a native of Persia, in the province of Ghilan on the Caspian Sea. It was also seen by Loureiro in the north of China; and Pallas, who saw it in Taurida and south of the Caucasus, supposed it indigenous there.



Royal or Common Walnut-Tree (*Juglans regia*).

1, a catkin of male flowers; 2, a single male flower; 3, a cluster of female flowers.

The Walnut-Tree was known to the Greeks under the name of Persicon, Basilicon, and Caryon. It is uncertain at what time it was first cultivated in Europe, but it was cultivated by the Romans before the death of the emperor Tiberius. Its wood was much valued by the Romans, and the nuts were also eaten. There is no history of the introduction of this tree into Great Britain, but it is now very commonly cultivated in this country, although it fails to propagate itself by its seeds. It is only however in the southern and middle parts of England that the walnut brings its fruit to perfection.

The walnut, when full-grown, is a large handsome tree with strong spreading branches. Its trunk is thick and massive, and covered with a deeply furrowed bark; the branches are of a gray colour, and smooth. The leaves, when bruised, give out a very peculiar aromatic odour, and in the heat of summer this scent is sometimes so powerful as to produce unpleasant effects on persons who approach these trees. The foliage is graceful and light, and of a bright yellowish-green colour, which contrasts well with trees having foliage of a darker shade. Its leaves are almost the latest to appear, and the first to fall. It grows very rapidly and vigorously in the climate of London, and trees will attain a height of 20 feet in ten years. It sends down into the earth a large tap-root, with numerous branches, and, on account of the size and strength of the roots, there is no tree more able to resist the effects of wind, or better adapted for exposed situations. It is said that plants will not grow under its shade; this probably arises from the bitter properties of its leaves: when they are not allowed to accumulate, the shade of the walnut does not appear more injurious than that of other trees.

The uses of the walnut are very various. Before the introduction of mahogany and other woods, the wood of the walnut was held in higher estimation than that of any other European tree. It is on this account that it was so extensively cultivated in this country and on the continent three or four centuries since. The timber of the walnut is light, a cubic foot weighing when green 58¼ lbs., and when dried scarcely 47 lbs. When the tree is young, the wood is white, and in this state very much subject to be worm-eaten; but as the tree grows older, the wood becomes more compact, and is of a brown colour, veined and shaded with brown and black. In France and Germany it is still much used by turners, cabinet-makers, joiners, coachmakers, and musical-instrument makers, who prefer the wood which has grown on poor hilly soils. The wood of the roots is the most beautifully veined. One of the most important uses of walnut-timber is the making of gun-stocks. For this purpose it is well adapted on account of its strong lateral adhesion, its lightness, and its not being liable to splitting or warping in the working. The demand for walnut-wood for this purpose was immense during the last war on the continent, and it was stated in 1806 that France required 12,000 trees annually for the making of guns. The government of France still maintains large plantations of walnut-trees for supplying her army with gun-stocks. In England the walnut has seldom been used except for the higher-priced fire-arms, but such was the demand for it for that purpose at the beginning of the present century, that single walnut-trees were sold for as much as 600*l.* This led to the importation of walnut-timber from the Black Sea, and also of the timber of the black walnut from America, so that the cultivation of the tree as timber is almost at an end in England.

The walnut is of more value at the present day on account of its fruit than of its timber. In almost every stage of its growth the fruit of the walnut is used for the table. When young, green, and tender, it is pickled and preserved with the husks on. About the end of June they may be preserved with or without their husks. "The green and tender nuts," says Gerarde, "boyled in sugar and eaten as suckade, are a most pleasant and delectable meat, comfort the stomach, and expell poyson." When they are about half ripe, a liqueur is distilled from them, which is considered to possess medicinal properties. In August, before they are quite ripe, the French eat them in what they call 'cerneaux,' scooping out the kernel with a knife, and eating it with vinegar, salt, pepper, and shallots. When the nuts are fully ripe, which is generally at the end of September or the beginning of October, the kernel, deprived of its investing skin, is eaten in great quantities. As long as the skin can be easily removed they are a nutritious and healthy article of diet; but when they get dry, so that their skins stick to them, they become indigestible. In no part of England do they constitute an important article of diet, but in many parts of France, Spain, Germany, and Italy, people live during the season of their ripening almost entirely on walnuts. A great number of the walnuts consumed in England are of foreign growth. In 1831 there were imported from France and Spain 23,578 bushels, which then paid a duty of 2*s.* per bushel. As they are now free of duty, the importation is not registered. On account of the large consumption of the fruit, both as an article of diet at home and for exportation, the walnut-tree is still largely cultivated on many parts of the continent. The district of the Bergstrasse on the Rhine, between Heidelberg and Darmstadt, is almost entirely planted with walnut-trees. Evelyn states that such is the importance attached to the growth of this tree, that "in several places between Hanau and Frankfort in Germany, no young farmer is permitted to marry a wife till he brings proof that he is a father of a stated number of walnut-trees; and the law is inviolably observed to this day for the extraordinary benefit which this tree affords the inhabitants." The fruit of the walnut is commonly gathered by thrashing the tree with a long pole. By many this process is thought to be beneficial to the tree, and barren walnut-trees are often thrashed to make them bear. But although barren trees may be made to bear by reducing the excessive growth of their shoots by breaking them off, it is no proof that the same process is good for healthy-bearing trees. The natural process of separating the fruit from the tree is undoubtedly the best, and gently shaking the branches till the fruit falls has been recommended by many walnut-growers as much preferable to thrashing. The nuts should be gathered at the time they easily fall out from the husk, and then exposed to dry for a day or two in the sun. The best mode of keeping the nuts fresh for eating is to bury them in dry soil or sand, so deep as not to be reached by frost or the heat of the sun, or by rain: or they may be placed in dry cellars, and covered with straw. "When the nut is to be preserved through the winter for the purpose of planting in the following spring, it should be laid in a rot-heap as soon as gathered, with the husk on; and the heap should be turned over frequently in the course of the winter." (Loudon.)

The albumen which constitutes the bulk of the seed of the walnut contains an oil, which is used in large quantities, especially on the Continent. It is obtained by reducing the seeds to a pulp by means of a stone wheel and basin, and then expressing the oil, first without heat and then by the application of heat. The oil requires great care in keeping, as it becomes tainted by slight changes in the state of the atmosphere. That which is cold-drawn keeps best, and is alone used for the purposes of diet. It has however always the taste of the walnut, which is to some persons disagreeable. The oil obtained by heat is used by artists, and also for lamps. Artists use this oil in mixing white, or any delicate colour; and they prefer it on account of the rapidity with which it dries. In copper-plate printing also, in Paris, walnut-oil is considered indispensably necessary in order to obtain a fine impression, whether in black or in colours. For this purpose the oil is prepared in various ways, according to the several colours with which it is to be mixed. In all cases it is reduced in bulk by boiling or by setting fire to it, so as to reduce it to the required consistency. One bushel of nuts, it is said, will yield about 7 lbs. of this oil. The mass which is left after the oil is expressed is made into cakes, and used as food for swine, sheep, and poultry, and in some places it is made into candles, which give a tolerably good flame.

The husks and root of the walnut both yield a dye, which is much used by gipsies and theatrical performers for staining the skin brown. It is also used by cabinet-makers and joiners to stain white and yellow woods of a dark-brown or black colour, like that of the walnut. In the preparation of the dye from the husks they should be allowed to rot, and then boiled in water, adding to the decoction fresh water, according to the colour required to be produced by the solution. The sap of the walnut-tree contains a large quantity of saccharine matter; and in some countries the trees are tapped for the purpose of obtaining the sap, which by evaporation is converted into sugar. It is also in many parts of Europe and Asia fermented and made into wine, and a spirit is also distilled from it. The leaves of the walnut, as well as other parts of the tree, contain a large proportion of alkali in them; and in some parts of France they are collected and burned for the sake of the potash contained in the ashes.

The bark of the leaves, the husks, and the oil of the walnut have all been used in medicine, and had at one time a great reputation. All parts of the plant, excepting the albumen of the seed, possess a bitter principle, which acts as a tonic and an anthelmintic, and has been its great recommendation as a medicine. Cowley, in his 'Plants,' sums up the virtues of the walnut in the following lines:—

"On barren scalps she makes fresh honours grow.
Her timber is for various uses good:
The carver she supplies with useful wood.
She makes the painter's fading colours last.
A table she affords us, and repast.
E'en while we feast, her oil our lamp supplies.
The rankest poison by her virtues dies;
The mad dog's foam and taint of raging skies.
The Pontic king, who lived where poisons grew,
Skilful in antidotes, her virtues knew."

Anglers employ an infusion of the leaves or husks for pouring upon the earth, in order to procure worms, which it speedily brings to the surface.

There are several distinct varieties of the walnut cultivated. The *J. maxima* is known by the large size of its nuts, and is called the Double Large French. The nuts are twice the size of any other; but in drying the kernels shrink to half their size, so that they ought to be eaten as soon as they are gathered. This is a fine handsome tree with large leaves, but its timber is not so durable as that of the Common Walnut.

J. r. tenera, the Thin-Shelled or Titmouse Walnut, has very thin shells, so much so that birds of the titmouse family pierce them with their bills, and eat the kernel. The fruit of this variety is considered the best for eating, and it also yields the largest quantity of oil.

J. r. serotina, the Late-Leaved Walnut, is a very desirable variety in districts where the frosts are severe in spring. Its leaves do not appear before the end of June, and it ripens its fruit as early as the other varieties. There is a variety known in Norfolk and Suffolk by the name of the Highflier, which is said to yield the best nuts of any of the English varieties. Several other varieties are enumerated in continental lists; and in the 'Fruit Catalogue of the Horticultural Society for 1832,' nine varieties were recorded as growing in the gardens of the Society.

J. nigra, the Black Walnut-Tree, has leaves with from 13 to 17 leaflets, which are unequal at the base, serrated, and somewhat downy. The fruit is globose, roughish, with minute prominent points, situated upon a short inflexible peduncle. The nut is globose, somewhat compressed at the sides, ridged, and furrowed. This is a North American tree, and is found in all parts of the United States, as far as 40° 50′ N. lat. It is abundant in the forests about Philadelphia, and is met with from Goshen to the banks of the Mississippi, throughout an extent of 2000 miles. It is one of the first trees that was introduced from America to Europe, having been brought to England by the younger Tradescant in 1656. The Black Walnut is a rapid-growing tree, and attains a height of 50 or 60 feet in about forty years. It bears fruit in this country, but it is very much inferior to that of the European walnut. The wood of this tree is used almost for the same purposes as that of the last. It is heavier, stronger, susceptible of a finer polish than the European species, and is not so liable to be attacked by worms.

J. cinerea, the Gray Walnut or Butternut-Tree, has 15 to 17 leaflets, rounded at the base, serrate, and tomentose beneath; the petiole villous; the fruit oblong-ovate with a taper tip, downy, and covered with small transparent vesicles containing a viscid matter. The nut is oval with very prominent irregular ridges. This tree is from North America. It is found in Upper and Lower Canada, and in the temperate regions of the United States. This tree attains in its native regions a height of about 50 or 60 feet. Although it was introduced into this country about the same time as the last species, there are very few large specimens at the present time. The kernel of the nuts is thick and oily, and soon becomes rancid, and hence probably the names of Butter-Nut and Oil-Nut. The wood is used in the districts where it grows for the same purposes as the last. Its bark possesses considerable medicinal powers, and is used in the United States as a purgative and as an application in toothache. Its leaves also are so acrid that they are employed, when powdered, as a substitute for cantharides.

All the species of walnuts are best propagated by the nut, which, when the tree is intended for ornament or timber, should be sown in the place where it is wished it should remain, as the large tap-root of these trees is likely to be injured by removing them, although with great care they may be successfully transplanted. When trees are planted for the sake of their fruit they are mostly increased by budding, grafting, and sometimes by layering. "The most approved and successful mode of budding, and which is the one chiefly adopted on the continent, is that called the 'flute' method; in performing which an entire ring of bark, containing one or more buds, is exactly fitted to the upper extremity of the stock, which is also denuded of its bark; should the stock be larger than the ring containing the buds the ring requires to be slit up, but if this exceeds the stock, then a small portion requires to be cut out so as to make it fit. Mr. Knight also invariably succeeded in budding the walnut by using the minute buds that are found at the base of the annual shoots of this tree, which, as he says, 'are almost concealed in the bark, and which rarely if ever vegetate, but in the event of the destruction of the large prominent buds which occupy the middle and opposite ends of the annual wood.'" (Selby.) These he inserted on yearly stocks which grew in pots, the vegetation of which had been retarded by exposing them during the spring and early part of the summer in a northern aspect, until the above-mentioned buds were formed on the current year's shoots of the trees intended to be propagated, when the pots containing the young plants were brought into a forcing-house, and there budded. There is no tree that requires less pruning than the walnut, and where large branches are cut off it is almost invariably followed by a decay of the tree at the spot where abscission was performed. The best soil for the walnut is a deep, stiffish, dry-bottomed loam. It will thrive however almost anywhere, provided the soil is free from stagnant moisture. The best fruit is obtained from trees growing on calcareous soils.

Previous to the time of the publication of Nuttall's 'Genera of North American Plants,' the various species of North American trees called Hickory were regarded as species of the genus *Juglans*. These Nuttall referred to a new genus, *Carya*. [CARYA.] There is another species, formerly referred to *Juglans*, and called *J. fraxinifolia*, that Kunth has made into a genus called *Pterocarya*. It differs from *Juglans* in its fruit having two wings, and in the embryo not being accompanied by albumen. It is a native of moist woods at the foot of the Caucasus, and hence called *P. Caucasica*. It is a small tree with an ample bushy head, attaining a height of 30 or 40 feet. Its leaves are alternate, very large, commonly having 19 leaflets, which are oblong, denticulate, with blunt teeth. Each of the leaflets has one of the sides shorter than the other. It has not been much planted in Great Britain, but is well adapted for small gardens and arboretums as an example of the natural order *Juglandaceæ*.

(Loudon, *Arb. et Frut. Brit.*; Selby, *British Forest-Trees*; Burnett, *Outlines of Botany*; Michaux, *North American Sylva*; *Encyclopædia of Gardening*.)

JUGULAR VEINS, the large venous trunks by which the greater part of the blood is returned to the heart after having circulated in the head, face, and neck. There are two on each side, an external or superficial, and an internal or deep. The external jugular lies on each side just under the skin, and extends from near the angle of the jaw to the middle of the clavicle, behind which it opens into the subclavian vein. It conveys the blood of the confluent streams from the jaws, temples, and front and sides of the neck, and of some of those from the face. The internal jugular, which is far larger than the external, lies deep in the neck, by the side of the carotid artery. It receives all the blood from the skull and the brain, from the eyes and ears, and from the scalp, face, tongue, palate, pharynx, &c. The internal jugular veins extend from the base of the skull just in front of the vertebral column, down the neck, to some depth behind the clavicles, where they unite with the subclavian veins, by which all the blood is brought from the arms and upper part of the chest and neck to form the venæ innominatæ, which by their union form the vena cava superior, which opens directly into the right auricle of the heart. [HEART.]

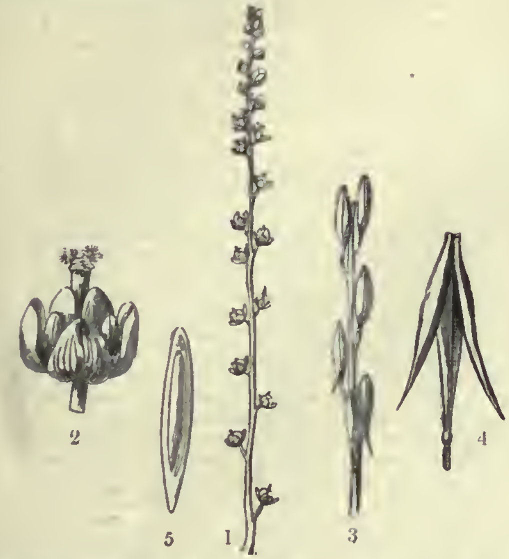
JULIS, a genus of Fishes belonging to the family *Labridæ*. The head is smooth; cheeks and gill-covers without scales, the lateral line bent suddenly downwards when opposite the end of the dorsal fins. In other respects this genus resembles *Labrus*. [LABRIDÆ.] An example of a very beautiful species of this genus, known under the name of the Rainbow-Wrasse, was described by Donovan as taken off the coast of Cornwall. It is the *J. Mediterranea* of Risso, the *J. vulgaris* of Fleming and Cuvier. This fish is most remarkable for its varied colours. Its back is greenish-blue; the longitudinal band is orange; beneath that are lilac-coloured bands on a silvery ground; the head is varied with brown, yellow, blue, and silver; the dorsal fin orange, with a purple spot on the membrane connecting the three spinous rays. (Yarrell, *British Fishes*.)

JUNCA'CEÆ, *Rushes*, a small natural order of Endogenous Plants, so named from *Juncus*, the Rush, which is considered its type. It is principally composed of obscure herbaceous plants, with brown or green glumaceous hexandrous flowers, and would perhaps be with more propriety considered a section of *Liliaceæ* than a separate order. It forms one of the transitions from complete Endogens to the imperfect glumaceous form of that class. The species are chiefly found in the colder parts of the world, some even in the coldest; two existing in the ungenial climate of Melville Island. Some however are known in the tropics. Eight are mentioned as inhabiting the tropical parts of Australia. They are only employed for mechanical purposes, as the rush and others. There are 13 genera and 200 species. [RUSHES, in ARTS AND SC. DIV.]

Juncus articulatus.

1, a flower spread open; 2, a capsule; 3, a seed cut through its longer axis, showing the embryo.

JUNCAGINA'CEÆ, *Arrow-Grasses*, a small and unimportant order of Endogenous Plants, consisting of marsh plants with thin minute scaly flowers formed of 3 sepals, 3 petals, and as many stamens, which are opposite them. Their ovaries are 3 or 6 in number, contain each one or two ascending ovules, and when ripe form a dry fruit. The embryo has a lateral slit for the emission of the plumule, on which account they are regarded as allied to *Araceæ*. The genus *Scheuchzeria* is a transition from Arrow-Grasses to Rushes. *Triglochin* is the commonest genus of the order, and inhabits the fresh or salt marshes of most parts of Europe. Marshy places in most parts of the world may be expected to indicate traces of this order, which is found in Europe, Asia, North America, the Cape of Good Hope, and equinoctial America.



1, *Triglochin palustre*; 2, a flower magnified; 3, a spike of ripe fruit; 4, a ripe capsule; 5, a section of one of the cells of the capsule, with the seed inclosed in it.

Potamogeton occurs in ditches and swamps as far north as Iceland. The root of *Potamogeton natans* is said to be eaten in Siberia; the foliage of others is regarded as a styptic. There are 7 genera and 44 species.

JUNCALES. [Endogens.]

JUNCUS, a genus of Plants belonging to the natural order *Juncaceæ*. This genus is distinguished by its inferior perianth, composed of 6 glumaceous leaves; its 3-celled 3-valved capsules, the seed-bearing dissepiments of the valves being in their middle. The species are numerous, and are found mostly in moist boggy situatious in the colder parts of the world: several are however inhabitants of tropical regions.

J. effusus, the Soft Rush, and *J. conglomeratus*, the Common Rush, are used in many parts of the country for plaiting into mats, chair-bottoms, and for constructing small toy-baskets. The wicks also of the candles known as rush-candles are made from the pith, or more properly speaking the soft inner portion of the stem of the same species, which is chiefly composed of cellular tissue. The species is cultivated in Japan like rice entirely for making floor-mats.

Rushes of various kinds form frequently very troublesome weeds in agriculture. They grow best on rich land that is wet and cold. They may be destroyed by covering them over with dry materials of various kinds, as ashes, lime, aud drift from roads; but the best mode of getting rid of them is to fork them up by the roots in the summer, and after letting them lie for a fortnight or three weeks to dry to burn them. This however will be found only a temporary mode of getting rid of them unless the ground on which they grow is well drained.

JUNGERMANNIA'CEÆ, *Scale Mosses*, a rather extensive natural order of Cryptogamic Plants, or Acrogens, resembling mosses in appearance, but very distinct from them in many points of structure. Their foliage is much more cellular; their seed-vessel, or theca, splits into four valves, has no operculum, and instead of a central column has a number of tubes, each furnished internally with a double elastic spiral thread, and called an elater, to which the spores stick, and by the aid of which they are supposed to be dispersed. The species inhabit the trunks of trees, damp earth, or even the young shoots and leaves of other plants in hot moist climates. Some have the stem and leaf formed into a frond, or thallus, resembling that of a lichen, but more commonly the species have leaves with stipules at their base. A large number of genera has of late been formed out of the old genus *Jungermannia*, but the opinions of botanists are much divided as to the value of these new divisions; and they have not been generally adopted. Hooker's 'Monograph of the British Jungermanniæ' gives a valuable account of the species inhabiting these islands. A more recent account of the whole European genus is to be found in Nees von Esenbeck's 'Naturgeschichte der Europäischen Lebermoose,' 2 vols., 8vo., with plates.

The following is a synopsis of the genera:—

Sub-order *Jungermanneæ*.

Metzgeridæ.
Metzgeria.
Aneuridæ.
Trichostylium.
Aneura.
Haplolaenidæ.
Blasia.
Symphyogyna.
Pellia.
Diplomitridæ.
Hollia.
Codonidæ.
Fossombronia.
Jubulidæ.
Lejeunia.
Phragmicoma,
Frullania.
Physananthus.
Ptychanthus.
Madotheca.
Radula.
Ptilidæ.
Ptilidium.
Trichocolla.
Mastigophoridæ.
Sendtnera.
Schisma.
Trichomanidæ.
Physiotium.
Herpetium.
Lepidozia.
Mastigobryum.
Calypogeia.
Geocalycidæ.
Gongylanthus.
Geocalyx.
Saccogyna.
Jungermannidæ.
Gymnoscyphus.
Cheiloscyphus.
Harpanthus.
Gymnanthe.
Lophocolea.
Jungermannia.
Plagiochila.
Gymnomitridæ.
Alicularia.
Acrobolbos.
Sarcoscyphus.
Gymnomitrium.
Haplomitrium.

Sub-order *Anthoceroteæ*.

Anthoceros.
Cladobryum.
Monoclea.

Jungermannia nemorosa, highly magnified.

1, a branch in fruit; 2, a leaf, with sori upon it; 3, the contents of those sori; 4, the calyptra, before it is burst by the theca; 5, abortive thecæ, in a very young state; 6, elaters.

JUNIPER. [Juniperus.]

JUNI'PERUS, a genus of hardy evergreen woody Plants, belonging to the natural order *Coniferæ*. Its distinctive character consists in its female fructification being succulent, consolidated, and reduced in the number of its parts below what is usual in the order to which the genus belongs. Like other *Coniferæ*, its fruit is composed of scales representing carpels spread open, and collected in a spiral manner round a common axis. But they are not more than six in number, generally three, and when ripe are fleshy, and consolidated into a body resembling a drupe. In the language of the Pharmacopœia they are berries, in that of botanists they are termed *Galbuli*.

About 20 species are known, the most important of which are the following:—

J. communis, the Common Juniper. This is a common bush, with long narrow sharp-pointed leaves, which are coucave and glaucous on the upper side, but convex and green on their under, and with blackish fruit. It grows wild iu all the northern parts of Europe, and, as is said, in North America also and the north of India, but it is doubtful whether the plants called Juniper by travellers in the Himalaya Moutains are not some other species. Occasionally the Juniper becomes a small tree. The fruit is used in considerable quantities in the preparation of gin, and in medicine as a powerful diuretic; a kind of beer called genévrette is also obtained in some parts of France by fermenting it with barley. The words 'gin' aud 'Geneva' are derived from the French uame of this species, Genevre. Oil of Juniper, obtained from the *Galbuli*, is said to be a useful diuretic.

J. Sabina, the Savin. This species is readily known from the last by its leaves being small, scale-like, and pressed close to the stem, besides which, its fruit is a light bluish-green. It forms a compact gloomy-looking bush, in some cases spreading near the ground, in others acquiring the stature of a low tree. It is found wild in the middle of Europe and the west of Asia, inhabiting the most sterile soil, and is frequently met with in this country in shrubberies. Like the common Juniper, it is a diuretic aud uterine stimulant. For this purpose it is ofteu used criminally, but whilst it often destroys life it seldom accomplishes the object for which it is taken. Oil of Savin is a local irritant, producing blisters when applied to the skin; taken iuternally it is drastic and emetic.

J. Virginiana, the Red Cedar. Notwithstanding its popular name this is not generally the plant that yields the cedar wood used by cabinet-makers and pencil-manufacturers, the Bermuda cedar being principally so employed; its timber however is of great excellence and durability. It is a native of North America, from Cedar Island in Lake Champlain as far as the southern side of the Gulf of Mexico, chiefly preferring the vicinity of the sea. In general it is a large bush; but in favourable situations, and in such a climate as that of Virginia aud Carolina, it becomes a tree 40 feet high. The branches of this species are erect, the leaves arranged in threes, small, scale-like, and but little spreading; the fruit is deep blue, covered with a mealy resinous powder. A great many fine plants occur in this country; it is not however with us an object of any importance to the forester, except for the sake of variety.

J. Bermudiana, the Bermuda Red Cedar. Very little known in Great Britain, in consequence of its not bearing the climate without protection. It is a native of the Bermudas, where it becomes a large tree, with a soft fragrant wood, the value of which is well knowu from its use in cabinet-work and the manufacture of pencils. It has, when young, long narrow spreading leaves growing in threes, but on the branches of old trees they become shorter, are placed in fours, and thus give the shoots a four-cornered appearauce.

Of the other Junipers, *J. excelsa* aud *J. Chinensis* are handsome hardy trees; *J. Lusitanica*, the Goa Cedar, is also of great beauty, because of its drooping habit and light gray branches, but it will not live loug in Euglaud except in the warmest of the southeru couuties; and *J. Phœnicea* is a handsome bush: the others are of little moment.

JUNKERITE. [IRON.]

JURA KALK, the German equivaleut of the Oolitic system of England.

JURGON. [ZIRCONIA.]

JUSTI'CIA, a genus of Exogenous Plants belonging to the natural order *Acanthaceæ*. The species of this genus inhabit all the tropical parts of the world, preferring however damp woods to dry and open plaius. It is especially in the forests of Brazil and India that they occur. Many of them are never woody, some are bushes or small trees, and a small number are valued by gardeners as objects of ornament. As limited by Linnæus, the genus compreheuded a very discordant collection of species; modern writers have accordingly broken it up into many new genera. As now limited, *Justicia* itself scarcely coutains a plant of any importauce.

As among the species now removed from *Justicia* to other genera there are some which are useful as medicinal agents, especially in India, it may be as well to mention them here, instead of referring to genera which are not yet generally known. Thus *J. Adhatoda*, celebrated in Sauscrit works by various names, as Vidiumatri, Vasika, &c., has been called *Adhatoda Vasika*, and is chiefly esteemed as a demulceut in coughs. *J. nasuta* is now *Rhinacanthus communis*, and is much employed in Indian medicine, especially for the cure of ringworm and other cutaneous affectious, mixed, according to Dr. Roxburgh, with lime-juice and pepper. It is also one of their remedies for suake-bites, but is no doubt inefficacious for such purposes. *Andrographis* (formerly *Justicia*) *paniculata* is the best known and probably the most valuable of all, as one of its names, Muha-tita, implies Chief, or King of Bitters; it is also very commouly called Kalup-uath, and well known to Europeans in the peninsula of India by the uame of Creyat, or Kreat, and has been prescribed with benefit as a bitter in this country. It forms one of the ingredieuts of the Drogue Amère, which is well known in India, and at one time obtained cousiderable repute as a cure for cholera; but it can be useful ouly as a stimulant and tonic.

K

KÆMPFE'RIA, a small genus of Indian *Scitamineæ*, or *Zingiberaceæ* of some authors, of which the species are indigenous to the Islands of the Archipelago and the southern parts of the continent of India, as Bengal and the districts on its eastern frontier. All are furnished with tuberous roots like the turmeric and ginger plants. The spikes of the flowers are short and rising from the root, in some species before, in others with, and nestled among the leaves; all are highly ornamental, and *K. rotunda*, called by the natives Bhooi Chumpa, or Ground Chumpa, is much cultivated in gardens on account of the beauty and fragrance of its flowers. It was supposed to yield the round Zedoary of the shops, but incorrectly, as Dr. Roxburgh thinks, since he considers his *Curcuma Zedoaria* to be the plant. So *K. Galanga* was, equally incorrectly, long supposed to yield the Galanga of the shops. [GALANGA.] It is a native of the mountainous districts beyond Chittagong, and there called Kumula, and is cultivated by the Mugs; by them it is sold to the people of Bengal, who use it as an ingredient in their betel. The roots possess an agreeable fragrant smell, and a somewhat warm, bitterish, aromatic taste. The Hindoos use them, according to Dr. Roxburgh, not ouly as a perfume, but also medicinally. The roots of *K. angustifolia* are, according to the same authority, used as a medicine for cattle by the people of Bengal.

KAFFIR-BREAD [ENCEPHALARTOS.]

KAHAU. [NASALIS.]

KAIL, or KALE. [CRAMBE.]

KAKATERRA-TREE. [DACRYDIUM.]

KAKOXENE, a Mineral occurring in small crystals, which appear to be 6-sided prisms terminated by pyramids, disposed in radiating tufts. The colour yellow of several shades, and sometimes brownish-red. The lustre silky, sometimes adamantine. Adheres to the tongue, and has an earthy smell.

It occurs in clayey brown iron-stone at Zbirow, in Bohemia. Analysis by Steinman:—

Phosphoric Acid	17·86
Fluoric Acid and Water	25·95
Peroxide of Iron	36·82
Alumina	10·01
Silica	8·90
Lime	0·15
	——99·69

When placed on a hot coal it emits a green phosphoric light, and before the blow-pipe on charcoal decrepitates: with borax forms a deep green-coloured glass, and with soda a blackish mass.

KALE, SEA. [CRAMBE.]

KALI, the name of the Maritime Plant from the ashes of which soda is obtaiued by lixiviation; and from the name of this plant, with the Arabic article *al*, is derived that of a class of substances possessing peculiar properties, which are called alkalies. Kali was also formerly employed to designate the alkali Potash.

KALIPTRITE, a Mineral consisting of the oxide of iron, manganese, and zinc, with water and silica.

KALMIA, a genus of Plants named by Linnæus in honour of Peter Kalm, professor at Abo in Finland, belonging to the natural order *Ericaceæ*. It has a small 5-leaved calyx, a cyathiform corolla, with an angular very open limb, having 10 niches in its sides. The capsules 5-celled and many-seeded. The species are evergreen shrubs, with alternate or verticillate leaves.

K. latifolia has its leaves on long petioles, scattered or three in a whorl, smooth and green on each side. It is a native of North America from Canada to North Carolina, on the sides of stony hills. It has various names in the United States, Laurel Ivy, Spoon-Wood, Calico-Bush, &c. The flowers are red, and when in blossom have a very elegant appearance. The leaves of this species are said by Barton to be poisonous to man and beast, but their action can be but feeble and unimportant, for animals are known to feed on the plant without any evident effect. Bigelow however states that the flesh of pheasants having eaten this plant has produced some cases of severe disease attributable to this cause alone. The flowers of the *K. latifolia* exude a large quantity of sweet nectarous juice, which is greedily collected by bees and wasps, but the honey formed from it is injurious to man, and the juice, if swallowed by itself, will produce an intoxication of an alarming kind. A brown powder which adheres to the shoots and branches is used as a sternutatory by the Americans.

K. angustifolia, Haulm-Leaved Kalmia, has petiolate leaves, scattered or three in a whorl, oblong, obtuse, rather rusty beneath; corymbs lateral, bracts linear; peduncles and calyxes clothed with glandular pubescence. It is a native of North America from Canada to the Carolinas, in bogs and swamps, and sometimes in dry mountain lands. It is a shrub 7 or 8 feet in height, with dark red flowers, It is called Sheep-Laurel in North America, as it is supposed to be very injurious to sheep. Several varieties of this plant with lighter and darker flowers have been described. There are several other species, all of them natives of North America. They are all remarkable for the irritability of their stamens, and each of the stamens has a little cavity formed for it in the corolla, to serve as a protection to the anthers.

They are handsome shrubs when in blossom, and are great favourites in gardens and shrubberies. They grow best in a peat soil, or they may be planted in a very sandy loam or vegetable mould. They may be propagated by layers or seeds. When the seeds are used they should be sown early in the spring in flat pans or pots filled with peat-earth, and very slightly covered over; the pots may be then set in a close frame, or in the front of a hothouse, till the plants come up, when they may be transplanted to other pots, which should stand in a close frame till they have struck root; they should then be hardened to the air by degrees.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines of Botany*.)

KAMMERERITE, a Mineral, consisting of a hydrous silicate of alumina and magnesia which occurs crystallised and massive. The common form of the crystal is a 6-sided prism. The cleavage is perpendicular to the axis only. Cleavage planes have a pearly lustre. Colour, that of some crystals, which, by daylight is so dark that their red colour is scarcely perceptible, appears by candlelight quite red. Massive variety, usually composed of fine laminæ. The colours are sometimes dark violet-blue, sometimes yellowish or greenish, or greenish-white. Translucent on the edges, particularly after immersion in water. Fracture compact, fine-grained, becoming splintery or leafy on the less compact varieties; flexible. Dull, or of a greasy lustre, often glistening. When scratched it gives a light peach-blossom red or almost white streak. Hardness 2·0 to 2·5. Specific gravity 2·64. Found in the Ural Mountains. Analysis, by Hartwell:—

Silica	37·0
Alumina	14·2
Magnesia	31·5
Lime	1·5
Oxide of Chromium	1·0
Water	13·0
	98·2

KANGAROO, the common name of the animals belonging to the genus *Macropus*, and the family *Marsupiata*. [MARSUPIATA.]

KANGAROO APPLE. [SOLANUM.]

KAOLIN. [CLAY; FELSPAR.]

KARPHOLITE, a Mineral which occurs in minute crystals and in stellated silky fibres. It scratches fluor-spar, and is scratched by felspar. Colour wax or straw-yellow. Lustre of the crystals vitreous; of the fibres silky. Specific gravity 2·93.

Before the blow-pipe on charcoal it fuses into a dark glass, which becomes darker in the interior flame. With borax it melts into a transparent glass, which in the exterior flame has a manganese colour, and in the interior becomes greenish. The following are analyses by Stromeyer and Steinman:—

	Stromeyer.	Steinman.
Silica	36·154	37·53
Alumina	28·669	26·48
Oxide of Manganese	19·160	17·09
Oxide of Iron	2·290	5·64
Lime	0·271	...
Fluoric Acid	1·470	...
Water	10·780	11·36
	98·794	98·10

KARPHOSIDERITE, a Mineral consisting of a hydrous phosphate of iron, which occurs in reniform masses. Its structure is granular, compact. Fracture uneven. Hardness 4·0 to 4·5. Specific gravity 2·5. Colour pale and bright straw-yellow, and streak the same. Lustre resinous. Feels greasy. Opaque. When heated in a tube gives off water, and a vapour which reddens litmus paper.

Before the blow-pipe, per se, it becomes black, and melts into a globule which obeys the magnet; with salt of phosphorus, it forms a black scoria. It is found at Labrador.

KAWRIE-PINE. [AGATHIS.]

KEELING, a Fish. [MORRHUA.]

KELLIADÆ, a family of minute *Mollusca* belonging to the Lamellibranchiate *Acephala*. Forbes and Hanley place this family between *Lucinidæ* and *Cycladidæ*. The British *Kelliadæ* embrace the genera *Montacuta*, *Turtonia*, *Kellia*, *Lepton*, and *Galeonura*. [MONTACUTA; TURTONIA; LEPTON.] The genus *Kellia* has two British representatives, *K. suborbicularis* and *K. nitida*. They are small but elegant bivalves, living in the crevices of rocks, or on shells or sea-weeds, spinning a byssus, or lying free. There are about a dozen species known in different parts of the world. This genus, from which the family takes its name, was named after Mr. O'Kelly of Dublin.

KEMAS. [CAPREÆ.]

KERMES-MINERAL. [ANTIMONY.]

KERODON (F. Cuvier), a genus of *Rodentia*, bearing in some respects resemblance to that of *Cavia*, but differing both in the locomotive and masticatory organs.

Dental Formula:—Incisors, $\frac{2}{2}$; molars, $\frac{4-4}{4-4} = 20$.

Teeth of *Kerodon*. F. Cuvier.

The molars all resemble each other, and are composed of two equal parts, each of a triangular or rather cordiform shape, united on the external side of the tooth, and separated on its internal side. These triangles, or 'hearts,' are each surrounded by their enamel and filled with bony matter, and their separation produces an angular notch partly filled with cortical substance.

When F. Cuvier wrote but one species, *K. Moco*, was known, and this was discovered by Prince Maximilian of Neuwied, and noticed by him under the name of *Cavia rupestris*. The fur is ash-gray mixed with reddish-yellow, blackish above and whitish below. Size, smaller than that of the Guinea-Pig.

This species was found in the rocky places of the interior of Brazil, near Rio San Francisco.

In 1836 Mr. Bennett exhibited to a meeting of the Zoological Society of London a Rodent sent home among the animals collected by Captain Phillip Parker King, R.N., during his survey of the Strait of Magalhaens, and presented by him to the Society, which Mr. Bennett regarded as a second species of *Kerodon*, and for which he proposed the name of *K. Kingii*. It was chiefly distinguishable from that discovered by Prince Maximilian by its more uniform colour. Excepting a slight dash of white behind the ear, and a longer line of the same colour marking the edge of each branch of the lower jaw, the animal is entirely gray; the upper surface being distinguished from the under by a greater depth of tint, and by the intermixture of a free grizzling of yellow and black. The crowns of the molar teeth, as in the typical species, consist of bone surrounded by two triangles of enamel, the bases of which are connected by a short line of enamel passing from one to the other, all the lines being slender and sharply defined.

This species was found at Port Desire, on the eastern coast of Patagonia. ('Zool. Proc.,' 1835.)

Mr. Waterhouse refers the genus *Kerodon* to *Cavia*. [HYSTRICIDÆ.]

KEROLITE, a Mineral, consisting of a hydrous silicate of alumina and magnesia, which occurs massive and reniform. Structure lamellar or compact. Colour white, yellow, or green; streak white. Fracture conchoidal. Hardness 2·0 to 2·25. Lustre vitreous or resinous. Transparent, translucent. Specific gravity 2·0 to 2·2. Feels greasy, but does not adhere to the tongue. It is found at Frankenstein in Silesia, and at Zöblitz in Saxony, and also in New York and New Jersey, United States. The following is an analysis by Pfaff:—

Silica	37·95
Alumina	12·18
Magnesia	16·02
Water	31·00
	97·15

KESTREL. [FALCONIDÆ.]

KEUPER, in Geology, the German term for the upper portion of the New Red-Sandstone formation. It is supposed by some geologists that certain sandstones in Warwickshire, Worcestershire, and other parts of England, correspond to this group of strata. Remains of reptiles are said to have been found in it near Warwick.

KHAYA, a genus of Plants of the natural family of *Cedrelaceæ*, which is often made a tribe of the *Meliaceæ*. *Khaya* contains only a single species, *K. Senegalensis*, which has been well figured in the 'Flore de Senegambie,' i. t. 32. It forms one of the largest and handsomest of the trees which are found along the banks of the Gambia and in the valleys near Cape Verd. It attains a height of from 80 to 100 feet, and is also one of the most common of the trees of the forest, being called Cail by the negroes, and Cail-Cedra by Europeans. The wood is of fine quality, reddish-coloured like that of mahogany, which belongs to the same natural family. The bark is remarkable for its bitterness and febrifuge properties, and is taken by the negroes in the form of infusion and decoction, as a cure for the fevers so prevalent in their country.

KIANG. [EQUIDÆ.]

KIDNEYS are two glands lying in the lumbar region, on each side of the spinal column. They are composed of numberless and delicate tubular ramifications, on whose walls there is a fine network of capillary arteries and veins, and which are all collected into one mass of a firm fleshy consistence, inclosed in a fibrous capsule.

The ureter, through which the urine secreted by the kidney is conveyed to the bladder, dilates at its extremity into a wide pouch, the pelvis of the kidney, which is divided into several portions called calyces. Into each calyx a nipple-like process, or papilla, projects, at whose extremity there are several minute orifices, each opening into a very fine canal, which, as it is continued into the substance of the kidney, ramifies and becomes tortuous. On all these canals, or tubuli uriniferi, minute bloodvessels ramify, and secrete the urine, which is conveyed from the tubuli into the calyces, and from them through the pelvis and the ureter into the bladder.

The papillæ, and the conical bodies called pyramids, of which they are the extremities, being chiefly composed of the excretory canals, are nearly white, and of a firm dense structure; but as the tubuli ramify, their branches separate in a somewhat radiating manner, and the bloodvessels filling the intermediate spaces between them give to all the exterior part of the kidneys a deep red-colour, and a softer and more fleshy consistence. Hence the kidney is generally described as divided into a cortical, or vascular, and a medullary or tubular portion.

The general structure of the kidney may be best shown by making a section from its convex border into the pelvis. The surface of each part then presents several whitish conical bodies, the pyramids, whose rounded apices, the papillæ, project into corresponding tubular calyces, and whose bases are surrounded by the vascular cortical substance. In the latter no distinct arrangement of vessels can be seen, but there are scattered irregularly through it minute granular bodies called the acini, or corpuscles of Malpighi, which are composed of delicate tortuous arteries.

In the early embryo of *Mammalia* each papilla, with the tubules opening on it and its bloodvessels, forms a separate body; but during growth the several renculi are united into one mass, their original separation being however indicated by the more or less deeply lobulated form of the organ in various animals, and occasionally in man. [URINARY SYSTEM; URINE.]

KILLAS, the local name of a group of rocks in Cornwall, ranked by geologists with the Clay-Slate, or Grauwacke Slate of other countries. The term is perhaps most properly applied to denote fissile argillaceous rocks, such as are usually called clay-slate; but it is often extended to other earthy compounds allied to these by geological position. (Conybeare, 'Ann. Phil.,' new series, vol. vi.) Near granite the Killas is supposed by many geologists to undergo great alterations of character, to become 'metamorphic,' so as to assume more or less of the characters of pyrogenous rocks. In these 'altered' rocks lies a great part of the mineral wealth of Cornwall; tin and copper veins abound in them, as well as in the contiguous granite, to whose influence their mineral characters are ascribed. Dr. Borlase, in his work 'On the Geology of Cornwall,' assigns to these rocks the title of *Cornubianite*.

KILLBRICKENITE. [ANTIMONY.]

KILLENITE, a Mineral which occurs both crystallised and massive. The crystals are imperfect: the primary form appears to be a rhombic prism. The cleavage is parallel to the lateral faces and short diagonal. Fracture uneven. Structure lamellar. Colour greenish and brownish-yellow. Streak yellowish-white. Lustre glimmering, dull, vitreous. Translucent. Opaque. Specific gravity 2·698. Hardness 4·0; scratched by the knife. Frangible.

It occurs in granite veins at Killeny near Dublin, and is stated by Dr. Thomson to consist of—

Silica	49·03
Alumina	30·60
Potash	6·72
Oxide of Iron	2·27
Water	10·00
	——98·67

By the blow-pipe it becomes white, swells up, and fuses into a colourless enamel.

KING-CRAB. [LIMULUS.]

KING-FISH. [LAMPRIS.]

KINGFISHERS. [HALCYONIDÆ.]

KINGLET. [REGULUS.]

KINGSCLERE, a village in Hampshire, remarkable for the exhibition of the Greensaud Formation in the midst of the elevated chalk downs, on the line of an anticlinal axis passing east and west. The anticlinal axis passes through the middle of a valley (hence called a 'valley of elevation') in which the greensand appears; and it might seem on a first view that the discontinuity of the chalk was simply owing to elevation and fracture, but by considering the areas and slopes of the strata, in plans and sections on a true scale, it will immediately appear that a considerable mass of chalk must have been removed by denudation. For the knowledge of this interesting 'valley of elevation' we are indebted to Dr. Buckland. ('Geol. Trans.,' 2nd series, vol. ii.) Sir Charles Lyell has contemplated it in connection with the more extensive denudation of the Weald of Kent and Sussex. (*Principles of Geology.*)

KINGSTON, a Fish. [SQUALIDÆ.]

KINIXYS. [CHELONIA.]

KINKAJOU. [VIVERRIDÆ.]

KINO. [PTEROCARPUS.]

KINOSTERNON. [CHELONIA.]

KIRWANITE, a Mineral consisting of silicate of iron, &c. It occurs filling cavities in a kind of basaltic rock. The texture is fibrous, fibres diverging from a centre and forming brushes. The colour is dark olive-green. Opaque. Hardness 2·0. Specific gravity 2·941. It is found on the north-east coast of Ireland. The following analysis is by R. D. Thomson:—

Silica	40·50
Protoxide of Iron	23·91
Lime	19·78
Alumina	11·41
Water	4·35
	——99·95

KITE. [FALCONIDÆ.]

KITE. [RHOMBUS.]

KITTA. [CORVINÆ.]

KITTIWAKE. [LARIDÆ.]

KLEY, a Fish. [MORRHUA.]

KLIPPSPRINGER. [ANTILOPEÆ.]

KNAPPIA, a genus of Plants belonging to the natural order *Gramineæ*. It has an inflorescence, with a somewhat one-sided raceme. The flowers solitary; glumes not keeled, and blunt. It has 2 paleæ, which are scarious, very hairy, obtuse, unequal, and without awns. There is but one species of *Knappia*—

K. agrostidea, an elegant but very small grass, with a small fibrous root, having numerous stems and short rough leaves. The spikes are slender, consisting of from 5 to 10 mostly sessile alternate spikelets. It is found in sandy maritime pastures, but is a rare grass.

(Babington, *Manual of British Botany.*)

KNAP-WEED. [CENTAUREA.]

KNAUTIA (named after Christopher Knaut, a German botanist), a genus of Plants belonging to the natural order *Dipsaceæ*. The inner calyx is cup-shaped, with radiant teeth, the outer one forming a thickened margin to the germen. It has a 4-fid corolla, a fruit with 4 sides and 8 little depressions, the receptacle with spinous scales shorter than the involucre.

K. arvensis, the Field Scabious, has its lower leaves simple, the stem-leaves pinnatifid, the inner calyx with 8 or 16 somewhat-awned teeth. The stem rises from 2 to 3 feet in height, is slightly branched, and with but few leaves. The flowers are purple, in large convex long-stalked heads. This is the only British species of this genus. There are a few species of *Knautia* natives of Europe.

(Babington, *Manual of British Botany*; Don, *Dichlamydeous Plants.*)

KNEBELITE. [MANGANESE.]

KNOT. [SCOLOPACIDÆ.]

KNOT-GRASS. [POLYGONUM.]

KNOTWORTS. [ILLECEBRACEÆ.]

KNOWLTONIA, a genus of Plants belonging to the natural order *Ranunculaceæ*. It has 5 sepals, from 5 to 15 petals, with the margins naked. The stamens and ovaries numerous; many 1-seeded succulent fruits, not pointed by the style, which is deciduous. The species are 1-seeded perennial herbs, with greenish-yellow flowers.

K. vesicatoria is a plant which has the appearance of an umbelliferous perennial. It has biternate leaves, the segments somewhat cordate, rigid, and smooth, the lateral obliquely truncate at the base. The umbels are nearly simple, and few-flowered. The leaves are used as vesicants in the Cape of Good Hope. There are four other species, natives of the Cape of Good Hope, where these plants grow in abundance. They will thrive well in a mixture of loam and peat, and may be increased either by dividing the root or by seed.

(Don, *Dichlamydeous Plants*; Lindley, *Flora Medica.*)

KOALA. [MARSUPIATA.]

KOBELLITE, a Mineral resembling sulphuret of antimony, but is more brilliant. The structure is radiated, crystalline. Streak and powder black. Specific gravity 6·29 to 6·32. It is found in the cobalt-mine at Huena in Sweden. Analysis by Setterberg :—

Sulphuret of Lead	46·36
Sulphuret of Bismuth	33·18
Sulphuret of Antimony	12·70
Sulphuret of Iron	4·72
Sulphuret of Copper	1·08
Gangue	1·45
	99·49

KOBRE'SIA, a genus of Plants belonging to the natural order *Cyperaceæ*. It has the spikes aggregate; the lower flower pistiliferous, the perigone of one scale inclosing the germen and covered by the glume. The upper flower staminiferous without any perianth. There is but one species of this genus, *K. caricina*, which has an erect stem from 6 to 12 inches in height, slender leaves shorter than the stem, from 4 to 5 spikes aggregated at the summit of the stem, and from 6 to 8 flowers. There is often an abortive stamen at the base of the nut. This plant is found throughout Europe and in Great Britain, on moors in Yorkshire, Durham, and Perthshire. (Babington, *Manual of British Botany*.)

KOBUS. [ANTILOPEÆ.]

KOELE'RIA, a genus of Plants belonging to the natural order *Graminaceæ*. It has unequal glumes, the upper one with 2 or 3 ribs, shorter than the spikelet, which is compressed. The outer palea is nerved, keeled, and acuminate; the seed loose, and the styles terminal. There is but one British species of this genus :—

K. cristata has a compact panicle, spiked, oval, and interrupted below, the outer palea 3-ribbed and acute; the leaves narrow, rough at the edges, and ciliated. In dry places the leaves are much shorter than the stem; in damper places elongated, and often nearly as loug as the stem.

(Babington, *Manual of British Botany*.)

KOGIA. [CETACEA.]

KOLLYRITE, a Mineral consisting of a hydrous silicate of alumina, which occurs massive. Colour white. Fracture earthy. Nearly opaque. Lustre somewhat vitreous. Hardness 3·25. Specific gravity 2·06 to 2·11. It is found at Schemnitz in Hungary, and in a lead-mine on the bank of the river Oo, in the Pyreuees. The following analysis is by Berthier :—

Silica	19·0
Alumina	40·5
Water	40·5
	100

KONIGA, a genus of Plants belonging to the natural order *Cruciferæ*. It has an oval compressed pouch, from 1 to 2 seeds in each cell, simple filaments, and 8 hypogynous glands. But one British species of this genus has been discovered, *K. maritima*, which is a procumbent plant, with bipartite hairs, linear-lanceolate acute leaves, oval pointed glabrous pods. It is the *Lobularia* of Koch, and the *Glyce* of Lindley. The flowers are white and sweet-scented. (Babington, *Manual of British Botany*.)

KONIGITE, a Mineral consisting of sulphate of copper which is insoluble. *Krisuvigite* is one of the same species.

KOODO. [ANTILOPEÆ.]

KRAMERIA, a genus of Plants belonging to the natural order *Polygalaceæ*. It has 4 or 5 sepals, irregular, coloured, spreading, deciduous; petals 5 or 4, irregular, smaller than the calyx, the three inner unguiculate; stamens 1, 3, or 4, hypogynous, unequal; ovary 1-celled, or incompletely 2-celled; style terminal; stigma simple; ovules in pairs, suspended. Fruit between hairy and leathery, globose, covered with hooked prickles by abortion, 1-seeded, indehiscent. The species are spreading many-stemmed undershrubs. The leaves alternate, simple, entire, or 3-foliate, spreading; racemes simple, spiked.

K. triandra is found on dry gravelly and sandy hills in Peru, flowering all the year round. It is known by the name of Ratanhy Root. It is a suffruticose plant, with a horizontal very long and branched root, with a thick bark, reddish-brown outside, red inside. It has a procumbent stem, much branched and taper; the branches are from 2 to 3 feet long, when young, silky; leaves alternate, sessile, oblong and obovate, acuminate, entire, hoary on each side; flowers solitary, axillary, and stalked; calyx silky externally, smooth and shining inside, of the colour of lac. The two upper petals are separate, spathulate, the two lateral roundish and concave; the drupe is dry and hairy, barred, with dull red hooks. The extract of the plant is styptic and tonic, and operates powerfully upon tumours, resolving and restoring tone to those parts. When administered internally the extract of Ratanhy is apt to be rejected by the stomach till three or four doses have been taken. It is best to take it in the form of pills. It is commonly used in Peru as tooth-powder.

(Lindley, *Flora Medica*.)

KRAMERIACEÆ. [POLYGALACEÆ.]

KRAURITE. [IRON.]

KRISUVIGITE. [KONIGITE.]

KROKYDOLITE, a Mineral containing silica and iron. It occurs asbestiform, fibrous, and compact. Colour lavender or indigo blue. Streak lavender blue or leek green. Lustre silky. Opaque. The fibrous variety is flexible and elastic. It is found on the Orange River in Southern Africa. The following is an analysis of the fibrous variety by Stromeyer :—

Silica	51·64
Protoxide of Iron	34·38
Soda	7·11
Magnesia	2·62
Oxide of Manganese	0·02
Lime	0·05
Water	4·01
	99·83

KUPFERINDIG (*Indigo Copper*, *Blue Copper*), a Mineral which occurs in spheroidal masses, presenting superficial indications of crystallisation. Colour dark blue. Fracture uneven. Hardness about 2·0. Lustre faintly resinous, Opaque. Specific gravity 3·8. It is found at Sangerhausen in Thuringia, and also in the volcanic rocks of Vesuvius, in black or greenish blue incrustations. Its analysis by Walchner affords—

Sulphur	32·64
Copper	64·77
Iron	0·46
Lead	1·04
	98·91

KUPFERSCHAUM, a Mineral containing arsenate of copper, which occurs crystallised. Primary form a right rhombic prism. Occurs in rhomboidal plates, which present perfect cleavage parallel to the faces of the rhomb; generally in small aggregated and diverging fibrous groups of a pale apple-green or verdigris-greeu colour. Streak paler. Hardness 1·0 to 1·5. Lustre pearly on the faces of the rhomb. Translucent. Flexible in thin laminæ. Specific gravity 3·0 to 3·2. It is found at Matlock in Derbyshire, in the Bannat, at Lebether in Hungary, in Siberia, the Tyrol, and at Saalfeld in Thuringia. Its analysis by Von Kobell affords—

Arsenic Acid	25·01
Oxide of Copper	43·88
Carbonate of Lime	13·65
Water	17·46
	100

KYANITE (*Cyanite*, *Disthene*, *Sappare*). This Mineral occurs crystallised and massive. Its primary form is a doubly oblique prism. The cleavage is parallel to the faces of the primary form. Fracture uneven. Hardness of the sharp portions sufficient to scratch glass. Colour white, yellow, and various shades of blue and green. Streak white. Lustre vitreous, pearly. Transparent; translucent. Specific gravity 3·6.

By the blow-pipe it is infusible, aud merely becomes white even in a very strong fire; with borax it readily dissolves into a colourless transparent glass. The following are analyses by Laugier and Arfwedson :—

	Laugier.	Arfwedson.
Silica	38·50	34·33
Alumina	55·50	64·89
Lime	0·50	...
Oxide of Iron	2·75	...
Water and Loss	2·75	...
	100	99·22

It is found in Switzerland, in Scotland, and many other parts of Europe, and also in North and South America.

L

LA'BEO (Cuvier), a genus of Fishes belonging to the family *Cyprinidæ*. The species of this genus resemble the true Carps in having the dorsal fin long, but they do not possess the strong spine of the anal and dorsal fins. The lips are very thick and fleshy, and more or less crenulated. There are no cirri. An illustration of this genus will be found in the *Cyprinus Niloticus* of Geoffroy St. Hilaire. ('Poissons du Nil,' pl. xi. f. 2.) The *Cyprinus fimbriatus* of Bloch, 'Schn.,' p. 441, sp. 24, and the *Catostomus cyprinus* of Lesueur, also belong to the genus *Labeo*, which has no representative in the Europeau seas.

LABIA. [FORFICULIDÆ.]

LABIATÆ. [LAMIACEÆ.]

LABIDOURA. [FORFICULIDÆ.]

LABIDUS. [MUTILLIDÆ.]

LABLAB, a name, it is said, of Egyptian origin, which has been adopted by botanists to designate a genus of Papilionaceous *Leguminosæ* of the tribe *Phaseoleæ*. This genus, like *Dolichos*, from which it has been separated, is a twisting climber, with leaves composed of three large leaflets. The flowers are in racemes, and either white or purple-coloured. The legumes are large, scimitar-shaped, flat, and compressed, tubercularly muricated along the sutures, and having the seeds separated from one another by transverse partitions. It is on account of these seeds and legumes that the species are valued and cultivated in hot countries such as India, Egypt, and the West India Islands, as well as in China. In India *L. vulgaris* and *L. cultratus* are chiefly cultivated in the rainy season in gardens, and may be considered the analogues of the French and kidney beans of European gardens.

LABRADORITE (*Labrador Felspar*, *Glaucolite*), a Mineral which occurs in rolled or imbedded crystalline masses. Its cleavage is parallel to the planes of a doubly-oblique prism. Fracture uneven, conchoidal. Hardness 5·5 to 6·5. It scratches phosphate of lime, and is scratched by quartz. Colour white, gray; richly iridescent. Lustre vitreous. Translucent. Specific gravity 2·69 to 2·76.

When powdered and heated in muriatic acid it gelatinises. On charcoal before the blow-pipe it fuses into a compact glass, with a brilliant fracture.

It is found on the coast of Labrador, and in Devonshire imbedded in a trap rock. It is probably a variety of *Albite*.

The following is an analysis of the mineral from Labrador:—

Silica	55·75
Alumina	26·50
Lime	11·00
Soda	4·00
Oxide of Iron	1·25
Water	0·50
	99

LABRAX (Cuvier), a genus of Fishes of the section *Acanthopterygii* and family *Percidæ*. The fishes of this genus are closely allied to the true Perches, but may be distinguished by the opercular bones being covered with scales, the absence of denticulations on the suborbital and interopercular bones, the operculum being terminated by two spines, and likewise by the tongue being almost entirely covered with minute and closely-set teeth. There are two dorsal fins.

L. Lupus (Cuvier), a fish commonly known in this country by the name of the Basse, and sometimes called the Sea-Dace, is abundant in the Mediterranean; its flesh being excellent food, it has been long known, and was called by the Romans *Lupus*, and by the Greeks *Labrax*.

Head of Basse (*Labrax Lupus*).

The Basse is not unfrequently met with on our own shores: it is generally from about 12 to 18 inches in length, but sometimes attains a much larger size. The upper parts of the head and body are dusky blue, passing into silvery white on the sides and belly; the fins are pale-brown. In form it very much resembles the perch, and, like that fish, it has two distinct dorsal fins, the rays of the first being spinous, and those of the second being flexible: the scales are of moderate size.

L. lineatus of Cuvier and Valenciennes, the Rock-Fish or Striped Basse of the United States, also belongs to the present genus, and indeed very closely resembles *L. Lupus* in form, but attains a larger size, and is adorned with seven or eight longitudinal black lines on a silvery ground-colour. There is also a second American species of Basse, the *L. mucronatus* of Cuvier and Valenciennes, which differs from the former in having no black lines on the sides of the body, and in being of a smaller size and deeper and shorter form.

LA'BRIDÆ (Labroides, Cuvier), according to Cuvier's 'Règne Animal,' a family of Fishes of the order *Acanthopterygii*. The fishes belonging to this family are of an oblong form, covered with scales, usually of large size, formed of simple laminæ, and with the external or posterior margin smooth; they have a single dorsal fin supported in front by spinous rays, each of which is generally furnished with a membranous appendage; the jaws are covered by thick fleshy lips; two upper pharyngeals are attached to the cranium, and, together with a large lower pharyngeal, are armed with teeth, which are large and rounded, sometimes pointed or laminated, and generally very strong. The intestinal canal is without cœca, or when these appendages are present they are of small size, and there is a simple and strong natatory bladder. The following are the genera contained in this family:—

Labrus proper, the characters of which are—opercula and preopercula without spines or dentations; cheek and operculum covered with scales; lateral line straight, or nearly so. Of this genus, the species of which are called Wrasses, we have several examples on the British coast.

L. maculatus, Bloch, the Ballan Wrasse, is not unfrequently met with on various parts of our coast; it is about 18 inches long, of a red colour above, pale-orange beneath, and adorned with bluish-green oval spots; the fins and tail are green, with a few red spots, the dorsal fin is spotted at the base. The length of the head compared to the whole length of the fish is as one to four, and the depth of the body is equal to the length of the head. The fin-rays are—dorsal, 20 + 11; pectoral, 15; ventral, 1 + 5; anal, 3 + 9; caudal, 13. Besides this species Mr. Yarrell describes, in his 'History of British Fishes,' the following:—*L. lineatus*, the Green-Streaked Wrasse; *L. variegatus* (Gmel., Linn.), the Blue-Striped Wrasse; *L. vetula* (Bloch), the Sea-Wife; *L. carneus* (Bloch), the Red Wrasse; *L. comber* (Gmel., Linn.), the Comber-Wrasse.

Ballan Wrasse (*Labrus maculatus*).

Cheilinus, Lacép.—The species of this genus differ only from the true *Labri* in having the lateral line interrupted opposite the end of the dorsal fin, and commencing again a little below the break. The scales on the tail are large, and extend on the fin. These fishes inhabit the Indian Ocean, and are very beautiful in colouring.

Lachnolaimus, Cuv., may be thus characterised:—Anterior spines of the dorsal fin with long flexible filaments; pharyngeals furnished with a villous membrane, with rounded flat teeth on the hinder part. The known species are from America.

Julis, Cuv., is distinguished from *Labrus* proper by the head being entirely smooth and without scales, and the lateral line being suddenly bent opposite the end of the dorsal fin.

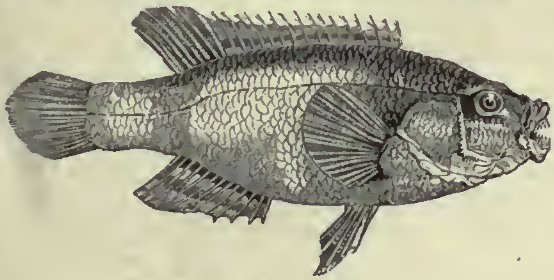
Julis Mediterranea, Risso (*J. vulgaris*, Cuv.), the Rainbow-Wrasse, has been caught off the British coast; but it appears here to be scarce, though a well-known fish in the Mediterranean. It is of a slender and elongated form, and remarkable for the elegant distribution of its colours, which change according to the light and position: on each side of the body is a broad dentated stripe, extending from the head nearly to the tail, of a silvery and fulvous colour. The fin-rays are—dorsal, 9 + 13; anal, 2 + 13; caudal, 13; pectoral, 12; and ventral, 1 + 5. A specimen described by Donovan, which exceeded seven inches in length, was caught off the coast of Cornwall, and is the only recorded instance of the occurrence of the species on the British coast.

Rainbow Wrasse (*Julis Mediterranea*).

The species of the genus *Anampses* of Cuvier differ from those of the genus *Julis* in having two flat teeth in each jaw, which project and curve outwards.

The genus *Crenilabrus* of Cuvier has the general characters of *Labrus* proper, but the margin of the pre-operculum is dentated.

Crenilabrus Tinca, Flem., called the Gilt-Head, Connor, &c., is found on many parts of our coast, and indeed is one of the commonest species of the family *Labridæ* we possess; it is from 8 to 10 inches in length; the upper parts are marked with alternate red and bluish longitudinal lines; below the lateral line the colour is bluish-green, spotted with dull red; head brownish-red, with undulating lines of an azure-blue colour; dorsal, caudal, and ventral fins bluish-green, spotted, and lined with red; pectorals pale and immaculate; greatest depth of the body very nearly one-third of the entire length.



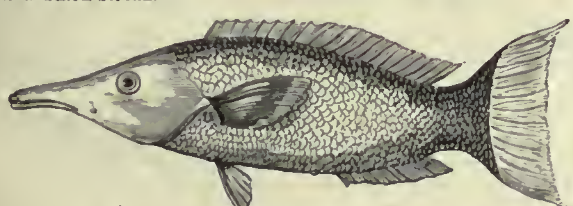
Gilt-Head (*Crenilabrus Tinca*).

The works on British fishes contain three other species of the present genus. The Goldsinny (*C. cornubicus*, Risso), the Gibbous Wrasse (*C. gibbus*, Flem.), and the Scale-Rayed Wrasse (*C. luscus*, Yarrell). [Crenilabrus.]

In the genus *Coricus*, Cuvier, we find the same characters as in *Crenilabrus*; but the mouth is protractile, though not quite in so great a degree as in the next genus, *Epibulus* (Cuvier), where the species have the power of extending the mouth to a great degree: in the fishes of the last-mentioned genus the head and body are covered with large scales, which extend both on the caudal and anal fins; the lateral line is interrupted, and there are two long conical teeth in each jaw, behind which the teeth are comparatively small and blunt. The only species known (*Epibulus insidiator*) inhabits the Indian Ocean. *Clepticus* (Cuvier), which is the next genus in succession, has for its distinguishing characters—the snout small and cylindrical, which may be suddenly protruded like that of *Epibulus*, but which is not so long as the head: the teeth are minute, the body oblong, and the head obtuse; the lateral line is continuous, and the dorsal and anal fins are almost entirely enveloped by scales. But one species is known (the *C. genizara*, Cuvier), and this is from the Antilles.

In the genus *Gomphosus* (Lacépède) the muzzle is remarkably long and slender, owing to the prolongation of the maxillary bones; the head is smooth, as in *Julis*. The species inhabit the Indian Ocean.

Gomphosus viridis, Bennett ('Fishes of Ceylon'), is found off the coast of Ceylon, and is of a dark green colour: the pectoral fin is marked with a black streak.



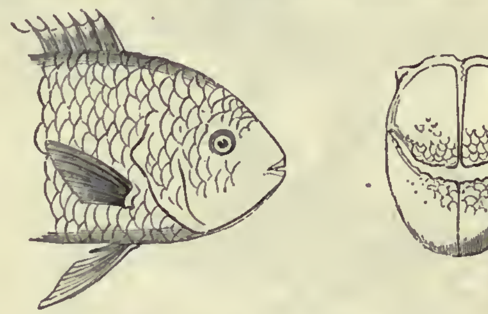
Gomphosus viridis.

Xyrichthys (Cuvier).—The fishes of this genus are of a compressed form, and have the profile of the head high and nearly vertical: the body is covered with large scales; the lateral line is interrupted; the jaws are furnished with a range of conical teeth, of which those in the centre are the longest; the pharynx is beset with hemispherical teeth. The compressed form and almost vertical profile of the head caused the older authors to arrange these fishes with the *Coryphænæ*. The *Xyrichthys novacula* (*Coryphæna novacula*, Linn.), or Razor-Fish of the Mediterranean, affords an example of this genus: it is of a red colour, irregularly striped with blue.

Chromis, Cuvier.—With the thick lips, protractile intermaxillaries, pharyngeal bones, filaments to the dorsal spines, and the general appearance of a *Labrus*, these fishes have the teeth in both jaws and on the pharyngeals slender and thickly set, or, as Cuvier describes them, 'en carde,' but in front of these there is a range of conical teeth. The vertical fins are filamentous. The ventral fins are often prolonged into long filaments. The lateral line is interrupted. A small species of this genus, which is of a chestnut-brown colour, is common in the Mediterranean; it is the *Sparus chromis*, Linn. Another species is found in the Nile, the *Labrus Niloticus*, Hassels, &c. The genus *Cychla* (Bloch, Schn.) differs from *Chromis* in having the body more elongated, and in having the whole of the teeth very slender and thickly set, like the pile on velvet, and forming a broad band: it contains numerous species. The genus *Pseliops* (Cuvier) differs from *Chromis* in having the head compressed, the eyes placed near to each other, and the ventral fins much elongated.

Malacanthus, Cuvier.—In this genus there are the general characters of *Labrus*; the maxillary teeth are nearly the same, but the pharyngeal teeth are 'en carde,' as in *Chromis*. The body is elongated, the lateral line continuous, the operculum is produced posteriorly into a little spine, and the long dorsal fin has but a small number of slender and flexible spines in front. One species is found in the Antilles, which is of a yellowish colour with irregular transverse violet stripes, and has a crescent-shaped tail: it is the *Coryphæna Plumieri* of Lacépède.

Scarus, Linn.—The species of this genus, commonly known by the name of Parrot-Fishes, are remarkable for the convex and rounded form of the jaws, which are beset with several series of scale-like teeth, which are so soldered together, that they usually appear to form solid masses of enamel: these teeth succeed each other from behind forwards; those at the base, being the most recent in formation, in time replace those above, and themselves form the cutting edge. When alive, the fleshy lips nearly cover the teeth. In general form and in the large scales with which the body is covered the Parrot-Fishes resemble the true *Labri*; their pharyngeals, like them, are furnished with teeth, but they consist of transverse laminæ.



Head of a Parrot-Fish (*Scarus*), and the jaws, natural size.

These fishes are chiefly confined to the seas of hot climates, and are of very brilliant colours, which last circumstance, combined with a fancied resemblance between the mouth and the beak of a parrot, has given rise to the name of Parrot-Fishes. Some of them have a crescent-shaped tail, and of these there are a few in which the forehead is very gibbous; in others, the tail is truncated. Cuvier has separated from the Parrot-Fishes, under the generic name *Calliodon*, those species in which the lateral teeth of the upper jaw are square and pointed, and in which there is an interior range of much smaller teeth in the same jaw; and lastly, M. Cuvier has established the genus *Odax* for the reception of those Labroid Fishes which approach the genus *Labrus* in having the lips thick and fleshy, and the lateral line continuous, and the jaws composed like those of *Scarus*, but which are however flat and not gibbous, and are covered by the lips; the pharyngeal teeth are as in *Labrus*. The *Scarus pullus* of Bloch (Schneider) belongs to this genus; the fish is found off the coast of New Zealand, is of a blackish brown colour, and furnished with small scales.

LABROIDES. [Labridæ.]

LABRUS. [Labridæ.]

LABURNUM, the common name of the European trees named by botanists *Cytisus alpinus* and *C. Laburnum*. It is a native of the Alps of Europe, and is well known in gardens for the beauty of its pendulous racemes of beautiful yellow flowers. The seeds of Laburnum contain a poisonous substance called Cytisine; and the wood, which is olive-green, hard, and compact, is occasionally used by the turner for ornamental purposes. [Cytisus.]

LABYRI'NTHODON, a genus of Fossil Reptiles from the New Red-Sandstone strata. (Owen.) [Amphibia.]

LAC. [Coccidæ.]

LACE-BARK TREE. [Daphne.]

LACERTA. [Sauria; Lacertiadæ.]

LACE'RTIADÆ, or LACERTIANS. Under the family name Lacertians Cuvier arranged—

1st. The Monitors and their subdivisions, namely, the Monitors properly so called, including the Ouarans of the Arabs (*Varanus*), &c.; the Dragons (*Crocodilurus* of Spix, *Ada* of Gray), and the Sauvegardes (*Monitor* of Fitzinger and Ameiva).

2nd. The Lizards properly so called.

This second group comprises, according to Cuvier, the genera *Lacerta*, *Algyra*, and *Tachydromus*.

Messrs. Duméril and Bibron make the Varanians, or Sauriens Platynotes (Broad-Backed Saurians), a family which comes immediately after the Geckotians in their 'Erpétologie.' They allow that the Varanians are nearly allied (ont très grands rapports) to the Lacertians, as modified by them, and rest the distinctions of the former family from the latter—1st, on the presence in the latter of polygonal scales which cover the head; 2nd, on the form of the scales of the back and of the belly, and their noncompressed tail; and 3rd, on the form and disposition of the teeth, which are not distant, obtuse, and conical, but placed on the same line, and trenchant at their summit in the antero-posterior direction.

For an account of the systematic arrangement of the Lizards and their congeners, see SAURIA.

LACHESIS. [CROTALIDÆ.]

LACHRYMAL GLANDS. [EYE.]

LACISTEMA'CEÆ, *Lacistemads*, a small and obscure natural order of incomplete Exogenous Plants, containing a few arborescent species, inhabiting the woods of tropical America, in low places. In appearance they resemble the genus *Celtis*; and in structure they approach very nearly to *Urticaceæ*, from which Von Martius first distinguished them. The principal characters on which the order is founded are the dehiscent 3-valved fruit and amentaceous inflorescence. Nothing is known of their properties. There are two genera and six species.

A branch of *Lacistema serrulatum* in flower and fruit. 1, a flower with its calyx; 2, an ovary with the double stamen below it; 3, a ripe fruit.

LACTEALS, a set of absorbent vessels which take their origin in the villi of the intestines, and are the principal means by which the food, in the form of chyle, is conveyed into the blood. [ABSORBENT SYSTEM; DIGESTION; CHYLE; INTESTINES.]

LACTU'CA, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Liguliforæ*, the tribe *Cichoraceæ*, and the sub-tribe *Lactuceæ* of De Candolle. It has a cylindrical imbricated involucre, with the scales membranous at the margin, and few-flowered; the receptacle naked; the achenium compressed, wingless, with a long filiform beak; the pappus hair-like in several rows.

L. virosa, Acrid Lettuce, has leaves with a prickly keel, horizontal, oblong, auricled, and clasping, mucronate, dentate or sinuated, the beak white, equalling the fruit, which is black. This plant is found on hedges, old walls, and the skirts of fields throughout Europe. It yields a milky juice, which when procured and dried has the name Lactucaricum. This substance is also procured from the Garden Lettuce (*L. sativa*), and in the 'London Pharmacopœia' the *L. sativa* is the only plant recognised for supplying this substance. Dr. Christison remarks:—"The London College however, and many cultivators, are wrong in restricting themselves to the garden lettuce for the preparation of lactucaricum. From information communicated to me several years ago by Mr. Duncan, chemist and druggist in this city (Edinburgh), who has often made lactucaricum on a large scale, it appears that the *L. virosa* yields a much larger quantity, and that the produce is of a superior quality. Nor is there any reason for dreading the narcotic properties of the wild lettuce, the scientific name of which has given rise to an exaggerated notion of its activity. The results obtained by Mr. Duncan have been since confirmed by those of Schultz in Germany, who found that a single plant of the garden lettuce yields only 17 grains of lactucaricum on an average, while a plant of wild lettuce yields no less than 56 grains." Mr. Duncan has made the observation also that, "although the milkiness of the juice increases till the very close of the time of flowering, namely in the wild-lettuce till the month of October in this climate, the value of the lactucaricum is deteriorated after the middle of the period of inflorescence; for subsequently, while the juice becomes thicker, a material decrease takes place in the proportion of bitter extract contained in it." For an account of *L. sativa* and its uses as a salad see LETTUCE, in ARTS AND SC. DIV. This plant appears to have been cultivated amongst the Greeks, and also used in medicine. It is the Θρίδαξ of Dioscorides (ii. 165); also of Theophrastus. Several varieties of the Garden Lettuce were used both among the Greeks and Romans as salads.

L. Scariola, Prickly Lettuce, has the leaves with a prickly keel, perpendicular, arrow-shaped at the base and clasping, sinuate, the beak white, equalling the pale fruit. It is found plentifully in waste places in many parts of Europe, but is a rare plant in Great Britain. It has a stem from 2 to 5 feet high, leafy and panicled. Its juice is not so acrid as that of *L. virosa*, but possesses the same properties. It is found on the higher hills of Greece, and is probably the Θρίδαξ ἀγρία and Θριδακίνη of Dioscorides. The Θριδακίνη of Theophrastus (i. 8 and vii. 3) and of Galen (lib. 2), according to Fraas, is the *L. coriacea* of Schultz.

There are two other British species of lettuce: *L. saligna*, with a white elongated beak, twice as long as the fruit, the upper leaves entire, acuminate; and *L. muralis*, with the beak much shorter than the fruit.

(Babington, *Manual of British Botany*; Fraas, *Synopsis Plantarum Floræ Classicæ*; Christison, *Dispensatory*.)

LACTUCA'RICUM is a substance obtained from the *Lactuca virosa*, being the inspissated milky juice of the plant, and which is at first white, but afterwards by exposure to the air and sun concretes and becomes brownish. The juice of the leaves only should be collected before the flowering has begun. Puncturing the leaves is the best mode of procuring it.

Other plants are often mistaken for it, as *Lactuca sativa*, *L. augustana*, *L. quercina*, *L. Scariola*, *Sonchus oleraceus*, and *Dipsacus sylvestris*.

According to Klink, Lactucaricum contains lactucic acid. It yields by distillation its odour and taste to water, which thus acquires some of the virtues of the plant. The inspissated concrete juice is said to resemble opium in its action, but is much feebler. In pulmonary diseases it is sedative. The common Garden Lettuce (*Lactuca sativa*) also possesses sedative properties, and eaten towards bed-time has been said to procure rest in cases of morbid vigilance, or to allay pains of the stomach. [LACTUCA.]

LACUNA. [LITTORINIDÆ.]

LA'DANUM, sometimes written *Labdanum*, but incorrectly, as it is the Λήδανον of the Greeks and the Ladun of the Arabs. It is first mentioned by Herodotus (iii. 112) as procured in Arabia, and used by the Arabs for fumigation. The word is not Greek, but an Arabic word with a Greek termination; the Greeks also used the word Λῆδος to indicate the shrub which produced the Ladanum. This gum-resin is produced by several species of *Cistus*, the Κίστος of Dioscorides, though the name and description are often confounded with those of the Κισσός, or *Hedera*. *C. ladaniferus*, *C. Creticus*, *C. laurifolius*, and *C. Ledon*, Lam., are usually mentioned as the species which are indigenous in the Grecian Islands, in Spain, Italy, and the south of France. That obtained from the Levant is the most celebrated. The juice exudes upon the leaves and branches of these shrubs, and is collected, according to Tournefort, by means of an instrument resembling a rake, with leather thongs instead of teeth, which is drawn over the plant; and as the juice adheres to the thongs, it is afterwards separated. Ladanum is also described by Dioscorides as being collected from the beards of goats which had been feeding on the leaves of *Cistus*. (Compare Herodot., iii. 112.) It is now seldom employed for any purpose, as it is with difficulty obtained of a sufficient degree of purity from the adulterations to which it is subjected; one analysis yielding 72 parts of ferruginous sand, and another 86 of resin, out of 100 parts. The purest kind, seen only in the places where it is produced, is described as blackish, homogeneous, and tenacious, easily softening under the fingers, and even sticking to them; having a grayish fracture, which however becomes black by exposure to the air; rather a bitter taste, and a very agreeable smell from the presence of a volatile oil. It was formerly employed as a stimulant, more recently as an expectorant, and is esteemed even in the present day by the Turks as a perfume, and used for fumigation.

LADY-BIRD. [TRIMERA.]

LADY-FERN. [ASPIDIUM.]

LADY'S-SLIPPER. [CYPRIPEDIUM.]

LADY'S SMOCK. [CARDAMINE.]

LÆMANCTUS. [IGUANIDÆ.]

LÆMODI'PODA, Latreille's fourth order of the *Crustacea*, placed by him between the *Amphipoda* and the *Isopoda*. He describes them as being the only forms among the *Malacostraca* with sessile eyes (*Edriophthalmia*) whose posterior extremity does not present distinct branchiæ, and which have hardly any tail, the two last feet being inserted at that end, or the segment to which they are attached being followed by not more than one or two other joints, which are very small. They are also, he states, the only ones in which the two anterior feet (which agree with the second jaw-feet) make a part of the head.

The *Lœmodipoda* of Latreille have all four setaceous antennæ carried upon a peduncle of three joints, mandibles without palps, a vesicular body at the base of four pair of the feet at least, beginning with the second or third pair, reckoning those of the head. The body, which is most frequently filiform or linear, is composed (reckoning the head) of from eight to nine joints, with some small appendages, in form of tubercles, at its posterior and inferior extremity. The feet are terminated by a strong hook. The four anterior feet, of which the second are the greatest, are always terminated by a monodactylous claw. In many the four succeeding feet are shortened, less articulated, without any hook at the end, or rudimentary, and not at all fit for ordinary use.

The females carry their eggs under the second and third segments of the body, in a pouch formed by approximated scales.

The *Lœmodipoda* are all marine, and Savigny considers them as approaching the *Pycnogonidœ*, and making, with that form, the passage from the *Crustacea* to the *Arachnia*.

Latreille brought the forms under one genus, *Cyamus*, with the following sub-divisions and sub-generic appellations.

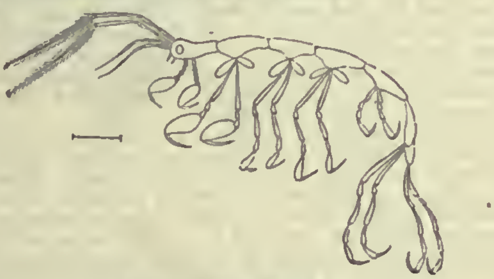
1. *Filiformia* (Latr.).

Body long and very slender, or linear, with longitudinal segments; feet similarly elongated and slight; stem of the antennæ composed of many small joints.

Leptomera, Latr. (*Proto*, Leach).—Feet fourteen (reckoning the two annexed to the head), complete, and in a continuous series. (Latr.)

In the *Leptomerœ* (*Gammarus pedatus*, Mull., 'Zool. Dan.') all the feet, with the exception of the two anterior ones, have a vesicular body at their base. In the *Proto* of Leach (*Cancer pedatus*, Montague, 'Trans. Linn. Soc.,' ii.) these appendages are peculiar to the second feet and the four succeeding ones.

Leptomera pedata may be given as an example.



Leptomera pedata, magnified.

Naupredia, Latr.—Feet ten, in a continued series; the second and two succeeding pairs have a vesicular body at their base.

The species are found on the coasts of Europe, France, &c.

Caprella, Lam.—Feet ten, but in an interrupted series, commencing with the second segment (inclusive), and not reckoning the head. This segment and the following one have each two vesicular bodies, and are totally deprived of feet.

The species are found in the northern and temperate European oceans.

The *Lœmodipoda* of this section keep among the marine plants and sponges, and walk like caterpillars, turn frequently with rapidity on themselves, or set up their bodies, vibrating their antennæ at the same time. In swimming they curve the extremity of the body.

2. *Ovalia* (Latr.).

In this subdivision the body is oval, with transverse segments. The stem of the antennæ appears to be inarticulated. The feet are short, or have but little length; those of the second and third segments are imperfect, and terminated by a long cylindrical joint without hooks; at their base they have an elongated vesicular body. These *Lœmodipoda* form the sub-genus.

3. *Cyamus*, Latr. (*Larunda*, Leach.)

M. Latreille states that he has seen three species, all of which live on *Cetacea*, and the most known of which, *Cyamus Ceti* (*Oniscus Ceti*, Linn.; *Squilla*, Degeer; *Pycnogonum*, Fabr. and Sav.), is found also on the Mackerel. The fishermen term it the Whale-Louse (Pou de la Baleine). Another species, very analogous to the first, was brought back by Delalande from his voyage to the Cape of Good Hope. The third and much the smallest is found on the Cetaceans of the East Indian seas. (Latr.)

Cyamus Ceti, magnified.

M. Desmarest gives the *Lœmodipoda* the same position as M. Latreille, and divides them also into two sections. The first, consisting of *Leptomera*, Latr. and Lam. (*Proto*, Leach; *Caprella*, Lam.); the second of *Cyamus* (*Cyamus*, Latr. Lam.; *Panope*, Leach; *Larunda*, Leach).

M. Desmarest remarks that M. Latreille never saw the *Leptomerœ* themselves, and that he has separated them from *Caprella* and *Proto* from published figures only.

M. Milne-Edwards makes his Legion of Edriophthalmians comprise the *Amphipoda*, *Isopoda*, and *Lœmipoda*.

LAGANA. [Echinidæ.]

LAGENA'RIA (from 'lagena,' a bottle), a genus of Plants belonging to the natural order *Cucurbitaceœ*. The flowers are monœcious, the calyx campanulate, with subulate segments shorter than the tube. The corolla is white, with obovate petals spreading below the edge of the calyx. It has five triadelphous stamens, the fifth one distinct; three subsessile granulated stigmas, obovate compressed seeds, tumid at the margin, 2-lobed at the apex.

L. vulgaris, Common Bottle-Gourd, is a musky-scented plant, and clothed with a soft down. It has a climbing stem, with tendrils from 3- to 4-cleft. The flowers are stellated, spreading, and in clusters; the fruit in shape like a bottle, when ripe of a pale-yellow colour, sometimes six feet in length. When dried it becomes hard, and is used to contain water; it is then of a pale bay-colour. In its wild state this plant produces a poisonous fruit, and Dr. Royle states that a very intelligent native doctor informed him that cases of poisoning have occurred from eating the bitter pulp in the district where it grows. Some sailors also are said to have died from drinking beer that had been standing in a flask made from one of those gourds.

These injurious effects seem however to be removed by cooking, for Don says that the poor people among the Arabians eat it boiled with vinegar, or fill the shells with rice and meat, and so make a kind of pudding of it. The pulp of the fruit is often employed in poultices: it is bitter and purgative, and may be used instead of colocynth. This species grows abundantly in Egypt and Arabia; the Arabians call it Charrah; it thrives wherever the mountains are covered with a fit soil. There are three other species enumerated by Don growing in Guinea and the East Indies.

L. idolatrica is held in great veneration by the Hindoos in their religious ceremonies.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica.*)

LAGENORHYNCHUS. [Cetacea.]

LAGERSTRŒ'MIA, a genus of Plants of the natural family of *Lythraceœ*, which extends from the Malayan Archipelago into China and Japan, as well as along the foot of the Himalayan Mountains to the northern parts of India. The genus was named by Linnæus in honour of Lagerstrœm, who was director of the Swedish East India Company and imported many interesting plants from India and China. The species are few in number, but most of them highly ornamental in nature. *L. Reginœ* especially forms a small tree and is conspicuous from its large rose-coloured flowers, of which the petals, standing out on rather long claws, more fully display the varied outline of its undulated limb. The bark and leaves are accounted purgative and hydragogue, the seeds narcotic. *L. Indica* and *L. parviflora* are small and shrub-like, and suited to our hot-houses, but all require moisture in the season of flowering.

LAGIDIUM. [Chinchillidæ.]

LAGOMYS. [Leporidæ.]

LAGOPUS. [Tetraonidæ.]

LAGO'STOMYS, or LAGOSTOMUS, a genus of *Mammalia* belonging to the order *Rodentia* and the family *Chinchillidœ*. *L. trichodactylus* is the Viscacha, or Biscacho. [Chinchillidæ.] The accompanying figure was taken from a specimen in the Zoological Gardens Regent's Park.

Viscacha, or Bischaco (*Lagostomys trichodactylus*).

LA'GOTHRIX, M. Geoffroy's name for a genus of South American Monkeys, thus characterised:—

Dental Formula:—Incisors, $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{6-6}{6-6}$ = 36.

Facial angle about 50°; muzzle projecting; head round; extremities proportioned to the body; anterior hands provided with a thumb; tail strongly prehensile, and having a part of its extremity naked below; hair strong and curly.

Two species are recorded, *L. Humboldtii* and *L. canus*.

The first of these, or the Caparro, was found by Humboldt and Bonpland in the hut of an Indian, who had captured it in an excursion to the westward. Size about 2 feet 2 inches without the tail. Head round and very large. Hair long, strong, and uniform gray, the tips black. Face naked and black; mouth beset with long stiff bristles. Tail rather longer than the body, prehensile, naked at the extremity. Habits gregarious; frequently seen raised on the hinder extremities.

It was found on the Rio Guaviare, one of the tributary rivers of the Orinoco.

The other species has shorter hair, and is of the size of the Sapajousal (*Cebus Capucinus*, Desm., *Simia Capucina*, Linn.).

It is a native of Brazil.

Dr. Gray places the form in his family *Sariguidæ*, and in the second sub-family of it, namely, *Atelina*.

Mr. Swainson arranges it in the family *Cebidæ*, between *Mycetes* and *Ateles*.

LAGOTIS. [CHINCHILLIDÆ.]

LAGRIIDÆ (*Lagriariæ*, Latreille), a family of Coleopterous Insects of the section *Heteromera*, the characters of which are:—Elytra soft; head and thorax considerably narrower than the elytra, the latter almost cylindrical, ovate or quadrate, and truncated; antennæ inserted near an emargination of the eyes, either filiform or insensibly larger towards the apex, the terminal joint being longer than the preceding, especially in the males; palpi thickened at the tip; terminal joint of the maxillary palpi of the form of a reversed triangle; femora oval and clavate; tibiæ long and slender; those of the anterior legs often curved; penultimate joint of the tarsi bilobed and the claws simple. The genus *Lagria* (Fab.), contains those species in which the antennæ are gradually thickened towards the apex, and have the last joint ovate; the fore part of the head is but little produced, but behind is prolonged and slightly rounded; the thorax is almost cylindrical or square.

One species of this genus exists in England, the *Lagria hirta*, an insect not unfrequently found in hedges and woods, and apparently most abundant on the white thorn. It is about 4-12ths of an inch in length, of an oval form, with a narrow head and thorax; these, as well as the body beneath, the antennæ, and the legs, are black; the elytra are dirty yellow, soft, and pubescent. The body of the males is rather narrower than that of the females, and the antennæ are longer.

The genus *Statyra* (Latreille) also belongs to the present family, and consists of species which have the body more elongated than those of *Lagria* proper; the antennæ are filiform, and consist of almost cylindrical joints, the last of which is very long and pointed; the head is considerably produced in front of the eyes, and is abruptly narrowed behind; the thorax is longer than broad, somewhat ovate, but truncated before and behind; the elytra are acutely terminated.

Lagria hirta.

The line *a* denotes the natural size; *b*, the antenna; *c*, the tarsus of the fore and middle pair of legs; *d*, the tarsus of the posterior pair of legs.

LAGURUS (from λαγὼς, a hare, and οὐρά, a tail), a genus of Plants belonging to the natural order *Gramineæ*. It has a spiked panicle, 1-flowered, scarious glumes ending in a long fringed seta. The outer paleæ end in two long setæ and with a dorsal geniculated twisted awn.

L. ovatus is the only species, and has a stem from 4 to 12 inches in height. The leaves are broad and lanceolate, the spikes ovate and pubescent. It is found in sandy places in Guernsey and on the continent of Europe.

(Babington, *Manual of British Botany*; Koch, *Flora Germanica*.)

LAITH. [MERLANGUS.]

LALO. [ADANSONIA.]

LAMA. [LLAMA.]

LAMANTIN. [CETACEA.]

LAMBRUS, Leach's name for a genus of Brachyurous Crustaceous Decapods.

LAMB'S LETTUCE. [VALERIANELLA.]

LAMELLARIA. [VELUTINIDÆ.]

LAMELLIBRANCHIA'TA, De Blainville's third order of *Acephalophora* (Acéphales Testacés of Cuvier).

De Blainville makes this order consist of the following families:—1st, *Ostracea* (Oysters, &c.); 2nd, *Subostracea* (*Spondylus*, &c.); 3rd, *Margaritacea* (*Vulsella*, *Malleus*, &c.); 4th, *Mytilacea* (Mussels and Pinnas); 5th, *Polyodonta*, or *Arcacea*; 6th, *Submytilacea* (*Anodon*, *Unio*, *Cardita*); 7th, *Chamacea*; 8th, *Conchacea*; 9th, *Pyloridea*; 10th, *Adesmacea* (*Pholas*, *Teredo*, *Fistulana*, &c.).

M. Rang separates the order into two divisions:—

I. *Monomyaria.*

Families:—1st, Ostracés, Cuvier (*Ostreadæ*); 2nd, Pectinides, Lam. (*Pectinidæ*); 3rd, Malléacés, Lam. (*Malleidæ*); 4th, Aviculés (*Aviculidæ*).

II. *Dimyaria.*

Families:—5th, Arcacés (*Arcadæ*); 6th, Mytilacés (*Mytilidæ*); 7th, Submytilacés (*Submytilidæ*: fresh-water, *Anodon*, *Unio*, &c.; Naiades of Lamarck and Lea: marine, *Cardita*, *Cypricardia*, &c.); 8th, *Chamacea* (*Chamadæ*); 9th, *Conchacea*; 10th, *Pyloridea*; 11th, Tubicolés, Lam. (*Aspergillum*, *Clavagella*, &c.). [CONCHIFERA; MOLLÚSCA.]

LAMELLICORNES (Latreille), one of the sections of the order *Coleoptera*. The insects of this section have five joints to all the tarsi. The antennæ are inserted in a small hollow in front of the eyes, short, usually composed of nine or ten joints, the last of which are large and flat, and open like a fan. [COLEOPTERA.] The number of these lamellated joints varies, but there are generally three. The clypeus is usually very large, and the labrum is small and hidden beneath the clypeus. The anterior tibiæ are dentated externally, and the posterior tibiæ are often more or less denticulated. The mandibles of some of the species are membranous.

The larva [COLEOPTERA] is soft, of a cylindrical form, or nearly so, and has a large vertical head. There are six small legs attached to the thoracic segments. The body is always bent. When about to assume the pupa state the larvæ inclose themselves in an oval case formed of particles of earth, rotten wood, or other surrounding substances, which are cemented by a glutinous matter. Some of them live in the ground, and feed upon the roots of plants, and others live in decayed animal and vegetable substances, upon which they feed. The perfect insects also feed upon these substances (many of them are found in dung); others feed upon the leaves of plants, or on the flowers.

Latreille divides the Lamellicornes into two great tribes, Scarabaides and Lucanides. [SCARABAIDÆ; LUCANIDÆ.]

LAMELLIROSTRES, Cuvier's name for the great family of the *Anatidæ*. [DUCKS.]

LAMIA'CEÆ, or LABIA'TÆ, *Labiates*, a very extensive and important natural order of Exogenous Plants, with irregular unsymmetrical monopetalous flowers, and a 4-lobed ovary, changing to 4 seed-like monospermous fruits. It is technically allied so nearly to *Boraginaceæ* as to differ apparently in little except having regular flowers; but in nature it belongs to a different series of vegetation. The leaves of *Lamiaceæ* are uniformly opposite, and their stems square or nearly so, and in the greater part of the order the flowers are disposed in short opposite clusters axillary to leaves, and appearing in consequence as if in whorls.

The species are generally aromatic and tonic, a property that is in most cases owing to the secretion of a volatile oil in little cysts or glands occupying the leafy organs. The aromatic qualities are familiar to us in the Sage, Marjoram, Thyme, Basil, and similar plants, commonly cultivated for the service of the kitchen, as condiments; of Lavender, so much valued for its peculiar fragrance; of Mint and Peppermint, well known for their stimulating power, and of many others. Betony, Ground Ivy, Horehound, and others are examples of the bitter tonic qualities of such plants; Rosemary appears to have the specific property of stiffening the hair and encouraging its growth; its oil is that which gives the green colour to bear's grease and such pomatums; and Cat-Thyme (*Teucrium marum*) and Cat-Mint (*Nepeta Cataria*) seem to be genuine feline aphrodisiacs.

Plants of this order are distributed over all the warmer and temperate parts of the world, generally being herbaceous, and never exceeding the size of small bushes. Mr. Bentham has given an elaborate view of their geographical distribution, from which it appears that out of 1714 species 1030 belong to the Eastern hemisphere, and 649 to the Western; 8 only are Arctic; 80 inhabit the temperate parts of Europe, 190 Spain, 149 the Himalayan Mountains, and only 157 the Equinoctial regions of both the Old and New World, and those are chiefly mountain plants.

Linnæus distributed the genera of *Lamiaceæ* through his *Didynamia*, *Gymnospermia*, and *Diandria Monogynia*. Writers on the natural system have devised much better modes of arrangement; the most perfect and recent is that of Mr. Bentham ('Labiatarum Genera et Species,' London, 1832-36, 8vo.)

There are 125 genera and 2350 species of this order.

Leaf and flowers of *Salvia pratensis*.

1, the ovary, upon the four lobes of which a part of the character of this order depends.

The British genera of this order are numerous. They are divided by Babington into the following tribes:—

I. *Menthoideæ.*—Corolla bell-shaped, nearly regular; stamens distant, straight, diverging upwards.

1. *Mentha.* 2. *Lycopus.*

II. *Monardeæ.*—Corolla 2-lipped; stamens 2, fertile, parallel under the lip of the corolla.

3. *Salvia.*

III. *Satureiineæ.*—Corolla 2-lipped; stamens 4, distant; cells of anthers separate, divergent, connective, dilated.

4. *Origanum.* 6. *Calamintha.*
5. *Thymus.*

IV. *Melissineæ.*—Corolla 2-lipped; stamens distant; anther cells connected above.

7. *Melissa.*

V. *Scutellarieæ.*—Stamens approximating, parallel under the upper lip of the corolla; calyx 2-lipped, closed in fruit.

8. *Scutellaria.* 9. *Prunella.*

VI. *Nepeteæ.*—Stamens approximating, parallel under the upper lip of the corolla, 2 inferior shortest; calyx tubular.

10. *Nepeta.*

VII. *Stachydeæ.*—Stamens approximating, parallel under the upper lip of the corolla, 2 inferior longest; calyx tubular, or bell-shaped, spreading in fruit.

11. *Melittis.* 15. *Stachys.*
12. *Lamium.* 16. *Ballota.*
13. *Leonurus.* 17. *Marrubium.*
14. *Galeopsis.*

VIII. *Ajugoideæ.*—Upper lip of corolla very short, or split and deeply bifid.

18. *Teucrium.* 19. *Ajuga.*

The genera are described under their respective names.

LAMINARIA. [ALGÆ.]

LAMINARITES. Brongniart, classing Fossil *Fuci* according to the analogy they offer to recent tribes, uses this term for one species found in the secondary strata of Aix, near La Rochelle.

LA'MIUM, a genus of Plants belonging to the natural order *Labiatæ*. It has a 2-lipped corolla, the upper lip arched, lower lip trifid. The lateral lobes minute, tooth-like, or obsolete, rarely elongated. The anthers approach in pairs, and forming a cross, burst longitudinally. The calyx is 5-toothed and bell-shaped, the teeth nearly equal. This genus includes the Dead, Blind, and Dumb Nettles of our peasants, so called from their resemblance to the *Urticæ* in many points, except their stings.

L. amplexicaule has roundish cordate obtuse leaves, the lower ones stalked, the upper ones sessile and clasping. The teeth of the calyx are longer than the tube, at length connivent; the lateral lobes of the lower lip of the corolla toothless; the nuts small, and of an obovate-oblong shape. It is found in sandy and chalky fields in Great Britain, the north of Africa, and Middle Asia.

L. intermedium has reniform, cordate, obtuse leaves, and is distinguished by the teeth of the calyx being longer than their tube, hispid, and always spreading. The lateral lobes of the lower lip of the corolla with a short tooth; the nuts twice as large as those of the former species, and of an oblong shape. This species is common in Scotland, Sweden, and the north of Germany.

L. purpureum has a pale purple corolla, spotted with red, the lateral lobes of the lower lip having two teeth. The nuts oblong, or about twice as broad as long. It is found in Great Britain and Sweden, where, according to Linnæus, it is boiled and eaten. It was formerly used in medicine, but is not now prescribed.

L. incisum has but one tooth in the lateral lobes of the lower lip of the corolla. It is a British plant, and is likewise found in France, Germany, and Sweden.

L. album is distinguished by having the calyx-teeth as long as the tube, all separated by acute angles, the upper one distant from the others. The corolla has three teeth, and is large and white. It was once used medicinally, but is now disregarded. Like *L. purpureum*, this species is eaten in Sweden as a pot-herb. It is found in Great Britain and the southern parts of Europe.

L. maculatum has the calyx-teeth longer than their tube, the three upper ones separated from the others by broad obtuse angles; the lateral lobes of the lower lip of the corolla with one tooth. It is found in Great Britain and on the continent of Europe.

L. striatum has deeply-cut ovate leaves, the corolla three times as large as the calyx, which is glabrous. It is a native of Greece in waste places, and is supposed by Fraas to be the Λευκὰς ὀρεινή of Dioscorides (iii. 103).

There are several other species of *Lamium*, growing chiefly in the southern parts of Europe. They are not worth cultivation for ornament, but will easily grow in any soil or situation, and are to be propagated either by division or by seed.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

LAMNA, a genus of Squaloid Fishes. Fossil in the Chalk, London Clay, &c., and recent. [SQUALIDÆ.]

LAMPERN. [PETROMYZON.]

LAMPREY. [PETROMYZON.]

LAMPRIS, a genus of Fishes belonging to the family *Scomberidæ*. It has an oval body greatly compressed; small scales; a single elevated and elongated dorsal fin; sides of the tail carinated; teeth wanting; branchiostegous rays 7.

L. guttatus, the Opah, or King-Fish, has been taken on the British coasts. It is a very rare fish, and as beautiful as rare. The upper part of the back and sides are of a rich green, reflecting both purple and gold in different lights, passing into yellowish-green below; above and beneath the lateral line are various round yellowish white spots, from which the fish received the name of Luna. The irides are scarlet; all the fins bright vermilion. It has been remarked, on account of these showy colours, that the Opah looks like one of Neptune's lords dressed for a court-day.

This fish was formerly referred to the genus *Zeus*, and called *Z. Luna* and *Z. imperialis*.

LAMPROTILA. [HALCYONIDÆ.]

LAMPROTORNIS. [STURNIDÆ.]

LAMPY'RIDÆ (*Lampyris*, Linn.), a family of Coleopterous Insects of the section *Malacodermi*. The insects of this family have five joints to all the tarsi; flexible elytra; the body usually elongated and somewhat depressed. The thorax projects more or less over the head; the mandibles are usually small, and terminated in a sharp point; the penultimate joint of the tarsi is always bilobed; the claws are simple, and the antennæ are approximated at the base.

The family *Lampyridæ* contains the following genera, and some others of minor importance.

Lycus, the distinguishing characters of which are—fore part of head prolonged into a snout; antennæ serrated; elytra most commonly dilated in the middle or towards their posterior part. One of the species of this genus is found in England, the *Lycus minutus*, Fab.; it is about a quarter of an inch in length, and of a black colour, with the exception of the elytra, which are brilliant red and have raised striæ.

Omalisus, Geoff.—Antennæ simple, the second and third joints much shorter than the following; head not sensibly prolonged in front; joints of the tarsi elongated and nearly cylindrical; the penultimate joint heart-shaped; elytra tolerably firm.

O. suturalis resembles in colouring and size the insect last described; the suture however is black. It inhabits France.

Lampyris.—Head not produced in front, hidden beneath the thorax; eyes in the male sex very large; antennæ short; females apterous. To this genus belongs the Glow-Worm (*Lampyris noctiluca*, Latr.). This insect is rather more than half an inch in length, of a blackish colour, the thorax is margined with dusky-red, the legs and the edges of the segments of the body of the same colour. The female resembles the male, but is quite destitute of wings, and the terminal segments of the abdomen beneath are yellowish; the thorax is semicircular; the body is very soft, of an oblong form, pointed at the extremity, and composed of 10 segments. The male Glow-Worm is said to emit the phosphorescent light in a slight degree, but it is chiefly the females from which the brilliant light proceeds which we so often see on banks, beneath hedges, and in various other situations. This light proceeds from the under part of the abdomen and near the tip, and it appears that the animal has the power of varying its intensity. Glow-Worms will live, we are informed by Latreille, a long time in vacuo, and in different kinds of gases, the nitrous acid, muriatic and sulphurous gases excepted, for in these they soon expire. When placed in hydrogen gas they sometimes detonate. If the luminous portion of the abdomen be removed, it retains its luminous property for some time, and when apparently extinct it may be reproduced by softening the matter with water. The insects emit a brilliant light if immersed in warm water, but in cold water it is extinguished. The females being apterous, and consequently restricted in their powers of locomotion, and the insect being nocturnal, it is supposed that the light emitted by the female is for the purpose of attracting the other sex. The larvæ have been kept alive for a considerable time, by the writer of this article, during which they lived upon snails, killing those of the largest size; sometimes they would seize a snail whilst crawling, and when the animal retired within its shell, they would still keep their hold, and allow themselves to be carried into the shell with the snail, and although they became enveloped in the mucous secretion, it very seldom appeared to adhere to their bodies. Upon being touched or disturbed in any way they emitted the phosphoric light, but not to so great degree as the perfect insect.

LAMPYRIS. [LAMPYRIDÆ.]

LANARKITE, a Mineral consisting of sulphato-carbonate of lead. It occurs in long slender crystals, single or aggregated into fibrous masses. The primary form is an oblique rhombic prism. Colour greenish, yellowish, or grayish. Streak white. Hardness 2·0 to 2·5. Lustre nearly resinous, but pearly on the cleavage planes. Transparent, translucent. Specific gravity 6·8 to 7. It is found at Lead Hills in Scotland. A massive variety has been met with in Siberia. The following is its analysis by Brooke:—

Sulphate of Lead	53·1
Carbonate of Lead	46·9
	——100

LANCELET. [BRANCHIOSTOMA.]

LANCE'OLA, a genus of *Crustacea* established by Mr. Say on a single species, *Lanceola pelagica*, two females of which only he appears to have seen taken on the coast of America in the Gulf Stream. M. Desmarest is of opinion that the genus belongs to the *Amphipoda* from its vesicular oblong branchiæ, to the number of ten, placed at the internal base of the feet, except those of the first and seventh pairs, and that it especially approaches *Phronima* in its caudal appendages, which consist of three pairs of lanceolate styles, which are double and supported by depressed linear peduncles annexed to the sides by three rings which compose the tail. Its mouth, provided with two triarticulate filiform palps and bifid jaw-feet, bears analogy to that of the *Cloportes*. Its general form is that of the genus *Praniza* (which M. Desmarest considers to be an Isopod); its antennæ, composed of four joints, have the last joint not divided, and the inferior antennæ are the longest. The superior antennæ have their base hidden. The eyes are elongated; the front is concave; the feet are 14 in number, and simple; the two first pairs are compressed, and the sixth is the longest. The head is short and transverse. The body is soft, and covered with membranous integuments; the tail is depressed, narrower than the body, and its terminal segment is attenuated between the posterior caudal styles.

LAND-CRAB. [GECARCINUS.]

LANDAKIA. [DRACONINA.]

LANGSDORFIA. [RHIZANTHEÆ.]

LANIADÆ, a family of Birds including the Shrikes, or Butcher-Birds (*Lanius*, Linn.).

Linnæus places his genus *Lanius* at the end of his first order, *Accipitres*, immediately following the Owls (*Strix*). The *Picæ* form the succeeding order.

Cuvier makes the Pies-Grièches (*Lanius*, Linn.) the first great genus of his *Dentirostres*, his second order; the Oiseaux de Proie (*Accipitres*, Linn.) being his first.

Vigors observes that in the characters of the notched, depressed, and angular bill, and the strong hairs or vibrissæ that surround its base, as well as in their manners, the *Muscicapidæ* partially correspond with the *Laniadæ*, from the earlier families of which they chiefly differ in their inferior power and robustness. Entering among the *Laniadæ* by the genus *Tyrannus* (Cuv.), which unites them with the preceding *Muscicapidæ*, and from which he would separate it chiefly on account of the strength of the bill, wherein the character of a Shrike is more conspicuous than that of a Flycatcher, Vigors proceeds by means of *Psaris* (Cuv.) and *Artamus* (Vieill.) to *Dicrurus* (Vieill.), the Fork-Tailed Shrikes of the Old World, where the base of the bill is still depressed and wide, as in the groups just quoted, but the apex gradually more compressed. Hence, he remarks, we are led by some intervening forms to the still more compressed bills of *Sparactes* (Ill.) and the true *Lanius* of authors, which by its short, compressed, and strongly-dentated bill exhibits the type of the family. "Here," continues the author, "we are met by some conterminous groups, among which *Falcunculus* (Vieill.) is conspicuous; and hence we descend by intermediate gradations to the more lengthened and slender-billed *Vanga* (Cuv.), together with *Prionops*, *Laniarius*, and *Thamnophilus* of M. Vieillot, which bring us in contact with the Thrushes. The extremes of the family will be found in the *Graucalus* and *Ceblepyris* of M. Cuvier, which by their bills, in some degree depressed at the base, lead back to *Tyrannus* and the other broad-billed groups which commence the family. This last-mentioned genus, *Ceblepyris*, has latterly been arranged among the Thrushes; but I feel inclined rather to leave it in its original station among the Shrikes, from the peculiarity of its tail-coverts, which form themselves into a kind of puffed-out cluster on the back. This character seems to prevail among the *Laniadæ* more generally and in a greater degree than in other birds: in one species of the family, the Puff-Backed Shrike of Africa, now rendered so familiar to our cabinets from our connection with the Cape, this singular protuberance is carried to so great an extent as to form an apparently artificial appendage to the back. In the genus before us this peculiarity seems even still further developed in the well-known conformation of the same tail-coverts, their shafts being elongated and projected beyond the webs in stiff and sharpened points. On looking to the general affinity which the extremes of this family bear to the *Musicapidæ*, and through them to the Fissirostral Birds of the last preceding tribe, we may perceive the character of feeding on the wing carried on to the *Tyranni*, the fork-tailed *Dicruri*, and more particularly to the *Artami*, or the Pie-Grièches Hirondelles of the continental writers; while the depressed bill of the same Fissirostral tribe is partially preserved in the groups just mentioned, together with that of *Ceblepyris*, which meets them at the opposite extreme of the circle of affinity." [MERULIDÆ; MUSCICAPIDÆ.]

In allusion to the rapacious habits of the *Laniadæ*, Mr. Swainson observes, that the comparisons which have been drawn between them and the Falcons are no less true in fact than beautiful in analogy, remarking that many of the *Falconidæ* sit on a tree for hours watching for such little birds as come within reach of a sudden swoop, when those birds of prey pounce on the quarry, seize it in their talons, bear it to their roost, and devour it piecemeal. These, he adds, are precisely the manners of the true Shrike; yet with all this, the structure of the Falcons and Shrikes, and their more intimate relations, are so different that they cannot be classed in the same order, though they illustrate that system of symbolic relationship termed analogy, which, in Mr. Swainson's opinion, pervades creation; but the two groups are, he remarks, in nowise connected, and there is consequently no affinity between them. The following, according to him, are the very decided external characters of the typical groups:—

The short and strong bill is abruptly hooked at the end, and the notch is so deep as to form a small tooth, more or less prominent, on each side. This projection, Mr. Swainson remarks, is analogous to the teeth of quadrupeds, so far as it enables the bird to take a firm grasp of its food, and is used to divide it into pieces: the claws also, as instruments of capture, are peculiarly fine and sharp in the typical group, and this character pervades more or less the whole family. The mode of darting suddenly on their prey (rather than hunting or searching for it) is most prevalent in those groups which are nearest related to the Flycatchers, whose general weakness however confines their depredations to the smaller insects—larger and more powerful tribes being the food of the typical Shrikes.

Mr. Swainson arranges the *Laniadæ* in five divisions or sub-families:—1, The *Tyranninæ*, or Tyrant-Shrikes; 2, the *Ceblepyrinæ*, or Caterpillar-Shrikes; 3, the *Dicrurinæ*, or Drongo-Shrikes; 4, the *Thamnophilinæ*, or Bush-Shrikes; and 5, the *Laniancæ*, or True Shrikes. According to Mr. Swainson's views the first three of these sub-families constitute the aberrant circle, or that in which the character of the Shrike is least conspicuous. The fourth is the subtypical; and in the fifth the laniue structure is most perfectly developed.

Tyranninæ.

Sub-Family Character.—Bill very straight, short, depressed its whole length; the culmen not arched, but the tip abruptly hooked. Nostrils and rictus defended by bristles. Feet short, small, and slender; lateral toes equal, or nearly so; claws long, slender, fully curved, and very acute.

Locality.—America only.

Genera.—*Ptilogonys*, Sw.; *Chrysolophus*, Sw.; *Saurophagus*, Sw., with its sub-genus *Megastoma*, Sw.; *Tyrannus*, Vieill., with its sub-genus *Milvulus*, Sw.; and *Tyrannula*, Sw.

Mr. Swainson observes that the connection between the family of Shrikes and that of the Flycatchers (*Muscicapidæ*) by means of the

Tyranninæ is so perfect that it is difficult at present to determine where one terminates and the other commences. The Water-Chats of Brazil pass by such imperceptible degrees into the lesser Tyrant-Shrikes (*Tyrannula*), that although an observer on the spot might, he remarks, draw a distinction, an ornithologist acquainted only with dried skins is at a loss to distinguish their remote ramifications. "The Water-Chats (*Fluvicolinæ*)," says Mr. Swainson in continuation, "which seem to connect the Tyrant-Shrikes to the Flycatching family, or the *Muscicapidæ*, like very many other tribes, have their plumage black and white variously blended, but without any mixture of green. The Lesser Tyrants (*Tyrannula*), on the contrary, are all of an olive-coloured plumage; that colour, in short, which is most adapted for concealment among foliage, and therefore suited to their manner of life: between these however we find some curious birds, which borrow the habits of both groups. The species called by Latham White-Headed Tody, for instance, is black and white: its general resort is on the sides of marshes, where it perches npon the reeds, and darts on passing insects in the same manner as a true Tyrant-Shrike; this we have ourselves repeatedly witnessed. Azara says that it likewise chases insects upon the ground; so that we have thus in this one bird the manners of both groups exemplified. Whether this, or the *Tyrannula ambulans* of Brazil, which lives on the ground like a lark, constitutes a generic type in this division is at present uncertain. The Lesser Tyrants (*Tyrannulæ*) are spread over the whole of America, where they represent the true Flycatcher (*Muscicapa*) of the Old World: both have nearly the same manners; and so closely do they resemble each other that they can only be distinguished by their feet, tail, and wings. From these we may pass to the True or Greater Tyrants, by a little sub-generic group (*Milvulus*, Sw.) having very long forked tails. The habits of the typical Tyrants intimately resemble those of the lesser, but they feed upon larger insects more suited to their own size: some imitate the Kingfishers, by diving in the water; and they will even prey upon small reptiles. The species, which are numerous, swarm in tropical America, where they are everywhere seen, perched upon naked branches, and uttering at short intervals a sharp and monotonous cry. The Tyrants are bold and quarrelsome birds, particularly during the season of incubation; the male will not then suffer any birds to come near its nest, and becomes so infuriated against snch unconscious intruders that it will attack both hawks and eagles, with a determination not to be resisted, until they are fairly driven away."

Ceblepyrinæ.

Sub-Family Character.—Bill broad at the base, but destitute of long bristles. Rictus nearly smooth. Wings pointed; the three first quills graduated. Feathers on the rump very thick, and apparently spinous. Tail with the centre emarginated, and the sides rounded. Feet short; lateral toes unequal.

Locality.—Warm latitudes of the Old World.

Genera.—*Ceblepyris*, Cuv.; *Oxynotus*, Sw.; *Campephaga*, Vieill., with its sub-genus *Phœnicornis*, Sw.; and *Erucivora*, Sw.

Mr. Swainson is of opinion that the passage from the Tyrant-Shrikes to the *Ceblepyrinæ* is sufficiently marked by tho Mexican genus *Ptiliogonys*, which brings them very close together. The *Ceblepyrinæ* are confined to the Old World; but, according to that author, not a single species had yot been found in Europe. They live upon soft caterpillars, for which they search among the foliage of high trees, as Le Vaillant, who first called attention to the group, pointed out. Mr. Swainson remarks that nearly all the species are distinguished by the feathers on the back, which are very thick set; and when the hand is passed over them in a direction towards the head they feel as if intermixed with little sharp spines concealed beneath the surface. This singular construction, he adds, is seen also in the Trogons, and, in a less degree, in the families of Orioles and Cuckoos. The genus *Phœnicornis*, in his opinion, unites this division to the Tyrants.

Dicrurinæ.

Sub-Family Character.—Bill compressed towards the ond; the culmen gradually arched and bent over the lower mandible. Feet short. Tail lengthened, generally forked. Wings long, and more or less pointed.

Locality.—The warm latitudes of the Old World.

Genera.—*Tephrodornis*, Sw.; *Melasoma*, Sw.; *Ocypterus*, Cuv., with its sub-genus *Analcipus*, Sw.; and *Dicrurus*, Vieill.

Mr. Swainson holds that wo are led to the *Dicrurinæ*, or Drongo-Shrikes of Le Vaillant, by those caterpillar-catchers (*Erucivora*, Sw.) which have only a few acute feathers on their back; or that the genus *Oxynotus* may possibly effect this junction. The Drongos, he states, are fly-catching birds, having their bill both compressed and depressed, and the mouth furnished with very stiff long bristles. "These," says Mr. Swainson, in continuation, "are entirely unknown in America, where they seem to be represented by the Fork-Tailed Tyrants (*Milvulus*, Sw.): like them they have the tail, almost universally, long and forked; and they associato, as do the American birds, in flocks, something like Swallows, pnrsuing insects upon the wing in every directiou. Bees appear to be a favourite food with these birds, as they are likewise with the King-Tyrant of North America (*Tyrannus intrepidus*). Some aro ornamented with littlo recurved crests in front of the head; others have the neck-feathers pointed, and of a rich metallic hue; most have the tail remarkably developed; and nearly all are of a uniform glossy black colour: hence it becomes very difficult to distinguish the species, which in truth are much more numerous than has been generally imagined. In the genus *Analcipus* we first havo a few bright colours. Only three species, natives of Madagascar and the Indian Islands, have yet been discovered; they lead us to the Swift-Shrikes (*Ocypterus*, Cuv.), so named from their very long wings; but in *Tephrodornis* these members again become like those of the Drongos. This latter genus is very remarkable; for, by the bristly nature and the incurved direction of the frontal feathers, we have a clear representation of *Chætoblemma*, and all those bristle-fronted birds which are analogical to *Prionops* and *Dasycephala*."

Mr. Swainson remarks with regard to these three groups, which form, according to him, the aberrant sub-families of the *Laniadæ*, that the approximation of the *Dicrurinæ* to the *Tyranninæ* has been thought so strong and so decisive that one ornithologist supposes they actually pass into each other; and he thinks that this union is not only highly probable, but what we should naturally expect; in which case the three aberrant groups would form their own circle.

Thamnophilinæ.

Sub-Family Character.—Lateral toes unequal; the outer connected to the first joint of the middle toe. Claws broad, and not very acute. Bill lengthened, abruptly hooked at its tip; the tooth prominent.

Genera.—*Thamnophilus*, Vieill.; *Malaconotus*, Sw.; *Prionops*, Vieill.; *Colluricincla*, Vig.

Mr. Swainson remarks that the habits of the *Thamnophilinæ*, or Bush-Shrikes, are strikingly opposed to those of the aberrant divisions, as he terms them. The Bush-Shrikes, he tells us, live among thick trees, bushes, and underwood, where they are perpetually prowling about after insects and young and sickly birds, and are great destroyers of eggs. They neither seize their prey with their claws, nor do they dart at it on the wing; the former therefore are thick and rather blunt, and the wings are so short as to indicate very feeble flight. Tho bill, which is the capturing instrument, is always stout, much more lengthened than in the True Shrikes, and very abruptly hooked at the end, which is armed with a strong tooth.

Only one species of *Prionops* (*P. plumatus*), according to the same author, was known until lately, and that is common in Senegal, where it is said to search for terrestrial insects in humid situations beneath the surface: it has a peculiar crest of rigid feathers falling back on the head, but also reversed over the base of the bill, and completely protecting the nostrils and the sides of the mouth. Mr. Swainson looks upon this bird as forming the point of union between the Bush-Shrikes and the Forked-Tailed Shrikes, or *Dicrurinæ*, the singular structure above-noticed being partially developed in the genus *Tephrodornis.*

Thamnophilus, which Mr. Swainson regards as strictly typical, shows, he observes, the perfectiou of that particular structure which distiuguishes the Bush-Shrikes. The bill is very powerful; and although many of the species far exceed a thrush in size, others are not much larger than a wren. The group is stated to be confined to the hotter latitudes of America, where the species are very numerous. Though the plumage is thick, the texture of the feathers is very soft and lax. The colours are sombre, but often elegantly varied with dark bands and white spots. Mr. Swainson looks upon the genus *Malaconotus* as representing these birds in Africa; and he observes that, although they were long confounded with them, their distinctions are very decisive, the African group being distinguished for the gaiety and brightness of their plumage; the brightest crimson, combined with glossy black or clear green, with orange or yellow, decorating most of the species. Others however have the sombre colours of the American group, but they are never banded: and a few so nearly approach the *Lanianæ* that it is very difficult to distinguish them otherwise than by the great inequality of their lateral toes, the inner one being always much shorter than the outer, and the latter often so connected to the middlo toe that the feet are partially syndactyle. The Australian genus *Collurisoma* (*Colluricincla ?*) he thinks, probably represents the tenuirostral type.

Lanianæ.

Sub-Family Character.—Lateral toes equal and free. Claws slender, acute. Bill generally short, with the tooth very prominent.

Genera.—*Lanius*, Linn.; *Telophonus*, Sw.; *Chætoblemma*, Sw.; *Nilaus*, Sw.; and *Falcunculus*, Vieill.

Mr. Swainson is of opinion that the precise passage between the *Thamnophilinæ* and the *Lanianæ* seems to be effected by the geuus *Chætoblemma*, a remarkable form discovered in South Africa by Mr. Burchell. This, Mr. Swainson observes, is the only short-billed Shriko that has the frontal feathers stiff and directed forwards upon the baso of the bill: in that respect, as well as in the length of its wings, it presents, in his opiniou, a curious analogy to *Prionops* among the Bush-Shrikes.

The samo author remarks that as the genus *Lanius* is pre-eminently typical, not ouly of its own family, but of the whole tribo of *Dentirostres*, or toothed-billed birds, every country in the world possesses examples of it: even in Australia the True Shrikes are, he states, represented by a peculiar type, tho *Falcunculus frontalis*, which however, instead of watching for its prey, and devouring birds or grasshoppers, by impaling them upon thorns, and feeding on them at leisure, like the True Shrikes, climbs among the branches of trees and devours the hard-coated beetles which lurk beneath. Here, he observes, is a bird having the form of a Shrike and the habits of a Woodpecker. This Australian Shrike, as being the scansorial type of the *Lanianæ*, becomes, in Mr. Swainson's opinion, the representative of the Titmice, and has the crest and nearly the same coloured plumage as the genus *Parus*. This analogy, according to his views, is further indicated by the great size of the hind toe, which is so unusually large, as at once to evince the climbing habits of the bird, as affirmed by Lewin. Nor is this, in his opinion, the only analogy indicated by the colours of this species; for in the Bentivi Tyrant (*Saurophagus sulphuratus*, Sw.), he sees a bird in all its most striking peculiarities of plumage coloured like the *Falcunculus cristatus*, with this difference only, that in one the back is olive-brown and in the other olive-green. "Now," continues Mr. Swainson, "it is precisely at this point where, according to our theory, the circle of the Shrike family is closed; and thus these two genera will stand in juxtaposition. Certain however it is that of all the Tyrants, the Bentivi is that which most resembles a True Shrike; not so much perhaps by its general structure as by its living upon reptiles, and even carrion, and thus becoming, like the shrikes, both insectivorous and carnivorous."

Of the two other genera comprised in this sub-family, *Telophonus* and *Nilaus*, the former, according to the same author, bears such a strong resemblance to the typical genus *Lanius*, as well as to *Malaconotus*, that, without a knowledge of the true characters of these three groups, an ornithologist may be much perplexed in detecting their essential differences. "The genus *Lanius*," says Mr. Swainson, "as already mentioned, is chiefly known in its outward appearance by its short and strongly toothed bill: but there is another character equally important, which all writers have hitherto overlooked—this is to be found in the equal length of the lateral toes and the acuteness of the claws. Now this structure of foot is also found, with a diminution hardly perceptible, in *Telophonus;* but then the bill is lengthened, so as to give these birds at the first glance an appearance of being *Malaconoti*. This union of characters is just what we should expect in such birds as were to represent the Bush-Shrikes in the circle of *Lanianæ;* for although the bill is moderately lengthened in *T. collaris*, and remarkably so in *T. longirostris*, still the culmen is regularly curved, and not abruptly hooked at the end, as in *Malaconotus*. We have no remaining doubt, in short, of the immediate union of *Telophonus* with the pre-eminently typical genus *Lanius*, this union being effected by the Corvine Shrikes in one division, and the *T. leucogrammicus* in the other. The second type is *Nilaus*, at present composed but of one species: it has the bill much like that of a True Shrike, but considerably attenuated; and the general organisation of the bird is weaker than in any other genus. This, we think, is the tenuirostral type of the circle; if so, it will consequently stand between *Chætoblemma* and *Falcunculus*. We have already shown in what respect this latter genus may be viewed as uniting the whole of the shrikes into one circular family; but as we have ventured so far as to trace out the smaller circle of the *Lanianæ*, the ornithologist may well inquire in what manner *Falcunculus* can be actually united to *Lanius*, seeing that its outward structure, no less than its scansorial habits, are so different. Now this union is effected by a singular bird of Brazil, long bandied about (to translate an expressive French phrase) in systems, from the Tanager family to the old genus *Lanius*, and then again to *Thamnophilus:* its structure was so peculiar, that some years ago we placed it as the type of a supposed genus, under the name of *Cyclaris:* a more minute analysis however of this sub-family, and more especially the recent discovery of *Chætoblemma* among the unexamined birds of our friend Mr. Burchell, has quite satisfied us that this is not one of the prominent types of the *Lanianæ*, but only an aberrant species of *Falcunculus;* we therefore cancel the name of *Cyclaris*, and propose for this bird the name of *Falcunculus Guianensis*."

The following is Mr. Swainson's table of analogies of this family:—

Tribes of Perchers.	Analogies.	Sub-Families of Shrikes.
Dentirostres	Bill short, toothed; seize their prey with their foot	*Lanianæ*.
Conirostres	Bill lengthened; compressed feet, strong robust . . .	*Thamnophilinæ*.
Scansores . .	Feet very short, hind toe lengthend .	*Dicrurinæ*.
Tenuirostres	Bill weak, mouth smooth; feed only on soft substances	*Ceblepyrinæ*.
Fissirostres .	Bill broad; feed upon the wing . .	*Tyranninæ*.

"Every one," observes Mr. Swainson, "must have perceived the resemblance, both in form and habits, between the True Shrikes and the Falcons, and that *Lanius*, which is the first division or genus, is typical of the whole family. The skulking thievish propensities of the Bush-Shrikes (*Thamnophilinæ*), and the jays (which belong to the *Conirostres*), in plundering the nests and destroying the eggs of other birds, is thus explained; since it is seen by the above table, that these two groups mutually represent each other. The very great development of the tail in nearly all the Drongo-Shrikes (*Dicrurinæ*) is also one of the most remarkable distinctions of gallinaceous birds and of the scansorial tribe, which latter is eminently characterised by the peculiar length of the hind-toe and by the tail-feathers ending in fine points: all these characters are found in the Drongos, but in no other shrikes. The soft and tender food of the Caterpillar-Catchers (*Ceblepyrinæ*) evinces that even the *Tenuirostres*—a tribe living chiefly upon juices—may be represented by insectivorous shrikes; while the great depression of the bill which has caused the Tyrants (*Tyranninæ*) to be confounded with the Flycatchers, their constant habit of capturing their prey upon the wing, and the recorded fact that more than one species dives in the water, all remind us of the fissirostral swallows and the aquatic order of *Natatores*."

Before dismissing his account of this family, Mr. Swainson makes the following remarks upon the genera *Vanga* and *Platylophus*—two modern genera, he observes, that appear to enter within its limits, but whose true situation he suspects is very different. "The name of *Vanga*," says Mr. Swainson, "was given by Buffon to a singular and very rare bird of Madagascar, as big as a jay, but with a long abruptly hooked bill like a *Thamnophilus*. It has been usual to place this genus, as well as that of *Platylophus*, in the same group: but when we find that even M. Cuvier joins them with the large Bush-Shrikes, and several of the African *Malaconoti*, in his genus *Vanga*, we immediately perceive that a group so composed is entirely artificial. The resemblance between *V. destructor* and the smaller species of *Barita*—which latter are obviously crows—is so perfect, that a suspicion has always existed in our mind that both belonged to the corvine family. As we have seen, in the genus *Falcunculus*, an Australian shrike assume all the manners of a woodpecker, may not *Vanga, Barrita* (*Barita*), &c., by analogy of reasoning, be true crows, disguised under the economy and much of the structure of shrikes? Again, does the *Vangæ* (*Vanga*) of Australia and that of Madagascar belong to the same genus, or even to the same natural group? The only specimen of this latter bird known to exist in collections is in the Paris Museum, but in too injured a state to allow of this question being answered. On the other hand we happen to know, from unquestionable testimony, that the *V. destructor* of Australia kills and eats small birds, in the same manner as the European species; and that it is actually called a Butcher-Bird by the colonists. Yet this, after all, seems to us only a relation of analogy, just as in the case of *Mniotilta*, which, although it climbs like a *Certhia*, is merely a representation of those scansorial birds, and truly belongs, by affinity, to the circle of warblers. Since our last observations upon *Vanga* were published, we have been fortunate in procuring two or three species, which so connect the Australian *Vangæ* with *Barrita* (*Barita*), that we no longer hesitate to place them all in the corvine family (*Corvidæ*); where also we now arrange *Platylophus*, since it certainly has a greater resemblance to *Vanga destructor* than to any of the Soft-Backed Shrikes (*Malaconoti*). This alteration does not however interfere with anything we have said regarding *Platylophus* being a rasorial type: as such it remains, but merely fills that station in another circle. *Platylophus*, in short, has all the outward aspect of a jay, combined with that of a shrike; while its remarkable crest indicates to which of the primary types of nature we should refer it." ('Classification of Birds;' see also 'Zoological Journal,' vols. i. and ii.; and 'Fauna Boreali-Americana,' vol. ii.)

Prince C. L. Bonaparte, in his 'Specchio Comparativo' (1827), places the genus *Lanius* between the genera *Vireo* and *Turdus*. In his 'Geographical and Comparative List of the Birds of Europe and North America' (1838), the Prince arranges the *Lanidæ* between the *Muscicapidæ* (its last sub-family being *Vireoninæ*) and the *Corvidæ*. In this arrangement the family consists of the sub-family *Laninæ*, which is composed of the genera *Lanius*, Linn., and *Enneoctonus*, Boie (*Lanius*, Vig.).

Mr. G. R. Gray makes the *Laniadæ* (his fifth family of the tribe *Dentirostres*) consist of but two sub-families—the *Lanianæ* and the *Thamnophilinæ*.

Lanianæ.—Genera, *Keroula*, J. E. Gray; *Corvinella*, Less.; *Lanius*, Linn.; *Collurio*, Briss.; *Eurocephalus*, Smith; *Oreoica*, Gould; *Falcunculus*, Vieill.; *Cyclarhis*, Sw.; *Laniellus*, Sw.; *Telophorus*, Sw.; *Nilaus*, Sw.; *Nopothera*, Mull.; *Prionops*, Vieill.; *Colluriocincla*, Vig. and Horsf.

Thamnophilinæ.—Genera, *Thamnophilus*, Vieill.; *Cymoilaimus*, G. R. Gray; *Pityriasis*, Less.; *Vanga*, Buff.; *Laniarius*, Vieill.; *Dryoscopus*, Boie; *Chaunotus*, G. R. Gray; *Cracticus*, Vieill.

The *Dicrurinæ* are placed by Mr. G. R. Gray as the last sub-family (the 6th) of the *Ampelidæ;* and the *Tyranninæ* occupy a position as the third sub-family in the family *Muscicapidæ*.

The *Laniadæ* in this author's arrangement come between the families *Ampelidæ* and *Corvidæ* (the first family of his tribe *Conirostres*. ('List of the Genera of Birds.' 1840.)

The European species of *Laniadæ* are *Lanii excubitor, meridionalis, minor, collurio*, and *rufus*, the two last belonging to the genus *Enneoctonus*, Boie.

We proceed to illustrate this family with the typical genus

Lanius.—Bill very short, strongly hooked; the tooth very prominent; wings moderate, somewhat pointed; tail rounded or slightly graduated; lateral toes free and equal; claws acute. (Sw.)

Lanius Excubitor, Linn., the Butcher-Bird, may be taken as an example.

Old Male.—Head, nape, and back, fine bright ash; a large black band passing beneath the eyes and covering the orifices of the ears; lower part pure white; wings short, black; origin of the quills and extremity of the secondaries pure white; two external tail-feathers white; the third black towards the centre, the fourth terminated by a great white space, and the fifth by a less extensive space; the two middle ones entirely black; bill and feet deep black. Length 9 or 10 inches.

The Young Male resembles the female.

Female.—Upper parts less bright ash; lower parts whitish, each breast-feather terminated by a crescent of bright ash; less white at the extremity of the secondaries, and more black on the origin of the tail-feathers.

Head and Foot of Butcher-Bird (*Lanius Excubitor*).

Varieties.—1. Nearly perfect white, only the black parts are lightly shadowed out by deep ash.

2. More or less variegated with white. (Temm.)

This is the *Castrica palombina* and Averla Maggiore of the Italians; the Pie-Grièche Grise and Pie-Grisatre of the French; Torn-Skade of the Danes; Warfogel of the Swedes; Klavert of the Norwegians; the Berg-Aelster, Grossere Neuntoder, and Gemeine Würger, of the Germans; Greater Butcher-Bird or Mattagess of Willughby; Mountain Magpie, Murdering Pie, Great Gray Shrike, Shreek, and Shrike, of the British; and Cigydd Mawr of the Welsh.

In England this species is only an occasional visitor, nor are we aware of any instance of its having bred here. "The Gray Shrike," says Mr. Yarrell, "has been obtained in several southern and western counties. In Surrey, Sussex, Wiltshire, Dorsetshire, Devonshire, Worcestershire, and Cheshire; and I am informed by Mr. Thompson of Belfast, that it has occurred in one or two instances in the North of Ireland. A specimen shot near Belfast is in the collection of Dr. J. D. Marshall. North of London, it has been killed in Suffolk, Cambridgeshire, Norfolk, Yorkshire, Cumberland, Northumberland, and Durham. No Shrikes appear to have been seen either in the islands of Orkney or Shetland; but the Gray Shrike is included among the birds of Denmark, Norway, Sweden, Lapland, Russia, and Germany. In Holland it is rare; but it is rather a common bird in France, and remains there throughout the year, frequenting woods in summer and open plains in winter. It is an inhabitant also of Spain, Portugal, and Italy." ('British Birds.') Prince C. L. Bonaparte notes it as common near Rome in winter. ('Specchio Comparativo.')

"This Bird," writes Willughby, "in the north of England is called Wierangle, a name, it seems, common to us with the Germans, who (as Gesner witnesseth), about Strasburg, Frankfort, and elsewhere, call it Werkangel or Warkangel, perchance (saith he) as it were Wurchangel, which literally rendered signifies a 'suffocating angel.' In other parts of Germany it is called Neghen-Doer, that is, Ninekiller (Enneactonos), because it kills nine birds before it ceases, or every day nine. Our falconers call it the Mattagess, a name borrowed from the Savoyards, which is by Aldrovandus interpreted a Murthering Pie." Dr. Brookes writes the northern name differently, "Called in Yorkshire and Derbyshire the Were-Angel." The food of this species, which haunts bushes, the skirts of woods and plantations, consists of mice, field-mice, frogs, small birds, lizards, and beetles. "Although," says Willughby, "it doth most commonly feed upon insects, yet doth it often set upon and kill not only small birds, as finches, wrens, &c., but (which Turner affirms himself to have seen) even thrushes themselves: whence it is wont by our falconers to be reclaimed, and made for to fly small birds."

Mr. Yarrell states that the Gray Shrike feeds upon mice, shrews, small birds, frogs, lizards, and large insects. In the 'Portraits des Oyseaux' (1557), where, by the way, it is called Falconello, the bird is represented upon a field-mouse, with the following quatrain beneath its likeness:—

> "Ceste Pie est la moindre de corsage:
> Au demeurant, elle vit de Souris,
> Rats, et Mulots, qui sont par elle pris
> Parmy les champs, gastans bled et fourrage."

So that it seems to have been considered a useful bird in France. It derives its name of Butcher-Bird from its habit of suspending its prey, after it has deprived it of life, upon thorns, and so hanging it up, as a butcher does his meat, upon its sylvan shambles. Mr. Yarrell quotes part of a letter from Mr. Doubleday of Epping, who states that an old bird of this species, taken near Norwich, in October, 1835, lived in his possession twelve months. It became very tame, and would readily take its food from its master's hands. When a bird was given to it, it invariably broke the skull, and generally ate the head first. It sometimes held the bird in its claws, and pulled it to pieces in the manner of hawks; but seemed to prefer forcing part of it through the wires, then pulling at it. It always hung what it could not eat up on the sides of the cage. It would often eat three small birds in a day. In the spring it was very noisy, one of its notes a little resembling the cry of the kestrel.

In the 'Booke of Falconrie or Hawkinge' (London, 1611), we find the Matagesse immediately following 'the Sparrowhawke;' and at the end of 'A generall division of hawks and birdes of prey, after the opinion of one Francesco Sforzino Vyncentino, an Italian gentleman falconer,' we have the following account 'of the Matagasse:'—

"Though the matagasse bee a hawke of none account or price, neyther with us in any use; yet neverthelesse, for that in my division I made recitall of her name, according to the French author, from whence I collected sundries of these points and documents appertaining to falconrie, I think it not beside my purpose briefly to describe heere unto you, though I must needs confesse, that where the hawke is of so slender value, the definition or rather description of her nature and name, must be thought of no great regard;" and then the Matagasse is described.

"Her feeding," continues Turberville, the writer of 'The Booke,' "is upon rattes, squirrells, and lisards, and sometime upon certaine birds she doth use to prey, whome she doth intrappe and deceive by flight, for this is her devise. She will stand at pearch upon some tree or poste, and there make an exceeding lamentable crye and exclamation, such as birdes are wonte to doe being wronged, or in hazarde of mischiefe, and all to make other fowles believe and thinke that she is very much distressed, and standes needefull of ayde, whereupon the credulous sellie birdes do flocke together presently at her call and voice, at what time if any happen to approach neare her, she out of hand ceazeth on them, and devoureth them (ungratefull subtill fowle!) in requital of their simplicity and pains. These hawkes are in no accompt with us, but poor simple fellows and peasants sometimes do make them to the fiste, and being reclaimed after their unskillful manner, do beare them hooded, as falconers doe their other kinde of hawkes whom they make to greater purposes. Heere I ende of this hawke, because I neither accompt her worthe the name of a hawke, in whom there resteth no valour or hardiness, ne yet deserving to have any more written of her propertie and nature, more than that she was in mine author specified as a member of my division, and there reputed in the number of long-winged hawkes. For truely it is not the property of any other hawke, by such devise and cowardly will to come by their prey, but they love to winne it by main force of winges at random, as the round-winged hawkes doe, or by free stooping, as the hawkes of the tower doe most commonly use, as the falcon, gerfalcon, sacre, merlyn, and such like, which doe lie upon their wing, roving in the ayre, and ruffe the fowle, or kill it at the encounter."

With reference to the art which the Matagasse is here said to practise in order to entrap other birds, a device attributed to the Butcher-Bird by other authors, the communication of a writer in 'The Naturalist' becomes interesting. He states that his first acquaintance with this bird was occasioned by hearing notes not entirely familiar to him, though they much resembled those of the Stonechat. Following the sound, he soon discovered the utterer; and, while listening, to his surprise, the original notes were discarded, and others adopted of a softer and more melodious character, never however prolonged to anything like a continuous song.

Sir John Sebright, in his interesting 'Observations upon Hawking,' when treating of Passage Hawks, states that the Slight Falcons (*Falco gentilis*) which are brought to this country in the spring, to be used in flying herons, are caught in the preceding autumn and winter on the heaths near Falconsweard, as they pass towards the south and east. These hawks are taken, he tells us, by placing in a favourable situation a small bow net, so arranged as to be drawn over quickly by a long string that is attached to it. A pigeon of a light colour is tied on the ground as a bait; and the falconer is concealed, at a convenient distance, in a hut made of turf, to which the string reaches. A Butcher-Bird (*Lanius Excubitor*), "that is, the Warder Butcher-Bird, from the look-out that he keeps for the falcon, is tied on the ground near the hut, and two pieces of turf are so set up as to serve him, as well for a place of shelter from the weather, as of retreat from the falcon. The falconer employs himself in some sedentary occupation, relying upon the vigilance of the butcher-bird to warn him of the approach of a hawk. This he never fails to do, by screaming loudly when he perceives his enemy at a distance, and by running under the turf when the hawk draws near. The falconer is thus prepared to pull the net the moment that the falcon has pounced upon the pigeon."

The nest is generally built on trees, and is framed of grass-stalks, roots, and moss, with a lining of down or wool. The eggs, from four to six, or, according to Temminck, from five to seven, are bluish or grayish-white, spotted on the larger end with light-brown and ash.

Butcher-Bird (*Lanius Excubitor*).

In captivity, Bechstein states that, if the bird be captured when it is old, mice, birds, or living insects may be thrown to it, taking care to leave it quite alone, for as long as any one is present it will touch nothing; but as soon as it has once begun to feed freely, it will eat fresh meat, and even become accustomed to the universal paste. An ounce of meat at least is eaten at a meal, and there should be a forked branch or crossed sticks in its cage, across the angles of which it throws the mouse or any other prey, and then darting on it behind from the opposite side of the cage, devours every morsel. The same author states that it may be easily taken if a nest of young birds crying from hunger be suspended to lime-twigs, and that in autumn and winter it will sometimes dart on birds in cages which are outside the window. Bechstein further remarks, that, like the Nutcracker, it can imitate the different notes, but not the songs of birds. Nothing is more agreeable, according to him, than its own warbling, which much resembles the whistling of the Gray Parrot: its throat at the time being expanded like that of the Green Frog. He adds, that it is a great pity that the bird only sings during the pairing season, which is from March to May, and even then often spoils the beautiful melody of its song with some harsh discordant notes.

LANIOGERUS. [NUDIBRANCHIATA.]

LANNER. [FALCONIDÆ.]

LA'NSIUM, a genus of Plants belonging to the natural order *Meliaceæ*, established by the late Dr. Jack, and formed of the *Lansium* of Rumph., 1, p. 151, t. 54, which is the *Lansai* of Marsden's 'Sumatra,' pl. v. p. 101, and the Langsal or Lanseh of the natives of the Malay Islands. This forms one of the highly-esteemed fruits peculiar to the Malayan Archipelago, or what was termed India Aquosa by old writers, though unnoticed in many works where we might expect to find it fully described. The genus is characterised by—Calyx deeply 5-parted; corolla 5-petalled, petals roundish. The tube formed by the union of the stamens is subglobose, with its mouth nearly entire, having the 10 anthers included within it. Ovary 5-celled, cells with 1-2 ovules; style short, columnar; stigma flat, 5-rayed; berry cortical, 5-celled, 5-seeded, with one or two cells only perfecting their seed; seeds enveloped in a semitransparent pulpy tunic or aril, exalbuminous; cotyledons unequal, peltate, the short radicle being inserted into their centre. The Lanseh forms a moderate-sized tree with tomentose branches. Leaves alternate, pinnate; leaflets 7 to 9, alternate, short-pedicelled, elliptic-oblong, very smooth; the young leaves are pubescent on the under surface; stipules none; racemes springing from the trunk and naked branches, at first suberect, afterwards drooping by the weight of the fruit. The fruit is of an agreeable taste, according to Marsden, though the skin contains a colouring juice, extremely bitter, and which is apt to taint the fruit if not opened with care.

The Ayer-Ayer is another fruit so nearly resembling the Lanseh in most particulars that Dr. Jack, hesitating to rank it as a species, mentions it as a permanent and well-marked variety under the name var. *β. L. aqueum*. The fruit of the Ayer-Ayer is rounder, and the pulp more watery, and dissolves more completely in the mouth than the Lanseh. Both are highly esteemed by the Malays, and are equally agreeable to the European palate. The juicy envelope of the seeds is the part eaten, and the taste is cooling and pleasant. ('Linnæan Transactions,' xiv. p. 114.)

LANTA'NA, a genus of Plants belonging to the natural order *Verbenaceæ*, named from one of the old names of *Viburnum*, which some of the species somewhat resemble in habit. They are often stated to be confined to America, but a species is found in Arabia, and two in India. They form small or moderate-sized shrubs, often with rugose aromatic leaves, and a somewhat peculiar odour in the clustered flowers, which are either pink, yellow, white, or changeable. Piso states that three species, which are confounded together in Brazil under the name *Camara*, are there used for making medicated baths for diseases of the skin. Martius states that the flowers of some species are employed for making demulcent drinks in catarrhal affections. *L. macrophylla* is employed in infusions as a stimulant, and *L. pseudo-Thea* as a substitute for tea.

LANTERN-FLY. [FULGORA.]

LAOMEDEA, a genus of *Polypifera*, established by Lamouroux to include species ranked by previous writers as belonging to *Sertularia*. [SERTULARIDÆ.]

LAPIS-LAZULI. [LAZULITE.]

LAPLYSIA. [TECTIBRANCHIATA.]

LAPPA, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Tubuliflorœ*, the tribe *Senecionideæ*, and the sub-tribe *Carduineæ*. It has an equal and many-flowered homogamous head, a globose involucre, with imbricated coriaceous scales. The receptacle is rather fleshy, flat, and with stiff fringes; the corollas are 5-cleft, regular, and with a 10-nerved tube; the stamens have papillose filaments, with anthers terminating in filiform appendages; the fruit is oblong, laterally compressed, smooth, and transversely wrinkled.

L. minor has a tapering fleshy root, an erect stem, 3 feet or more in height, solid, leafy, round, and with many wide-spreading branches; the leaves are stalked, broad, heart-shaped, and, being 3-ribbed at the base, somewhat hoary and downy beneath; the florets are axillary, with their anthers and stigmas purple. When in flower the involucre readily breaks from the stalk, and is known in the country by the name of a Bur. It adheres to the coats of animals and the hair and clothing of those who pass by, and it is almost impossible to become free from it without breaking the scales asunder and scattering the fruit. The root is reckoned tonic, aperient, and diuretic. It has had some reputation in the form of a decoction in rheumatism and diseases of the skin. Sir Robert Walpole recommends it as a remedy in gout, and some have used it as an excellent substitute for sarsaparilla. The fruit is bitter and slightly acid, and has been prescribed as a diuretic. It grows in waste places throughout Europe and the west of Asia.

L. major and *L. tomentosa* are species which are found in Germany and Switzerland, but are not used in the arts or in medicine.

(Lindley, *Flora Medica;* Koch, *Synopsis Floræ Germanicæ.*)

LA'PSANA, a genus of Plants belonging to the natural order *Compositæ*, the sub-order *Liguliflorœ*, the tribe *Achoraceæ*, and the sub-tribe *Lampsanæ*. There is but one British species of this genus—

L. communis, Nipple-Wort. It has dentate or lobed stalked leaves, the lower leaves lyrate; the involucres glabrous and angular; the stem panicled. The stem is from one to three feet in height, branched above, with yellow small-headed florets. It is found in waste uncultivated land, and derives its common name from its reputation in village medicine as a soothing application to inflamed nipples, and is used in many of our provinces as an external application in wounds and ulcerations.

L. fœtida is a species of this genus which grows in Switzerland and the regions of the Alps.

(Babington, *Manual of British Botany;* Koch, *Synopsis Floræ Germanicæ.*)

LAPWING. [CHARADRIADÆ.]

LARCH. [ABIES.]

LARDIZA'BALA, a genus of Plants belonging to the natural order *Menispermaceæ*, and named by Ruiz and Pavon after Michael Lardizala, of Uribe, a Spanish naturalist. It has diœcious and polygamous flowers. The sepals and petals disposed in a ternary order in 2 or 3 series. The stamens 6, monadelphous; berries 3- or 6-celled, the cells many-seeded. The pulp of the fruit sweet and eatable. It has leaves 2-3 ternate; the leaflets oblong, acute, unequal at the base, a little toothed; two large unequally cordate bracts situated at the base of the peduncle. This plant is a twining shrub, a native of Chili in woods at Concepcion, also in Peru about Arauco. It has an eatable fruit, which is gathered and sold in the markets of Chili and Peru. The pulp of the fruit is sweet and grateful to the taste. It is called in Peru Aguil-boguil and Guilbogui; and in Chili by that of Coquilvochi. *L. triternata* and *L. trifoliata* are climbing plants, natives of Chili and Peru, but their fruits are not eaten. (Don, *Dichlamydeous Plants.*)

LARDIZABALACEÆ, *Lardizabalads*, a small natural order of Plants, containing 7 genera and 15 species. The species are twining smooth shrubs with alternate compound leaves, without stipules. Racemes solitary or clustered; flowers coloured white, lilac, purple, or deep yellow, sometimes fragrant. The sepals of the male plant are 3 or 6 in 2 rows, deciduous; petals 6 in 2 rows, opposite the sepals, the inner ones smaller, or gland-like, or absent. Stamens 6, opposite the petals; filaments united into a tube, or even distinct; anthers turned outwards, rarely inwards, 2-celled, opening by a longitudinal slit. The female flowers as before, but larger, with 6 very imperfect stamens. Carpels distinct, 3, rarely 6 or 9, 1-celled, with a short style and a single stigma. Two of the genera inhabit the cooler parts of South America, the remainder are from the temperate parts of China. *Burasaia* is the only tropical form. These plants appear to be harmless. Some of them are eaten by the natives of Japan and India.

LARDIZABALADS. [LARDIZABALACEÆ.]

LARIDÆ, the name given by Leach to the family of Birds vernacularly known as Sea-Gulls, Sea-Mews, or Gulls, belonging to Mr. Vigors's fifth order *Natatores*.

Willughby, in his 'Ornithology,' under his section (vi.) 'Of Sea-Gulls, called in Latine *Lari*,' says in his first chapter of that section entitled 'Of Gulls in General'—"Gulls are a whole-footed fowl, with an indifferent long, narrow, sharp-pointed bill, a little crooked at the end; oblong nostrils; long and strong wings; short legs; small feet (for they do not swim much); a light body, but invested with many and thick-set feathers; a carrion carkass, the fat that is sticking to the skin (as in other birds); much upon the wing, very clamorous, hungry, and piscivorous.

"These we divide into two kinds:—1st, the greater, which have tails composed of feathers of equal length, and an angular prominency or knob on the lower chap of the bill underneath to strengthen it, that they may more strongly hold fishes; 2nd, the lesser, which have a forked tail, and no knob on the bill (or, he adds in a marginal note, 'but a very small one'). Both kinds may be divided into pied or particoloured, and gray or brown."

Willughby places the Gulls between the 'Douckers, or Loons, called in Latine *Colymbi*,' and the 'whole-footed birds with broad bills,' the first members of which are 'the Goose-kind,' commencing with the Swan.

Ray's 'Synopsis' places the Gulls between the *Colymbi* and the 'Aves Palmipedes rostro in extremo adunco, non serrato,' *Avis Diomedea* (Albatross), Shearwater, Puffinus, &c.; and he describes them as "Palmipede Birds, with a narrow, sharp, but not hooked (adunco) bill, long-winged, and much given to flight (volaticæ), called *Lari*, in English Guls or Sea-Mews, and in some places Sea-Cobs," with the following definition:—"The marks of Gulls are a strong, oblong, narrow, and acute bill, which is a little curved at the extremity, but in the smaller species straighter; nostrils oblong; wings oblong and strong; feet small; body very light, clothed with many and thick feathers; and to be clamourous, much on the wing, hungry, and piscivorous."

He divides the Gulls into three sections, namely:—

1. The Three-Toed Gulls, 'Lari tridactyli, seu postico digito carentes;'
2. Four-Toed Gulls, 'Lari tetradactyli, seu postico digito donati, and
3. Fork-Tailed Gulls, 'Lari minores, caudâ forcipatâ' (Terns, &c.).

Brisson placed in his twenty-third order (consisting of birds with four toes, the three anterior joined together by membranes and the posterior separate, and with a toothless bill), the Gulls, Petrels, Puffins, Terns, Sea-Skimmer, or *Rhyncopsalia* (*Rhynchops*, Linn.). &c.

The second division of the third order (*Anseres*) of Linnæus consists of those web-footed water-fowl which have an edentulous bill, and the following are the genera of that order:—*Rhynchops*, *Diomedea*, *Alca*, *Procellaria*, *Pelecanus*, *Larus*, *Sterna*, and *Colymbus*.

M. Lacépède's second sub-class of birds consists of those which have the lower part of the leg denuded of feathers, or many toes united by a large membrane. The first division of this sub-class comprises those birds which have three anterior toes, and one toe or none behind. In the first sub-division, the first order (the twenty-second reckoning from the beginning), consisting of palmiped water-birds with a hooked beak, we find *Diomedea* and *Procellaria*, among other genera; and in the third (twenty-third reckoning from the beginning) are placed, also among other genera, *Rhynchops*. In the fourth (twenty-fifth reckoning from the beginning), with a straight and slender bill, we have the genus *Sterna*; and, in the next but one (twenty-seventh), bill tumid (bec renflé), we have the genus *Larus*, the intervening genus being *Recurvirostra* (Avosets).

M. Duméril's third family (twenty-second in the series), consists of the long-winged *Palmipedes*, and includes *Rhynchops*, the Terns, the Avosets, the Petrels, the Albatrosses, and the Sea-Mews.

In the method of M. Meyer, we find the first sub-order (*Conirostres*) of his eleventh order, *Natatores*, comprising among other genera those of *Sterna*, *Larus*, and *Lestris*.

The Long-Winged *Natatores* (Longipennes) of Illiger consist of the genera *Rhynchops*, *Sterna*, *Larus*, and *Lestris*; and his *Natatores* with tubular nostrils (*Tubinares*), of *Procellaria*, *Haladroma*, *Pachyptila*, and *Diomedea*.

Cuvier's Long-Winged *Palmipedes* comprise the Petrels, Albatrosses, Gulls, Terns, and *Rhynchops*.

The fourth family (Pelagians) of M. Vieillot's first tribe (Teleopodes) of the order *Natatores* consist of *Stercoraria*, the Gulls, Terns, and *Rhynchops*.

M. Temminck places the whole of the *Palmipedes* in one order.

M. De Blainville's *Natatores* consist of the Macropteres (Gulls), the Syphonorhiniens (Petrels), the Cryptorhiniens (Pelicans), and the Colymhiens. In his method as developed by M. Lherminier, the Gulls (*Larus*) and the Petrels (*Procellaria*) are placed in his first sub-class, or Normal Birds.

Mr. Vigors ('Natural Affinities that connect the Orders and Families of Birds,' 'Linn. Trans.,' vol. xiv.) states that *Phaëton*, a genus belonging to the immediately preceding family (*Pelecanidæ*), bears a considerable resemblance in general appearance and habits to *Sterna*, belonging to the succeeding family of *Laridæ*, the structure of their foot alone effecting a separation between them. Even here however, he remarks, we may observe the gradation that exists between the feet of the two families; the web that unites the toes of the Tropic-Bird, as well as of the Frigate-Bird, being but half the size of that of the *Pelecanidæ* in general; and thus their foot preserves a connection with that of the Terns, where the same membrane is equally contracted. "We thus," continues Mr. Vigors, "enter the family of *Laridæ* by means of *Sterna*, with which *Rhynchops* (Linn.) most intimately accords in habits and external characters, notwithstanding the dissimilitude of the bill. The *Sterna Anglica*, or Gull-Billed Tern of Colonel Montagu, conducts us from these genera to the groups which compose the Linnæan *Larus*, now justly subdivided into two genera, the *Lestris* (Ill.), and *Larus* of authors. From this group we are led to the genera *Diomedea* (Linn.) and *Haladroma* (Ill.), which are characterised by the absence of the hind toe, by means of the species *Larus tridactylus* (Lath.), where, though the hind toe is not absolutely deficient, as might be inferred from the specific name, there appears but the rudiment of one, or rather a stump without a nail. The last-mentioned genus, *Haladroma*, originally belonged to the *Procellaria* (Linn.), and was separated from it by its tridactyle foot. Even in this character however it forms a passage from *Larus* to the groups that compose the genuine *Procellaria*, all of which are distinguished by the singular peculiarity of having no true hind toe, but a nail adhering to the tarsus in its place. We thus arrive at the Petrels, separated into the groups of the *Procellaria* (Auct.), *Pachyptila* (Ill.), *Puffinus* (Ray), and the section denominated by M. Temminck Les Petrels Herondelles. These two latter groups appear to lead us back to the Terns, or Sea-Swallows, from whence we started. The whole of this family, which corresponds with the *Longipennes* of M. Cuvier, is distinctly characterised by the strength and expansiveness of their wings, with the aid of which they traverse immeasurable tracts of the ocean in search of their food, and support their flight at considerable distances from land, seldom having recourse to their powers of swimming. We may thus discern the gradual succession by which the characters peculiar to the order descend from the typical groups that swim and dive well and frequently, but make little use of their wings for flight, to the present groups, which are accustomed to fly much, but seldom employ their powers of swimming, and never dive. The family of *Laridæ* may thus be observed to stand at the very extremity of the order; and it assumes, as I have already observed, in conjunction with the other extreme groups, much of the habits of the land birds. A portion of the group before us, the Petrels, seem even to employ their feet in their own element as if on land, walking as it were on the surface of the waters. We have thus arrived at the termination of the last family of the order, and have to look for its connection with the first. This link is immediately supplied by the before-mentioned genus, *Pachyptila*, in which the bill, broad and depressed at the base, assumes the character of that of the *Anatidæ*. There is indeed a considerable approximation and interchange of character between the two groups. The bill of some species of *Anser* may be observed to become gradually less broad and more compressed, so as to bring them closely to the Petrels; while again the web that connects their toes is equally curtailed in extent, until in one species, the Semipalmated Goose of Dr. Latham, figured in the supplement to his 'Synopsis,' we may observe no greater web than may be seen among many of the *Sternæ*. On the other hand, the same membrane is so extended in some of the Petrels, as to equal the most dilated web observable among the *Anates*. We may also add that the divisions of the *Procellariæ*, as they approach the *Anatidæ*, become gradually more nocturnal in their habits, and thus adopt a character common to a great portion of the latter family. Here then in the fifth and last order of birds we perceive the families of which it is composed following each other in a regular series of affinities, which returns into itself with a continuity similar to that which has been equally apparent in every other great department of the class."

M. Latreille places the Gulls, Puffins, Pelecanoides, Petrels, Albatrosses, Terns, Noddies, *Pachyptila*, and *Rhynchops*, in his third family (*Longipennes*), of his seventh order (*Palmipedes*), belonging, with the Échassiers (*Grallatores*), to his second section, Aquatic Birds.

Prince C. L. Bonaparte, in his 'Tabella Analitica de' Generi' ('Specchio Comparativo'), makes the *Longipennes* the first family of his order *Anseres*. He divides the family into two sections:—1, 'Narici senza margine rilevato,' consisting of the genera *Rhynchops*, *Sterna*, *Larus*, and *Lestris*; 2, 'Narici tubulose,' containing the genera *Procellaria* and *Diomedea*.

M. Lesson, in his 'Projet,' makes the *Palmipedes* (*Natatores*) his eighth order, being the third of his second section, Aquatic Birds. In the 'Table Méthodique,' at the end of his 'Manuel,' his fourth family of *Palmipedes* is named *Laridæ*, and consists of the genera

Sterna, Rhynchops, Larus, Stercorarius, Diomedea, Haladroma, Procellaria, Pachyptila, Puffinus, and *Thalassidroma*. The family is ranged by M. Lesson between the *Pelecanidæ* and the *Anatidæ*, which form his last family.

Mr. Eyton, in his 'Catalogue of British Birds,' enumerates the following genera and sub-genera as constituting the family of *Longipennata*:— Genus, *Procellaria*, Linn.: sub-genera, *Puffinus*, Ray; *Fulmarus*, Stephens; *Thalassidroma*, Leach. Genus *Lestris*, Temm.; genus *Larus*, Linn.: sub-genera, *Rissa*, Leach; *Larus*, Stephens: *Chroicocephalus*, Eyton; *Xema*, Leach; *Sterna*, Linn.; and *Anous*, Leach.

Mr. Swainson, who refers to Mr. Vigors's arrangement above noticed, speaks of the *Laridæ* as constituting a much more numerous family than either of the three *Colymbidæ, Alcidæ* (*Alcadæ*), or *Pelicanidæ* (*Pelecanidæ*) previously adverted to by him. The structure of the *Laridæ* too he considers to be more perfect in a general sense, although inferior in that particular construction which constitutes the perfection of the order, namely, the power of swimming and diving. The wings, he remarks, are very long; and the feet, although webbed, enable these birds to walk about with perfect ease on the shore in search of food; the hind toe is very small, sometimes wanting; but the legs are nearly as long as in some of the Wading Birds, of which he considers them to be the representatives. The bill he notices as being slender, much compressed, and as gradually but not abruptly bent. After referring to their gregarious and omnivorous habits, their tolerable facility of swimming, their inability to dive, and their great power of flight, Mr. Swainson notices the genera in the following order, and expresses his views in the following terms:—

"The Terns, or Sea-Swallows (*Sterna*), constitute the fissirostral type; they have remarkably long wings and slender bills; the tail is forked; and the plumage generally is a of a delicate pearl-white, with more or less black upon the head: the species are numerous, and occur in both hemispheres. The extraordinary genus *Rhynchops*, or Skimmer, although possessing much of the general habits of the terns, is eminently distinguished by the singular form of its bill, the upper mandible of which is considerably shorter than the under, and appears as if one-third of the length had been broken off: three species have been described, to which we add a fourth: they skim over the surface of the ocean with great swiftness, and scoop up small marine insects and other animals. The True or Typical Gulls (*Larus*) are a numerous race, dispersed in every clime, and so closely resembling each other in plumage, that many of the species are even now but imperfectly understood; they bear a close resemblance in general appearance to the terns, but the bill is stronger, and the upper mandible much more curved towards the end: many are of large size; and all are voracious devourers of fish, and of every marine animal, dead or alive, which is cast upon the shore; they particularly abound in northern latitudes, but seem to range over the whole world of waters. The Parasitic Gulls (*Lestris*) are the raptorial representative, and are almost confined to cold regions; they are known by their stronger conformation, their different shaped bill, and the rough scales upon their feet; these birds, like the frigate cormorants, derive their chief supply of food by robbing their more feeble congeners; they pursue the largest gulls, and make them disgorge or relinquish their hard-earned game. The black-toed and the arctic gulls belong to this group, and both are occasionally seen on the northern shores of Britain. The genus *Diomedia* (*Diomedea*) includes the well-known and gigantic albatrosses, the most powerful and bulky of the whole family; they are oceanic birds, living almost constantly out at sea, but are more particularly abundant in the Pacific Ocean: we have no examples in Britain, or indeed in Europe: the extent of their outspread wings is enormous, yet their flight, except in stormy weather, is by no means lofty; like all the rapacious birds of the ocean, they are most veracious, and their flesh is rank and repulsive. The genus *Haladroma* comprises such of the albatrosses as have the bill more resembling that of the petrels, while they agree with the former in being destitute of a hind toe; but only one or two species have as yet been clearly ascertained. The True Petrels (*Procellaria*) have the lower mandible truncated; we have a native example of this genus in the Fulmar (*P. glacialis*), but nearly all the rest inhabit the antarctic regions; they are continually out at sea, even in the most violent storms; Cuvier mentions that their French name of Petit Pierre is derived from their habits of walking on the water by the help of their wings. The Shear-Water Petrel and some others have been separated under the very objectionable name of *Puffinus*, from the different construction of their nostrils and of the lower mandible: there is one species, the English Puffin (*P. Anglorum*, Tem.), which appears to be confined to the northern coasts of Scotland. The genus *Thalassidroma*, Vig., differs from the other petrels, by having the legs longer and the bill somewhat shorter: it is composed of those small birds well known to sailors by the vulgar name of Mother Cary's Chickens. We may here also mention the sub-genus *Pachyptila*, as being that form which, of all this family, shows the nearest approach to the *Anatidæ*, with which we commenced the circle: the bill retains the general form of the petrels, but the base is considerably dilated, and its inner margins are found to be furnished with teeth-like laminæ. The most aberrant type of the *Laridæ* appears to be the genus *Dromas* of Paykull, a long-legged bird analogous to the flamingos: this we have never yet seen, but Temminck and others consider it has an affinity with the terns. The circle of the *Laridæ*, no less than that of the natatorial order, has now been traced, and we can only regret that our limited space prevents us from laying before the reader some of the very many analogies by which this arrangement is confirmed."

In the 'Synopsis' at the end of the same volume, Mr. Swainson makes the Gulls a sub-family under the name of *Laridæ*, with this definition: "Feet lengthened, formed both for walking and swimming;" the sub-family consists of the following genera and sub-genera:—*Sterna* (Terns), including *Sterna*, Linn.; *Thalassites*, Sw.; *Phaeton*, Linn.; *Rhynchops*, Linn.; and *Gavia*, Brisson; *Larus*, Linn. (Gulls); *Lestris*, Ill. (Jager); *Diomedea*, Linn. (Petrels), including *Procellaria, Diomedea*, Linn. (Albatross); *Haladroma*, Ill.; *Thalassidroma*, Vig.; *Pachyptila*, Ill.; and *Dromas*, Paykull.

Having given a general sketch of the views of authors respecting this extensive family, we shall here confine ourselves to the Gulls only, including in that term the genera *Xema*, of Leach; *Larus*, of Linnæus; and *Lestris*, of Temminck.

Xema (Leach).—Bill short, slender, straight, laterally compressed, its tip bent down; the lower mandible somewhat angulated beneath; nostrils very slender, linear; legs slender; tibiæ naked on the lower part; tail forked. (Gould.) Length about 14 inches.

X. ridibundus (*Larus ridibundus*, Linn.). Summer plumage.—Bill naked, skin round the eye, legs and feet, lively-red; head and throad deep-brown, between chocolate-colour and black; shoulders and back gray; outer edges of the quills (with the exception of that of the first, which is black) white, extremities of all but the first black, slightly tipped with white; rump, tail, and under surface, white.

Winter plumage like summer plumage, saving the head, which is gradually changed from the deep colour above-mentioned to pure white, by a process which Mr. Yarrell has proved to be different from moulting. ('Trans. Zool. Soc.,' vol. i. p. 13.)

Young of the Year.—Colour of bill and tarsi more obscure; top of the head and ear-coverts mottled with brown, which is also the colour of the back and shoulders, each feather having a lighter margin; tail broadly edged with black. (Gould.)

Xema ridibundus (adult in summer plumage, and young of the year). Gould.

This bird is the Mouette Rieuse ou à Capuchon Brun of the French; Gabblano cinerizio col Rostro e colli Piedi rossi, Gaimonc, and Corvo Bianco, of the Italians; Laughing Gull, Pewit, or Blackcap, Sea-Crow, and Mire-Crow, of the English; Yr Wilan Benddu of the Welsh.

The old birds in their complete winter plumage are, *Larus cinerarius*, Gmel.; *L. procellosus*, Bechst.; La Petite Mouette Cendrée, Briss.; Die alte Lachmeve im Winter Kleide, Leisler, &c.; Kleine Zeemeeuw, Sepp.; Gabbiano Cenerino, and Gabbiano Moretta, 'Stor degl. Ucc.;' and Red-Legged Gull of Latham.

In the summer or nuptial plumage the bird is *Larus ridibundus*, Linn., Gmel.; Mouette Rieuse à Pattes Rouges, Briss.; La Mouette Rieuse, Buff.; Schwarzköpfige Meve, Bechst., &c.; Bruinkop Meeuw, Sepp.; Gabbiano Moretta, 'Stor. degl. Ucc.;' and Black-Headed Gull of Latham.

The young of the year are *Sterna obscura*, Brown Tern, and Brown Gull of Latham.

The young in their moult and in winter are, *Larus erythropus*, Gmel.; La Petite Mouette Grise, Briss.; *Larus canescens*, Bechst.; Red-Legged Gull, Penn. 'Arct. Zool.;' Brown-Headed Gull and Red-Legged Gull variety, Latham. (Temm.)

The food of this species consists principally of insects, worms, spawn, and fry, and small fishes. In habits it resembles generally the other Gulls, but it walks better. The nest, contrary to the nidification of the other Gulls, which generally form their nests on the ledges of rocks near the sea, is placed, as is the case with other *Xemæ*, in low situations, such as meadows in the neighbourhood of the sea or æstuaries, among the herbage on the ground. The eggs, which vary much, are generally of a deepish olive, sprinkled with large brown and blackish spots.

They inhabit rivers, salt lakes, and fresh-waters; in winter only on the shores of the sea; a bird of passage in Germany and France; very abundant in Holland at all seasons of the year. (Temminck.) Mr. Selby says that in Britain they are very regular in their migratory movements (for such their departure to and from the sea-coast may properly be termed), and that their return in spring may, in some cases, be calculated upon almost to a day.

Selby speaks of the eggs of this bird as being well flavoured, free from fishy taste, and, when boiled hard, as not easily distinguishable from those of the Lapwing, for which they are sometimes substituted.

The young, he adds, are also eaten, although not held in such high estimation as they formerly were, when great numbers were annually taken and fattened for the table, and when the Gullery (or summer resort of the species) produced a revenue of from 50*l.* to 80*l.* to the proprietor. These are the See-Gulles of the ancient great festivals. In the Household Book of the fifth Earl of Northumberland, begun in 1512, these See-Gulles are among the delicacies for the principal feasts or his lordship's own 'mecs,' and they are charged at one penny or three-halfpence each.

In Willughby's time the price was higher. He mentions a colony of these birds "which yearly build and breed at Norbury in Staffordshire, in an island in the middle of a great pool in the grounds of Mr. Skrimshew, distant at least thirty miles from the sea. About the beginning of March hither they come; about the end of April they build. They lay three, four, or five eggs, of a dirty green colour spotted with dark brown, two inches long, of an ounce and a half weight, blunter at one end. The first down of the young is ash-coloured and spotted with black; the first feathers on the back after they are fledged are black. When the young are almost come to their full growth, those entrusted by the lord of the soil drive them from off the island through the pool into nets set on the banks to take them. When they have taken them they feed them with the entrails of beasts, and when they are fat sell them for fourpence or fivepence a piece. They yearly take about one thousand two hundred young ones, whence may be computed what profit the lord makes of them. About the end of July they all fly away and leave the island."

Dr. Plott, in his 'Staffordshire,' adds to the history of the birds that bred in Pewit Pool, in the parish above mentioned, that they would breed on no other land than that of the proprietor of that place, and that on the death of the owner they deserted the pool for three years, but only retired to another estate belonging to the next heir. The doctor was fond of the marvellous.

Larus.—Bill of mean length, strong, straight, cultrated, the upper mandible having the tip incurved; symphysis of the upper mandible strongly angulated, and ascending thence to the point. Nostrils placed in the middle of the bill, lateral, oblong, narrow, and pervious. Tongue pointed, with the extreme tip cloven. Wings long, acuminated. Tail even, or slightly forked. Legs placed near the centre of the body, of mean length and strength, with the lower part of the tibiæ naked. Feet of four toes, three before and one behind; the three in front united by a membrane; the hind one short and free. (Gould.)

L. marinus, Linn.; Goëland Noir Manteau of the French; Great Black-Backed Gull, Great Black and White Gull of Willughby (the provincial name is Cobb); Gwylan rûdd a gywn (Wagel) of the Welsh.

Great Black-Backed Gull (*Larus marinus*). Adult, in winter plumage.

Perfect Winter Plumage of Old Birds.—Summit of the head, region of the eyes, occiput, and nape, white, but all the feathers marked on their middle with a longitudinal stripe of bright brown; front, throat, neck, all the lower parts, back and tail, pure white; top of the back, scapulars, and the whole wing of a deep black, shaded with bluish; quills towards the end of a deep black, all terminated with a large white space; secondary quills and scapulars terminated with white; bill whitish yellow, angle of the lower mandible bright red; naked border round the eyes red; iris brilliant yellow marbled with brown; feet dirty white. Length 26 or 27 inches; females 24 to 25 inches. (Temminck.) Willughby's specimen measured, "from tip to tip of the wings distended," 67 inches.

M. Temminck observes (1820) that in this state the species had never been described. Willughby and Montagu however had each described one (the latter author in his 'Dictionary,' 1802) almost in the perfect state, and it is now beautifully figured in Mr. Gould's great work on 'The Birds of Europe.'

Summer or Nuptial Plumage of Old Birds.—Summit of the head, region of the eyes, occiput and nape, pure white without any brown; naked border round the eyes orange; rest of the plumage as in winter. In this state it is *Larus marinus*, Linn.; Le Goëland Noir Manteau, Buffon; Mantel Meve, Bechst.; Black-Backed Gull, Latham, &c. (Temminck.)

Young of the Year, and those One Year Old.—At this period the bird is *Larus nævius*, Linn.; *L. marinus junior*, Latham; Le Goëland Varié ou Grisard, Buffon; and Wagel Gull, Latham. (Temminck.)

The Young of the Year have the head and the front of the neck grayish-white covered with numerous brown spots, which are largest on the neck; the feathers of the upper parts are blackish-brown in the middle, all bordered and terminated with reddish-white, which colour forms transverse bands on the coverts of the wings; lower parts of a dirty gray, striped with large zigzags and brown spots; feathers of the middle of the tail more black than white, the lateral ones black towards the end, and all bordered and terminated with whitish; quills blackish, a little white on the point; bill deep black; iris and naked circle brown; feet livid brown.

After the First Year to the Age of Two Years.—All these colours change no otherwise than that the blackish-brown and yellow of the middle of the feathers occupy gradually less extent, giving place to pure white, which then surrounds all the feathers; the white begins to predominate over the gray in the lower parts, which have gradually less of the brown spots; the head becomes pure white, and the point and base of the bill assume a livid tint.

At two years, on the autumnal moult, the mantle is defined; it is then blackish, varied with irregular brown and gray spots; the white becomes pure, and only sprinkled with a few spots; the tail is pervaded with black marblings of varied forms; and the bill assumes the red spot with black in the middle,* the rest of that organ being livid white speckled with black.

At the third autumnal moult the plumage is perfect.

The young vary accidentally in having all the plumage grayish-white, with deeper spots, and spots very feebly indicated; the quills whitish. Sick individuals put on these appearances, as well as the greater part of those which are kept in captivity. (Temminck.)

This species is very abundant in the Orcades and Hebrides; common in its double passage on the coasts of Holland, France, and England; lives in the north; never or very accidentally found in the interior or on fresh waters; rather rare in the Mediterranean. (Temminck.) Common in many parts of the north of Europe, but does not appear to extend, at least in any considerable numbers, to very high latitudes, as Captain Sabine, in his 'Memoir of Greenland Birds,' states that it was only once seen in Baffin's Bay, and Sir John Richardson never mentions it. Met with, but by no means plentifully, upon most of our coasts, usually alone or in pairs, and rarely in a flock of more than eight or ten together. (Selby.) America (near Philadelphia), not very rare. (Prince C. L. Bonaparte.) United States. (Audubon.)

Fish, living or dead, fry, carrion, &c., form the food of this species, according to Temminck, who adds that it rarely feeds also on bivalve shell-fish. "It is," says Selby, "of very voracious appetite, and preys upon all kinds of animal substance that may happen to be cast on shore. It also keeps a close watch upon the lesser gulls, whom it drives from any food they may have discovered, appropriating the whole to itself." Montagu notices the damage it does to fishermen by severing and devouring the largest fish from their hooks, if left dry by the ebbing of the tide. Flight slow, but buoyant. Cry strong and hoarse, to be heard from a great distance when the bird is on wing, and most frequent in the spring and breeding season. Very wary; keeping by the shores of the sea, which it only quits accidentally. Nest on the rocks, Temminck says, in the regions of the Arctic Circle. Captain Sir James Ross however, in his 'Last Expedition of Sir John Ross,' does not mention it. Eggs three or four, very deep olive-green, with great and small blackish-brown spots. (Temminck.) Like those of the Herring and Lesser Black-Backed Gulls in colour and markings, but are larger. (Selby.) The author last quoted says that its breeding-stations in Britain are the Steep-Holmes and Lundy Islands in the Bristol Channel, Souliskerry in the Orkneys, the Bass Rock in the Frith of Forth, and one or two other stations upon the Scottish coast. Mr. Gould says that it also breeds in the marshes at the mouth of the Thames, making a nest on the ground of reeds, rushes, and flag-leaves.

* The individual described by Willughby as the Great Black-and-White Gull (*Larus ingens marinus Clusii*), and hereinbefore noticed, seems to have been in this stage of plumage, or rather more varied. Willughby took 'a plaise entire' out of its stomach. He also mentions another (which he supposes was a young one) with the head and neck particoloured of black and white, and the back and wings paler.

Lestris (*Catarractes*, Ray? *Catarracta*, Aldrov.?).—Bill moderate, hard, strong, cylindrical, very compressed, hooked at the point, the upper mandible covered with a cere, the under mandible with an angle on the inferior edge. Nostrils approaching the point of the bill, diagonal, narrow, closed on their posterior part, and pervious. Tarsi long, naked above the knee. Feet having three toes before, entirely palmated; hind toe very small; nails large and hooked. Tail slightly rounded, two middle feathers elongated. Wings, first quill-feather longest. (Gould.)

L. parasiticus. Old of both Sexes in Perfect Plumage.—Front whitish; on the summit of the head a sort of hood of blackish-brown, terminating at the occiput; throat, region below the eyes, all the neck, the breast, the belly, and abdomen, pure white; on the flanks some ash-coloured undulations; lower coverts of the tail, back, wings, and caudal feathers, uniform very deep ashy-brown, graduating into blackish on the end of the quills and tail-feathers; the two long tail-feathers terminated in a loose point (en pointe très-effilée); base of the bill bluish, point black; iris brown; feet deep black. Length 14 or 15 inches; the long feathers exceed from 3 to 5 or 6 inches. (Temm.)

In this state M. Temminck considers it to be *Larus parasiticus*, Linn., Gmel.; *Cataracta parasitica*, Retz; *Stercorarius longicaudus*, Briss.; Le Labbe à Longue Queue, Buff.; Stercoraria di Coda Longa, 'Stor. degl. Ucc.;' Die Polinowe, Lepechin; Struntmeve, Bechst.; Arctic Bird, Edwards; Arctic Gull, Latham.

Middle Age.—All the upper parts spotless ashy-brown; lower parts a shade brighter, equally spotless; interior base of the quills and the upper part only of the caudal feathers pure white, the rest blackish-brown; the two long feathers gradually diminishing towards the end, which is terminated in a very loose point; bill and feet as in individuals with perfect plumage.

In this state the bird is *Larus crepidatus* of the first edition of M. Temminck's 'Manuel;' Le Stercoraire of Brisson; Le Labbe ou le Stercoraire of Buffon, especially Pl. Enl. 991, and more especially Edw., t. 149. (Temm.)

Arctic Gull (*Lestris parasiticus*).

Young of the Year at the Time of their Leaving the Nest.—Top of the head deep gray; sides and upper part of the neck bright gray, sprinkled with brown longitudinal spots; a black spot before the eyes; lower part of the neck, back, scapulars, small and great coverts of the wings umber-brown, each feather being bordered with yellowish-brown, and often with reddish; lower parts irregularly variegated with deep brown and yellowish-brown on a whitish ground; abdomen and tail-coverts striped transversely; quill and tail-feathers blackish, white at their base and internal barbs, all terminated with white; tail rounded only; base of the bill yellowish-green, black towards the point; tarsi bluish-ash; base of the toes and membranes white, the rest black; posterior nail often white. (Temm.)

In this state M. Temminck considers the bird to be *Larus crepidatus*, Gmelin; *Catarracta* (Catharacta) *Cepphus*, Brunnich; Le Labbe ou Stercoraire of authors: Labbe à Courte Queue, Cuv.; and Black-Toed Gull of Latham and Pennant; Yr Wylan Ysgafn of the Welsh.

Mr. Gould, whose figure we have copied, says that he believes the bird in question to be the true *Parasiticus* of Linnæus, Buffon, and Temminck; and although Mr. Gould thinks it probable that the species undergoes variations in plumage similar to those of *Lestris Richardsonii*, he is by no means able, from his own knowledge, to state this to be the case, as in all the specimens which he had opportunities of examining the markings were clear and decided, the birds exhibiting a well-defined, dark-coloured cap on the head, light under parts, and very long middle tail-feathers.

Localities.—Shores of the Baltic, Norway, and Sweden; spreads itself habitually in the interior on lakes and rivers; of periodical or accidental passage in Germany, Holland, France, and Switzerland, where the young only ordinarily are seen: the old rarely wander. (Temminck.) "In its young state, as the Black-Toed Gull (*Larus crepidatus*) of authors, this species," writes Mr. Selby, "is not of unfrequent occurrence, during the autumnal months, upon the northern coast of England, to which it is attracted by the Gulls that follow the shoals of herring on their approach to the shallows for the purpose of depositing their spawn. Like the other Skuas it obtains the greater part of its subsistence by continual warfare on the above-mentioned birds, vigorously pursuing and harassing them till they are compelled to disgorge the food previously swallowed. In this occupation its dark plumage and rapid flight are certain to attract the attention of the spectator: and there are few probably who have visited the coast of Scotland and the northern districts of England who have not witnessed and admired the aërial evolutions of the Teazer, and the distress of its unfortunate objects of attack. It is but very rarely met with beyond the precincts of the Shetland and Orkney Isles in its adult state, and only one instance has occurred within my own observation, namely, on an excursion to the Fern Islands in the month of May, when two of these birds flew ahead of the boat in a northerly direction, and which were perfectly distinguishable by their lengthened and slender middle tail-feathers, and the black and white of their plumage. This Skua does not appear to be a permanent resident in any part of the British dominions, for Low, in his 'Fauna Orcadensis,' describes it as a migratory bird, arriving there and in Shetland in May, and departing in autumn, or as soon as the duties of reproduction have been effected." Mr. Gould says that he has not been able to ascertain whether it breeds among the British Isles, and adds that it is certainly of rare occurrence. Its natural habitat, he thinks, is more confined to the north, namely, the shores of the Baltic Sea, Norway, and the Polar regions. All our Arctic voyagers mention it, down to Captain James Ross inclusive, and it appears to be common in the Polar Seas of Europe and America.

The account given by Mr. Selby above will prepare the reader for the principal source whence this and other Jäger Gulls derive their subsistence, namely, by pursuing and buffeting the peaceable gulls and compelling them to render up the produce of their toils. But they also feed on fish, insects, and worms, and Temminck particularly mentions the *Janthina*, or Oceanic Snail, as forming a part of its sustenance. In truth no animal substances seem to come amiss to it. Mr. Richards, of her Majesty's ship Hecla, saw this bird feeding on the bodies of some young children whose graves of ice had vanished on the thaw, near Igloolik, on the 21st of June 1823.

Temminck says that it nestles not far from the sea-shore. Selby, who states that it breeds upon several of the Orkney and Shetland Isles, and that it is gregarious during that period, informs us that the situations selected are the unfrequented heaths at some distance from the shore, and that the nest is composed of dry grass and mosses. The eggs are two, of a dark oil-green with irregular blotches of liver-brown; and Mr. Selby adds that the bird at this time is very courageous, and, like the Common Skua, attacks every intruder by pouncing and striking at the head with its bill and wings. Occasionally it endeavours, according to the same authority, to divert attention by feigning lameness in the same manner as the Partridge and the Lapwing. In the Appendix to Parry's 'Voyage' (1819-20) this 'Arctic Lestris' is stated to be equally abundant in the islands of the Polar Sea as in Baffin's Bay. Captain Edward Sabine, who drew up the account, states that it is frequently met with inland, seeking its food along the water-courses which occupy the bottom of ravines; differing in this respect from the Pomarine Lestris, which is exclusively a sea-bird.

The following is a list of the British *Laridæ*, according to Yarrell:—

Sterna Caspia, the Caspian Tern.
S. Boysii, the Sandwich Tern.
S. Dougallii, the Roseate Tern.
S. Hirundo, the Common Tern.
S. arctica, the Arctic Tern.
S. leucopareia, the Whiskered Tern.
S. Anglica, the Gull-Billed Tern.
S. minuta, the Lesser Tern.
S. fissipes, the Black Tern.
S. leucoptera, the White-Winged Black Tern.
S. stolida, the Noddy Tern. [STERNA.]
Larus Sabini, Sabine's Gull.
L. minutus, the Little Gull.
L. capistratus, the Masked Gull.
L. ridibundus, the Black-Headed Gull.
L. atricilla, the Laughing Gull.
L. tridactylus, the Kittiwake Gull.
L. eburneus, the Ivory Gull.
L. canus, the Common Gull.
L. Islandicus, the Iceland Gull, or Lesser White-Winged Gull
L. fuscus, the Lesser Black-Backed Gull.
L. argentatus, the Herring Gull.
L. marinus, the Great Black-Backed Gull.
L. glaucus, the Glaucous Gull, or Large White-Winged Gull.
Lestris cataractes, the Common Skua.
L. pomarinus, the Pomerine Skua.
L. Richardsonii, Richardson's Skua.
L. Buffonii, Buffon's Skua.
Procellaria glacialis, the Fulmar Petrel. [PROCELLARIA.]
Puffinus major, the Greater Shearwater.
P. anglorum, the Manx Shearwater. [PUFFINUS.]

Thalassidroma Bulwerii, Bulwer's Petrel.
T. Wilsonii, Wilson's Petrel.
T Leachii, the Forked-Tailed Petrel.
T. pelagica, the Storm Petrel. [THALASSIDROMA.]

LARK. [ALAUDA.]

LARKSPUR. [DELPHINIUM.]

LA'RRIDÆ, a family of Hymenopterous Insects of the section *Fossores*, distinguished by the labrum being either entirely or partially concealed, and the mandibles deeply notched on the inner side near the base. It contains the following genera:—1. *Palarus* (Lat.), in which the antennæ are very short, and are gradually thicker towards the apex: the eyes are closely approximated posteriorly, and inclose the ocelli: the second cubital cell is petiolated. 2. *Tachytes* (Panzer), antennæ filiform, the basal joint slightly incrassated, the rest cylindrical; superior wings with one marginal cell, slightly petiolated and three submarginal cells, the third narrow and oblique; mandibles with a dentate process on the inner side near the base. *T. pompiliformis* is about 2½ lines in length; black, with the basal segments of the abdomen red. It is not an uncommon insect in various parts of England. 3. *Larra*: this genus differs from *Tachytes* (which is *Lyrops* of Illiger) in having no tooth on the inner side of the mandibles at the base; the eyes not being approximated posteriorly, and the metathorax and abdomen being decidedly larger. 4. *Dinetus*: eyes converging posteriorly; antennæ filiform in the female, with the first joint incrassate, in the male larger, with a deep lateral impression, the four following joints submoniliform, and the five next slightly compressed and convoluted, the remaining three filiform; superior wings, with one appendiculated marginal cell, and three submarginal cells. But one species of this genus has been found in England. 5. *Miscophus* (Jurine) has one marginal cell, which is not petiolated, to the superior wing, and two submarginal cells, the second being petiolated; the antennæ are filiform in both sexes. There is but a slight projection at the base of the mandibles. *M. bicolor* (Junine) is the only species found in England, where it is apparently rare. (Shuckard, *Essay on the Indigenous Fossorial Hymenoptera*.)

LARVA, a term applied to that state in which an insect exists immediately after its exclusion from the egg, and which precedes the pupa state. The animals commonly called Grubs, Maggots, and Caterpillars are larvæ. Grub appears to be a general term analogous to larva; the term Maggot is most generally applied to the larva state of Dipterous Insects; and Caterpillar, in the most common acceptation of the term, is used to designate the larva state of Lepidopterous Insects. These three terms however are used in a very vague manner.

The most striking difference perhaps which exists between the larva and the perfect insect consists in the superior powers of locomotion and consequently better developed skeleton possessed by the latter.

Though larvæ never possess wings, they vary much as regards the development of the locomotive organs, and as these are more or less perfect, so do the larvæ resemble or recede from the insect in its imago state. Hence Messrs. Kirby and Spence divide larvæ into two sections: those which, in general form, more or less resemble the perfect insect; and those which are unlike the perfect insect. The larvæ of both sections moult, or cast their skin, several times during their progress to maturity; the number of moults varies according to the species, and the period intervening between the moults depends upon the length of the insect's existence in the larva state. In these moults, not only is the whole external covering of the insect cast, but even the lining of the intestinal canal and of the tubes of the tracheæ is shed.

The greater portion of the larvæ of the orders rthoptera, *Hemiptera*, and *Homoptera*, excepting that they have no wings, bear a considerable resemblance to the perfect insect, and hence belong to the first of the sections just mentioned. As however the muscles which serve to support and give motion to the wings are attached to the skeleton of the thorax, so, as might be expected, we find this part in the perfect insect more unlike that of the larva perhaps than any other; and again where (as in the imago state of *Scutellera*) a portion of the thorax is greatly produced behind and serves to protect the wings when folded,—the larva, having no wings, does not possess this peculiarity.

Belonging to the second division, in which the larva does not resemble the perfect insect, are the orders *Hymenoptera*, *Coleoptera*, *Neuroptera*, *Lepidoptera*, and *Diptera*.

The larvæ of Hymenopterous Insects are usually of a short ovate form, and short and fleshy substance, devoid of legs or distinct head, and the body lies in a bent position. In the *Tenthredinetæ* (Latreille) however we have a remarkable exception, the larvæ of these insects not only being furnished with six legs attached to the thoracic segments, but also possessing a great number of prolegs. These prolegs are usually sixteen in number, and attached in pairs to the abdominal segments; in some there are but fourteen, and in others only twelve prolegs. The larvæ of the *Tenthredinetæ* very much resemble those of Lepidopterous Insects, but differ in the greater number of their prolegs; the head is large, rounded, flattened in front, and vertical in position; the body is always bent under, and when touched they roll themselves up like the *Iuli*. In the genus *Pamphilius* (Lat.), the larva possesses six thoracic legs, but no prolegs.

The larvæ of the *Coleoptera* are most commonly of an elongate, cylindrical, or slightly depressed form; the thoracic segments are almost always provided with six legs, and there are seldom any prolegs on the abdominal segments. The head is furnished with mandibles, maxillæ, labrum, labium, and antennæ, and very frequently with ocelli. The parts of the mouth and the antennæ however do not resemble those of the perfect insect. The antennæ are usually very small, and composed of but three or four distinct joints. The ocelli of the larva are replaced by compound eyes in the perfect insect. The thoracic segments are often protected by a horny plate on the upper surface: the prothorax, which is usually the largest, is generally so protected. The legs, of which these segments have each a pair, are of moderate size in most larvæ of this order, and composed of a coxa, trochanta, tibia, and tarsus; the last however appears to be represented by a small jointless claw. The body is often soft, but sometimes, like the thorax, protected by horny plates, as in some of the *Carabidæ*, *Silphidæ*, &c. In the *Carabidæ*, *Staphylinidæ*, and indeed many families, it is somewhat depressed. In many of the Heteromerous Insects it is cylindrical, of a coriaceous texture throughout, and the terminal segment is often furnished with horny appendages at the apex, and one or two prolegs beneath. The larvæ of many of the *Elaterides* are also of a coriaceous texture and cylindrical form, and the terminal segment of the abdomen is generally furnished with horny appendages. These appendages are indeed very commonly met with in Coleopterous larvæ. In those species belonging to the sections *Lamellicornes*, *Rhyncophora*, and *Longicornes*, however, we have not met with them, and the body is always of a soft and fleshy texture. The larvæ of the two last-mentioned sections have extremely minute legs.

In the order *Neuroptera* the larvæ very much resemble in general appearance many of those of the order *Coleoptera*: they always possess six thoracic legs, but seldom any prolegs. In the Case-Worms (*Trichoptera*) and some others there are a pair of prolegs attached to a terminal segment of the abdomen.

In the order *Lepidoptera* the larvæ (or caterpillars) are soft and fleshy, and usually of a cylindrical form. They possess 6 thoracic legs and generally ten prolegs. The prolegs vary in number, and are attached in pairs to the under side of the abdominal segments; but none are ever found on the 4th, 5th, 10th, or 11th segments. In the larvæ of the *Geometræ* there are but four prolegs, two of which are attached to the anal segment, and the other two to the ninth. Some of the *Tinnæ* have but two prolegs, and these are anal. In the genus *Apoda* (Haworth) the larvæ have no distinct prolegs, but in their stead a number of small transparent shining tubercles, without claws. "The prolegs of almost all lepidopterous larvæ are furnished with a set of minute, slender, horny hooks, crotchets, or claws of different lengths, somewhat resembling fish-hooks, which either partially or wholly surround the apex like a palisade. By means of these claws, of which there are from 40 to 60 in each proleg, a short and a long one arranged alternately, the insect is enabled to cling to smooth surfaces, to grasp the smallest twigs to which the legs could not possibly adhere; a circumstance which the flexible nature of the prolegs greatly facilitates." "When the sole of the foot is open, the claws with which it is more or less surrounded are turned inwards, and are in a situation to lay hold of any surface; but when the animal wishes to let go its hold it begins to draw in the skin of the sole, and in proportion as this is retracted the claws turn their points outwards, so as not to impede its motion." (Kirby and Spence.)

The larvæ of Dipterous Insects are for the most part soft and fleshy, and without legs; none have true jointed legs: some however have prolegs. The head is usually soft and indistinct, but in certain species the head is somewhat corneous, and of a determinate shape. [INSECTS.]

LARVA'RIA, the name of a group of Tertiary Fossils, proposed by M. Defrance. (Blainville, *Actinologie*, p. 442.)

LARYNX is the organ of the voice; its framework is composed of five cartilages, which are capable of being moved on each other in various directions by muscles, so as to act upon two elastic bands, on which the voice essentially depends, and which are called the vocal ligaments.

The first, the Thyroid Cartilage (*fig.* 1), consists of two plates (a, b) of dense tough fibro-cartilaginous substance, of an irregularly quadrilateral form, which are united at the lower part of their anterior edges (c, c) at an angle of about 60°. The prominence of this angular union is felt in the front of the throat, forming what is called the Pomum Adami, at the sides of and behind which the form of the cartilage may be easily traced out with the fingers. The posterior edge of each plate bears at each angle a process or horn (d, d, e, e), by which the thyroid cartilage is attached by ligaments above to the hyoid bone, and below to the cricoid cartilage.

The Cricoid Cartilage (*fig.* 2) has somewhat the form of a signet ring. It is inclosed within the angle of the thyroid cartilage, beneath whose lower edge the front and narrowest portion (a) of its ring may be felt, with an interval of about a quarter of an inch between them. It has an articulating surface on each side, by which it is moveably connected with the inferior horns of the thyroid cartilage; and two other smooth convex surfaces (b, b) on its upper and posterior edge, by which it is articulated with the two arytenoid cartilages.

The Arytenoid Cartilages have each the form of an irregular triangular pyramid (*fig.* 3). They are placed upon the upper edge of the broad part of the cricoid cartilage, just within the most expanded part of the angle formed by the receding plates of the thyroid. The base (*a*) by which each is articulated with the cricoid is slightly concave, perfectly smooth, and capable of moving to a certain extent in every direction.

Fig. 1.

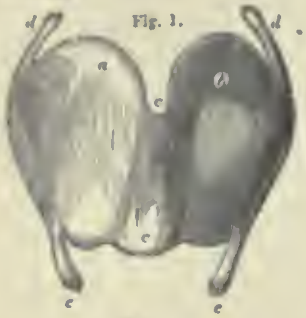


Fig. 4.

Fig. 3.

Fig. 2.

The Epiglottis (*fig.* 4) is of a somewhat ovate form. It is attached by its apex to the angle of union of the plates of the thyroid cartilage, and projects obliquely backwards and upwards over the cricoid and arytenoid cartilages like a shield, guarding them from the contact of foreign bodies passing from the mouth.

These cartilages are connected chiefly by elastic ligament, which is arranged in bands of varying thickness throughout the whole of the larynx, uniting the upper edge of the thyroid cartilage to the os hyoides, and its lower edge to the cricoid cartilage; passing also from the arytenoid cartilages to the epiglottis, and uniting the rings of the trachea and bronchi; affording to all a firm but yielding connection, and endowing them by its elasticity with the power of resounding in accordance with the vibrations originating in the vocal ligaments.

The Vocal Ligaments are two narrow bands of highly-elastic tissue, stretched between the anterior angle of the thyroid and the anterior surfaces of the the arytenoid cartilages. The substance of which they are composed is a yellowish dense fibrous tissue, which is placed in those parts of the body where a permanent elasticity is required, as in the spaces between the laminæ of the vertebræ, the coats of arteries, the rings of the trachea, &c. In *fig.* 5 a profile view of the

Fig. 5.

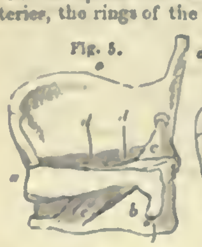

Fig. 7.

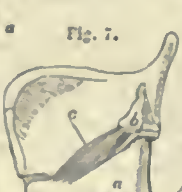

Fig. 6.

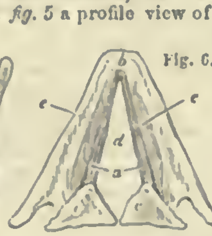


right vocal ligament is drawn: *a*, *a*, *a* is the outline of the thyroid cartilage, of which part of the left side is removed; *b* is the cricoid cartilage, and *c* the arytenoid cartilage of the right side; *d*, *d* is the vocal ligament. In *fig.* 6 the view of the vocal ligaments (*a*) is taken as seen from above; they are attached anteriorly to the inside of the thyroid cartilage at *b*, and posteriorly to the front of the arytenoid cartilages (*c*, *c*). Between them is the aperture through which we breathe, the glottis (*d*); it is bounded posteriorly by the inner edges and anterior angles of the arytenoid cartilages; anteriorly by the inner edges of the vocal ligaments. When at rest, as during quiet breathing, the glottis is of a somewhat lanceolate form (*fig.* 11, as outlined by the dots), but when speaking or singing it is very much narrowed (*fig.* 11, the continued lines).

The Muscles acting on the parts of the larynx just described are arranged symmetrically and attached to corresponding points on each side of the larynx; and their names are compounded of those of the cartilages on which they are inserted, as follows:—

The Crico-Thyroideus (*fig.* 8, *a*, *a*, and *fig.* 5, *e*) is attached on each side, at one of its extremities, to the upper edge of the narrow front part of the cricoid cartilage; and at the other, to the lower edge of the thyroid, just before its lower horn. Its fibres are directed upwards and backwards, and its immediate action would therefore be to approximate the adjacent edges of the thyroid and cricoid cartilages. But the thyroid is fixed on each side by a ligament passing from its inferior horn to the side of the broad part of the cricoid (*fig.* 5, *f*), and the crico-thyroid muscle will therefore produce a rotatory motion of the cricoid cartilage around the horizontal axis drawn through *f*. When the anterior edge of the cricoid cartilage is thus raised towards the anterior angle of the thyroid its posterior and upper part will be moved backwards and downwards to a greater distance from the front of the thyroid; and if the arytenoid cartilages be fixed on the top of the cricoid, they will of course move with it in the same direction. The distance between their anterior edges and the angle of the thyroid (*fig.* 5) will thus be increased, and the vocal ligaments (*d*, *d*), which are attached to those points, will be proportionally stretched.

The Thyro-Arytenoidei (*fig.* 6, *c*, *c*) are attached anteriorly by the sides of the angle of the thyroid cartilage to the outer side of, and above, the vocal ligaments, and posteriorly to the anterior angles and outer edges of the arytenoid cartilages. Their simplest action will therefore be to approximate the same points which the preceding muscles render more remote; they will thus shorten and relax the vocal ligaments. Some of their fibres extend on each side for a short distance above and below the vocal ligaments; those below have the power of narrowing the access to the glottis, while those above the ligaments may compress together the sides of the larynx directly over the glottis. Lastly, there are other fibres which are attached to the outer edges of the vocal ligaments themselves.

The Crico-Arytenoidei Postici (*fig.* 9, *b*, *b*) are attached to the posterior surface of the cricoid cartilage (*a*, *a*), and pass obliquely outwards, to be inserted into the outer angle of the arytenoid cartilages. In contracting therefore, if the arytenoid cartilages be moveable, they will draw their anterior angles outwards, and thus increase the width of the glottis; but if the arytenoid cartilages be fixed by other muscles, the crico-arytenoidei postici will merely draw them backwards and stretch the vocal ligaments.

Fig. 8.

Fig. 9.

The Crico-Arytenoidei Laterales (*fig.* 7, *c*) are attached on the one hand to the inner sides of the cricoid cartilage (*a*), and on the other to the outer angles of the arytenoids (*b*); they rotate the latter inwards, so as to approximate their front portions and narrow the anterior part of the glottis.

The Posterior Arytenoid Muscles (*fig.* 9, *c*, *c*) lie behind the arytenoid cartilages, and consist of fibres passing transversely and obliquely from one to the other. They therefore simply approximate these bodies, and narrow or close the back part of the glottis.

The simplest actions of all these muscles in regard to the voice may therefore be thus stated: the crico-thyroidei stretch the vocal ligaments; the thyro-arytenoidei relax them; the crico-arytenoidei postici open the glottis; the crico-arytenoidei laterales and the arytenoidei postici narrow or close it.

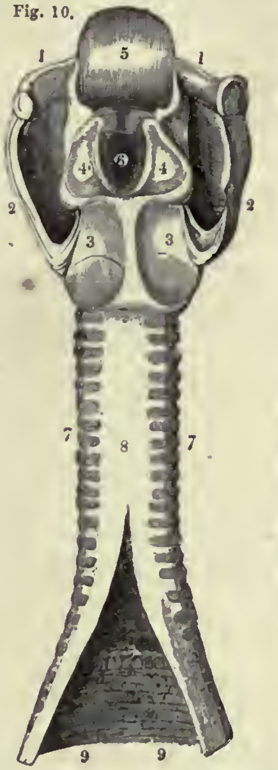
A band of muscular fibres may be also mentioned as passing from the arytenoid cartilages to each side of the epiglottis, and thus serving to draw down the latter so that it may cover the glottis more closely than when left to its own elasticity.

Below, the larynx opens into the trachea (*fig.* 10, 8), which is continued into the chest, and there divides into two branches, the bronchi, whose ramifications and terminations form the air-passages and air-cells of the lungs. The lungs, being exactly contained in the cavity of the chest, are compressed by the contractions of its walls. The walls of the chest are therefore the power by which the air is forced from the lungs through the glottis for the production of the voice, and it is by their more or less powerful contraction that the various degrees of intensity of the same note are produced. The trachea is composed of a series of cartilaginous incomplete rings which are united behind by muscular fibres, and are connected together by longitudinal elastic bands. It is thus capable of variations both of length, breadth, and tension; and of entering into vibrations with the column of air contained in it, and of assisting in communicating those vibrations through its branches to the walls of the chest.

At the upper part of the trachea the windpipe gradually narrows towards the glottis (see view of its section in *fig.* 12); and above the glottis it suddenly dilates, so that the edges of the elastic vocal ligaments stand out from the wall of the larynx, and have space in which they may vibrate freely, like the lips in the mouthpiece of a trumpet. About half an inch higher the passage again contracts, so as to form a narrow recess on each side, directly above the vocal cords. This is called the ventricle of the larynx, and the prominent bands above it are called the false vocal cords, or the upper ligaments of the larynx. They are formed of elastic tissue, like the inferior or true vocal ligaments, but in less quantity, and mixed with fatty tissue, so that they do not vibrate so freely. The walls of the ventricle are capable of being approximated by some of the fibres of the thyro-aryteuoid muscles, which are thinly distributed upon them; and thus the recess may be nearly obliterated, and the upper ligaments brought almost into contact.

The highest part of the larynx is formed by two folds of membrane passing from the arytenoid cartilages to the epiglottis (*fig.* 10), forming an oval aperture which admits of variations of size by the action of the muscles already mentioned. At this aperture the larynx communicates with the upper and most expanded part of the pharynx, the cavities of the mouth and nose, and the frontal and other sinuses which open into the latter. These sinuses are walled round by bone, but the pharynx and its communications with the mouth and nose, as well as the external apertures of the two latter cavities, are in great part muscular, and may be thus subject at will to alterations of form, size, and tension.

Fig. 10.



1, 1, Os hyoides; 2, 2, Thyroid cartilage; 3, 3, Cricoid cartilage; 4, 4, Arytenoid cartilages; 5, Epiglottis; 6, Aperture of communication between glottis and pharynx; 7, 7, Rings of trachea; 8, situation of transverse posterior muscular bands; 9, 9, portion of trachea cut open from behind.

The larynx has been compared to a variety of musical instruments, and it will be seen that in its different parts it unites the principles of several. In its essential vocal apparatus it most nearly resembles the reed-instruments, as the reed-pipes of the organ, the clarionet, &c., or rather a modification of them, in which the vibrating body is not fixed in its dimensions as a metallic tongue, or a reed, but consists of a lamina of elastic membrane, capable of varied degrees of tension, as well as of alterations in its length. No musical instrument has yet been constructed on this principle, unless we consider as such the various kinds of trumpet in which the vibrations are produced by the air impelled against the edges of the lips, rendered more or less tense by the action of their orbicular muscle. The principle has been applied in the formation of artificial larynges by Biot, Cagniard de la Tour, Willis, &c., who have chiefly used caoutchouc membrane; and by Müller and Henle, who have employed besides either the vocal ligaments themselves, or laminæ of the elastic coat of an artery. The most complete examination of the subject is that made by Müller, and published in the first part of the second volume of his 'Physiologie des Menschen.'

It is evident that by adapting to one of the open extremities of a tube two portions of thin elastic membrane, so that their opposite edges leave a narrow space in the middle, through which the air blown into the other end of the tube may pass and excite vibrations, one obtains an imitation of the essential vocal apparatus of the larynx; the trachea being replaced by the tube, the vocal ligaments by the bands of elastic membrane, and the glottis by the space between them, while the parts above the glottis may be imitated by adapting tubes of different sizes and forms above the membranes.

In such an apparatus Mr. Willis found ('Cambridge Philosophical Transactions,' 1832) that in order that two laminæ of elastic membrane inclosing a narrow interval should produce sound, the parts near their edges must be parallel to each other. Applying this law to the case of the larynx, he observes that something more is necessary for speaking or singing than a certain degree of tension of the vocal ligaments, for they are always more or less tense; and even when their tension is increased, and all the cartilages are in the position for producing sound, we may yet breathe quietly, the edges of the vocal ligaments not being parallel.

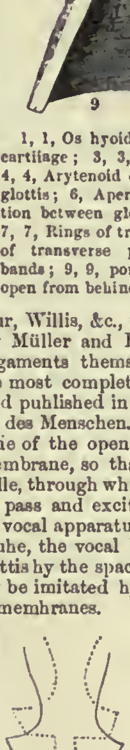


Fig. 12.

Fig. 11.

Fig. 12 represents two vertical transverse sections of the larynx, the continued line indicating the position of its parts when not sounding, the dotted line the same parts in the vocalising position, in which the edges of the ligaments are parallel to each other. Mr. Willis considers it to be one of the functions of the thyro-arytenoid muscle to place the ligaments in this essential position.

When the vocal ligaments are thus placed, the modulations of the notes are effected by the changes in their length and tension; for, like those of other elastic membranes stretched at both ends, they follow in many respects the same laws as cords. [CORD, in ARTS AND SC. DIV.] Thus, the degree of tension being the same, the height of the note is inversely as the length of the membrane; and the length being the same, the height of the note, as expressed by the number of vibrations, is directly as the square root of the power employed in producing the tension. The application of these laws to the vocal ligaments was experimentally proved by Müller. In a part of his experiments on the dead larynx he succeeded in producing the complete scale of notes and half-notes through a range of 2½ octaves, by gradually increasing the tension of the vocal ligaments by weights appended to one of their extremities. The weights produced extension in the same direction in which the crico-thyroid muscles act, when, the arytenoid cartilages being fixed, they throw them backwards with the cricoid as already explained. If instead of stretching the vocal ligaments they were left to their own elasticity, or still more relaxed by artificial means, in imitation of the action of the thyro-arytenoid muscles, still lower notes could be produced.

In the course of these experiments Müller found that the tones of the dead larynx, which in the lower notes closely resembled the chest-notes of the human voice, were very apt, as they ascended in the scale, to assume the characters of the falsetto voice. He was thus led to discover the mode in which the latter class of notes (whose origin had long been the subject of great doubt) is produced. In sounding the chest-notes, and in the common voice of speaking, the whole vocal ligaments vibrate, and with them part of the ventricles, and of the thyro-arytenoid muscles; but in the falsetto notes it is only the thin edges of the ligaments which are thrown into vibrations. He found also that he could prevent the tones of the chest-notes from breaking into those of the falsetto, as he ascended in the scale, by compressing the part of the larynx immediately below the glottis, in imitation of the action of the lower fibres of the thyro-arytenoid muscles.

As in all reed-instruments, the velocity of the current of air exciting the vibrations of the vocal ligaments has an influence on the note produced; thus Müller found that the natural note of the vocal ligaments at a given tension could be raised to its fifth by blowing with increased force. He believes that in singing the same note with varied degrees of force, a compensation is effected by lessening the tension of the ligaments in the same proportion as the velocity of the current is increased; but it seems more probable that the tension of the ligaments is always the same for the same note, while it is the office of the epiglottis to prevent the notes from rising with the increased force of the air. It may effect this on a principle discovered by M. Grenié (Magendie's 'Précis de Physiologie,' i. 253), who found that to remedy the inconvenience arising from the ascent of the note when the current of air blown into a reed organ-pipe was increased, it was sufficient to place within the pipe directly over the reed a supple elastic tongue, which shielded it very nearly in the same manner as the epiglottis covers the vocal ligaments.

Müller found that sounds were most easily produced from the dead larynx when the anterior angles of the arytenoid cartilages were in contact, so that only that part of the glottis was open which is bounded by the vocal ligaments. The tension of the ligaments being fixed, the same note could be produced whether the glottis were widely open or nearly closed; but it is probable that, though not essential, the varying apertures of the glottis are auxiliary to the complete and pure sounds of the different notes; for Magendie (l. c., p. 247) distinctly saw it become narrower as the notes emitted by a dog were higher; and in singing high notes one clearly feels that the air passes through a narrower aperture and with more difficulty than in singing the low notes.

The notes produced at the glottis are subjected to modifications in timbre, strength, and purity, by the parts connected with the larynx both above and below the vocal ligaments. To illustrate this, one need only refer to the difference of tone which may be drawn from a clarionet-reed when it is only attached to the mouth-piece, and when the mouth-piece is fixed on the body of the instrument. This part of the subject has been particularly illustrated by M. Savart, Mr. Wheatstone, and Mr. Bishop. It is well known that in all reed instruments, unless the tube or body be adapted to the reed so as to be capable of the same number of vibrations as it is, there is always a discordance of sounds. If for example the tube be unalterable in length, while the reed is capable of varied modifications of pitch, the sounds will be irregular in intensity, and in some parts of the scale will be totally extinguished. Thus it is that in organs, in each pipe, the tongue and the tube have to be adapted to each other, and that in clarionet-playing much of the perfection of the tone depends on the adaptation of the pressure of the lips on the reed to the length of the tube as determined by the number of holes covered by the fingers. Savart ('Journal de Physiologie,' t. 5) has shown that if the walls of the tube, instead of being fixed in their dimensions like those of reed-instruments, be capable of varying degrees of tension, an extraordinary variety and fulness of notes may be produced; and that the shrill whistle of the bird-call (with which he compared the larynx) is, with the same essential principle for the original formation of sound, converted into a full round tone. In the human body such a tube exists on both sides of the glottis, and is in both parts capable of varieties in tension, size, and form. Thus the trachea may be acted on by its posterior muscles and its elastic bands; and to a far greater extent the parts above the glottis will vary in their condition. In singing an ascending scale of notes, if the finger be placed in the interval between the angle of the thyroid cartilage and the front of the hyoid bone, it will be found that as the notes emitted become higher the interval diminishes and the whole larynx rises. Thus the tube above the glottis is shortened, just as in all wind-instruments the body is shortened by opening the holes at their sides, or by pushing one part of the tube within another. At the same time the lips are drawn in and compressed, the arches of the palate approximated, the uvula tightened, the back of the tongue and soft palate drawn near each other, and the oval aperture into the larynx constricted, all tending together, by a diminution of the size and an increase of the tension, to accord with the diminished length of the tube, that their vibrations may be in correspondence with those of the vocal ligaments. As the voice passes through the descending scale, the opposite changes occur; the vocal ligaments lengthen and are less tense, the larynx descends, the cavity of the mouth is expanded, and all the tissues are relaxed. Hence it is that the singer, when his voice is exerted in its highest notes, feels the greatest fatigue in the parts about the palate and pharynx; while in singing the lower notes he remains unwearied far longer, and at last feels fatigue chiefly in the muscles of the chest.

It is difficult to determine the circumstances on which the differences of the timbre of the voice in different persons depend. The difference between the male and female voices is probably owing to the comparative shortness of the vocal ligaments in the latter. According to Müller their average length in man is 18½ millimetres, in woman only 12¾ millimetres, or nearly as 3 to 2. But to account for the differences of tenor and bass, or of soprano and alto voices, no good evidence has yet been collected. The average compass of the voice is two octaves, but in different parts of the scale in different persons; thus a bass voice commonly has its lowest note four or five notes lower than a tenor, while a tenor has its highest note from four to five notes above the highest note of the bass voice. A soprano voice again has its lowest note at nearly the same part of the scale as the highest note of a bass voice; and thus the whole compass of the human voice, from the lowest of the bass to the highest of the soprano, would be nearly four octaves. The voices of children resemble very nearly those of women, but in males a remarkable change takes place at puberty, when the voice is said to crack; the change from the shrill treble voice of the boy to the fuller and rounder tone of the man is sometimes perfected almost suddenly; but in most cases it is for some time in progress, wavering between the two extremes, deep and manly during quiet enunciation, but when any exertion is used, suddenly starting up again to the shrill tones of boyhood. In old age, the cartilages of the larynx becoming bony, the ligaments hard and unyielding, and its muscles pale and powerless, the voice completely alters; it trembles as if there were not sufficient strength in the muscles to maintain a due tension of the vocal ligaments; it becomes harsh and monotonous, and

> "Turning again towards childish treble,
> Pipes and whistles in the sound."

Much yet remains unknown of the actions of the various parts of the larynx, but enough has been said to prove that it is perhaps the most perfect piece of complex mechanism in existence. Judging of it, as we must do, by comparison with the imperfect contrivances of art, it is not possible that we should be able to discern all the beauties of an instrument which in a space of about six inches by two inches produces a range of notes of between two and three octaves, all of perfect clearness and harmony, and with a tone far superior to any yet known—which is capable at the same time of giving a wide range of expression, and varied degrees of power—of executing difficult and intricate passages with the greatest rapidity and distinctness—and which above all will last for years without need of repair, and is even improved by a judicious use. The larynx fulfils all this, and is besides subservient to other functions of vital importance to the whole body. In breathing for example, its exquisite sensibility is immediately excited by the contact of any foreign substance, or of a deleterious gas, and the glottis is firmly closed by the thyro-arytenoid muscles, to prevent the entrance of the noxious body into the lungs. The same action occurs as we swallow each portion of our food, to prevent any of it passing into the lungs: and if a particle by accident touch the glottis, coughing is excited to ensure its speedy removal. Again, when about to make a violent exertion, a man first draws a full breath, and fixes his chest that he may have a firm support for all the muscles of his limbs; the same little muscles assist in this action by closing the glottis, and thus preventing any portion of the air from being forced from the chest, however great the exertion of the muscles attached to its walls.

LASER, a Gum-Resin highly esteemed among the ancients. It had become rare even in the time of Pliny, but it is described by Dioscorides (lib. iii. c. 84), and still more fully by Theophrastus under the name of Silphion (Σίλφιον, lib. vi. c. 3). In the edition of Bodæus à Stapel a most elaborate dissertation may be seen, in which apparently almost everything that occurs respecting it in ancient authors is brought together. Though the whole plant appears latterly to have been called Silphion, this name was originally that of the root. The stem of the plant is called *μαγύδαρις* by Theophrastus, the leaf *μάσπετον*, the seed *φύλλον*. These names are however differently applied by other authors. Laser was subsequently called Lasaron, and was applied to the juice alone. This was in such high estimation as to have been sold for its weight in gold, having many marvellous properties ascribed to it, but it was probably useful only as a stimulant to some of the functions and as an antispasmodic. The country where it was produced has been clearly laid down as the Cyrenaica Regio, and the physicians of Cyrene, we know, early attained a high reputation. Theophrastus gives a wider extent of distribution along the north of Africa, stating at the same time that the greater portion was collected near the Syrtes. Dioscorides gives Syria, Armenia, Media, and Libya, as the countries whence it was procured. The produce of this plant having been so valuable, it necessarily became a considerable source of revenue, and was represented on the coins of Cyrene; another is represented in the above edition of Theophrastus, with the head of a beardless man on the obverse, while a third is described as figured in Viviani's 'Flora Libyca,' in which the figure is bearded, but in all the plant is exactly the same.

From the descriptions and representations of the plant on those coins there can be no doubt of its being one of the *Umbelliferæ*, and it has successively been thought to be *Laserpitium Siler* and *gummiferum*, *Ligusticum latifolium*, *Ferula tingitana*, &c. But as the natural history of the countries becomes investigated, whence the ancients obtained the substances they have described, these doubts give way to certainties, or very near approximations to the truth. Della Cella, who travelled in the Cyrenaica in 1817, having found an umbelliferous plant on the mountains of Cyrene, and the only one at all resembling the representation on the coins, would appear to have finally determined the question. This plant has been described by Viviani in his 'Flora Libyca,' and named *Thapsia Silphion;* it is very closely allied to *T. garganica* of De Candolle, and a description of it may be seen in Dr. Lindley's 'Flora Medica,' p. 52. The root is said to yield a juice, which, according to the testimony of the natives of the country, is possessed of very valuable medical properties. M. Pacho, who travelled subsequently in the same country, thinks he has found the Laser, or *Laserpitium*, in Cyrenaica and Marmarica, and has called the plant *Laserpitium Derias.* ('Voyage dans la Cyrenaique,' Paris, 1827.)

There appears however to have been from the earliest times two kinds of Laser. Thus Pliny, "Diu jam non aliud ad nos invehitur laser, quam quod in Perside aut Media et Armenia nascitur large, sed multo infra Cyrenaicum." Dioscorides also states some to have been procured from Armenia and Media. Hence it is probable that some similar substance was substituted for the more highly esteemed Cyrenaican juice when this became scarce. There can be very little doubt that Assafœtida was at one time substituted for it, at least since the time of the Arabs, for Avicenna describes his Hulteet, which is assafœtida, as of two kinds, one fœtid, and the other fragrant, the latter from the 'regio Chiruana' in the Latin translation; while Anjidan, which are the seeds of the assafœtida plant, are translated *Laserpitium.* That assafœtida was an article of export from Persia in very early times we know, from seeing it noticed in the Sanscrit 'Amara Kosha,' which is at least of as early a date as the commencement of the Christian era. The juice and seeds of the assafœtida are likewise both used as medicinal substances, and the former esteemed even as a condiment by Asiatic natives. While the root of the Silphium, which grew on Paropamisus with pines, is mentioned by Arrian as affording food to numerous herds of cattle. This has been stated by Mr. Moorcroft to be the case, even in the present day, with another Umbelliferous Plant in the same regions, that is *Prangos pabularia*, which is therefore conjectured by Dr. Royle to be one of the kinds of Silphium. [SILPHIUM.]

LASERPITIUM (the name of the ancient Silphium), a genus of Plants belonging to the natural order *Umbelliferæ.* It has a calyx with a 5-toothed rim; the petals obovate, emarginate, with an inflected lobe; the fruit compressed from the back, or somewhat taper, 8-winged, that is, the half-fruits with five primary filiform ridges, and four winged secondary ones; a vitta in the channel below each secondary ridge. The species are herbaceous plants, with 2-3-pinnate leaves, and entire toothed or cut segments; many-rayed showy umbels; the involucres many-leaved; the flowers white, rarely yellow.

L. glabrum, glabrous Laserwort, has bipinnate leaves, quite glabrous in every part; the leaflets obliquely cordate, here and there mucronate and toothed; leaves of the involucre setaceous; wings of the fruit equal, rather curled. This plant is a native of mountainous districts of Europe in dry and stony places. It attains a height of 1 or 2 feet on the Alps, but in cultivation is a much larger plant. The root is filled with a gum-resin, which is acrid, bitter, and even somewhat caustic. It is said to be a violent purgative. The French call it Turbith aux Montagnes and Faux Turbith.

L. Siler has bipinnate quite glabrous leaves; leaflets lanceolate or oval, quite entire, mucronate, sometimes confluent, and then 3-lobed; the leaves of the involucre and involucels linear-lanceolate, slightly awned, acuminate, the wings of the fruit narrow. It is a native of the mountains of the middle and south of Europe. The root is extremely bitter, and yields an aromatic resinous substance which has been supposed to be the Silphion or Laser of the ancients. [SILPHIUM; LASER.] *L. Siler* is supposed by Fraas to be identical with the Λιγυστικὸν of Dioscorides, 3, 51. Sibthorp found this plant in Greece. *L. gummiferum*, a native of Portugal and Spain, also yields a gum-resin. There are several other species of *Laserpitium* described, and many of them yield a gum-resin, which is one of the secretions of the order to which they belong.

(Lindley, *Flora Medica;* Dou, *Dichlamydeous Plants;* Fraas, *Synopsis Plantarum Floræ Classicæ.*)

LASTREA, a genus of Ferns, belouging to the tribe *Aspidieæ.* It has a reniform indusium attached by the sinus, the veins distinct after leaving the midrib, and not uniting with those of the adjoining pinnule. [ASPIDIUM.]

L. Thelypteris, Marsh Fern, has pinnate fronds, linear-lanceolate; pinnæ slightly downy, but without glands. The lobes are entire, blunt, appearing acute on the fertile fronds from the revolute margins; the rhizome creeping. It is found in marshy and boggy places in Great Britain.

L. Oreopteris, Sweet Mountain-Fern, has pinnate fronds, the pinnæ linear-lanceolate, pinnatifid, glandular beneath, gradually decreasing from about the middle of the frond to near the root; lobes oblong, flat; sori marginal.

L. Filix mas, Male Fern, is known by its subbipinnate fronds, obtuse and serrated pinnules, sori near the central nerve, lateral nerves forked. It is found on woods aud banks in Cumberland and Yorkshire.

L. cristata has linear-lanceolate subbipinnate fronds, short triangular oblong pinnatifid pinnæ; pinnacles serrated, the lowermost lobed, and almost pinnatifid; lateral nerves of the lobes with several branches. It is found in bogs and boggy heaths in Norfolk, Nottinghamshire, and Cheshire.

L. spinulosa has the segments of the fronds serrate, and spinose mucronate; stipes clothed with broad roundish concolorous scales.

L. rigida has its fronds triangular, lanceolate, bipinnate, and glandular; segments of the piunules 2- to 5-toothed, not spinulose; stipes clothed with long-pointed concolorous scales. It is found at Inglebrough, Arnside Knot, and near Settle in Yorkshire.

L. dilatata is distinguished by tho stipes being clothed with long pointed scales, with a dark centre and diaphanous margin; the fronds are arched, often drooping, convex. It is found in woods and on banks in Westmoreland.

L. Fœnisecii has a triangular bipinnate frond; the stipes clothed with long, narrow, laciniated, concolorous scales. It is the *Nephrodium Fœnisecii* of Lowe. The frond is elongate, triangular, concave below. It is sweet-scented, and is found in damp places in Great Britain.

LATA'NIA, a genus of Palms of the tribe *Borassineæ* of Martius, which has been so-called from the uame, Latanier, of one of the species *L. Borbonica*, indigenous in the Isle of Bourbon. The other species, *L. rubra*, a much smaller plant, and remarkable for its red-coloured leaves, is a native of the Mauritius. Both are moderate sized, with all the leaves of a palmate fan shape, the flowers yellow, and the drupes yellowish ooloured. The leaves, like those of other palms, are employed by the natives for covering their huts, as well as for making fans and umbrellas. The leaf-stalks are split and employed for making baskets, sieves, &c. The fleshy part of the fruit is astringent, and the kernel bitter and purgative; and the sap is possessed of remarkable antiscorbutic properties, according to the statement of French authors.

LATHYRUS, a genus of Plants belonging to the natural order *Leguminosæ*, and the tribe *Vicieæ.* It has a campanulate 5-cleft calyx, the two upper lobes the shortest. Stamens diadelphous; style flattened, dilated at the apex, shaggy or downy in front; legume oblong, many-seeded, 2-valved; seeds globose or angular. The species are usually climbing herbaceous plants; the stipules half-sagittate; leaves cirrhose; leaflets 1, 3 pairs; peduncles axillary.

L. Aphaca is a common European field plant. It is a little smooth pale glaucous green aunual, branching from the root into several weak stems, either procumbent or climbing by means of numerous alternate simple tendrils, each of which springs from between a pair of large stipules of a broad arrow-shape, nearly entire. There are no true leaves or leaflets, except that now and then near the root, a pair of an elliptical shape on one or two rudiments of tendrils, very rarely on a real tendril, may be observed, but these soon wither away. The flowers are solitary on long simple stalks, accompanying some of the tendrils, small, drooping, and lemon-coloured. The bracts are in pairs, awl-shaped. The teeth of the calyx long and lanceolate, ribbed. The legume about an inch in length, somewhat cylindrical, smooth, with about six round seeds, which are somewhat narcotic, and produce excessive headache if oaten abundautly in the ripe state. When young and green they may be eaten without inconveuience, like green peas. It is a British species.

L. Cicera is a nativo of Spain. It is a nearly smooth plant, with spreading winged stems; the leaflets 2, linear-oblong; tendrils 3 to 4; stipules half-sagittate, lanceolate, somewhat toothed, ciliated, the length of the petiole, which is not membranous at the edge; peduncles 1-flowered, longer than the stipules; bractlets very small; calycine segments lanceolate, leafy, almost three times as long as the tube; corolla red; legumes broad, oblong, irregularly reticulated, channelled, not winged at the back; seeds 3-cornered, somewhat truncate, brown, and smooth. The seeds are poisonous, and the flour with which they are ground up is rendered unfit for use.

There are 9 British species of this genus mentioned by Babington in addition to *L. Aphaca.*

L. Nissolia is known by its leaf-like petioles, without leaves or tendrils, and with minute stipules.

L. hirsutus has linear-lanceolate leaflets, and globose tubercular seeds.

L. pratensis has many-flowered peduncles, and subulate calyx-teeth; the flowers are of a bright yellow; the hilum small and oblong. It is found in moist meadows and pastures.

L. sylvestris has a winged stem, many-flowered peduncles, the leaves of one pair of linear-lanceolate, or lanceolate leaflets; calyx teeth triangular, subulate; seeds compressed, smooth, and half surrounded by the hilum. The broad-leaved varieties often pass for *L. latifolius.*

L. latifolius is known by the leaves consisting of one pair of elliptical pointed leaflets; the seeds tubercular, rugose, one-third surrounded by the hilum. It is a doubtful native.

L. palustris has the leaves composed of 2 or 3 pairs of linear-lanceolate acute leaflets; the seeds a quarter surrounded by the hilum.

L. maritimus has an angular stem, not winged; the leaves of 3 to 8 pairs of oval leaflets; stipules large, oval, cordate, hastate. It is a rare plant found on pebbly sea shores.

L. macrorhizus is known by its simple winged stem; the leaves having two or three pairs of oblong or lanceolate blunt apiculate leaflets, without tendrils; cylindrical pods. It is the *Orobus tuberosus* of Smith.

L. niger has a branched stem, not winged; the leaves of 3 or 6 pairs of lanceolate or oblong leaflets, without tendrils; stipules linear, subulate, the lower ones arrow-shaped.

(Babington, *Manual;* Lindley, *Flora Medica.*)

LATIALITE. [HAUYNE.]

LATROBITE, a Mineral, which occurs crystallised and massive. Primary form a doubly oblique prism. Cleavage parallel to all the primary planes. Colour pale rose-red or pink. Fracture uneveu. Hardness 5·0 to 6·0. Lustre vitreous. Translucent. Specific gravity 2·72 to 2·80. Found at Amitok Island, Labrador, and in Finland. Analysis by Gmelin:—

Silica	44·65
Alumina	36·81
Lime	8·29
Potash	6·58
Oxide of Manganese	3·16
	99·49

LAUMONITE, a Mineral belonging to the group of Hydrous Silicates of Alumina. It occurs in oblique rhombic prisms. The cleavage is parallel to the acute lateral edge; also massive, with a radiating or divergent structure. The colour is white, passing into yellow or gray. Lustre vitreous. Hardness 3·5 to 4·0. Specific gravity 2·3. It contains—

Silica	48·3
Alumina	22·7
Lime	12·1
Water	16·0
	99·1

It is found exclusively in America. The best specimens are obtained at Peter's Point, Nova Scotia.

LAUNCE. [AMMODYTES.]

LAURA'CEÆ, *Laurels*, a natural order of Apetalous Exogens, consisting entirely of trees and shrubs, inhabiting the warmer parts of the world, and in most cases aromatic, on which account several are mentioned in works on officinal plants. The best known species in Europe is *Laurus nobilis*, the Sweet Bay, a beautiful evergreen, whose fragrant leaves are commonly employed to flavour confectionary. [LAURUS.] Other products of the order are cinnamon and cassia; sassafras, whose bark has great reputation in North America as a powerful sudorific; Pichurim beans, an indifferent substitute for nutmegs; and finally, not to mention other useful substances, camphor, obtained by the Chinese from the *Camphora officinarum* by means of dry distillation. [CAMPHORA.]

In geucral it may be expected that the trees of this order are valuable as aromatics and stimulants, although but a comparatively small number has yet been brought into uso. They are known by the peculiar structure of their flowers, which have no corolla, stamens iu one or several rows, often in part gland-like and sterile, a simple 1-celled superior 1-seeded ovary, and especially by the anthers bursting with recurved valves. [CINNAMOMUM; LAURUS; NECTANDRA; BENZOIN; SASSAFRAS.]

There are 46 genera and 450 species of this natural order. Its position is near *Thymelaceæ* aud *Cassythaceæ.*

LAUREL-CHERRY. [CERASUS.]

LAURUS, a genus of Plants belonging to the natural order *Lauraceæ*, to which indeed it has given its name. It includes as a species one of the most celebrated trees of antiquity, and until recent times some of the most elegant and useful of the vegetable kingdom, as among them were the trees yielding the camphor of Japan, Cinnamon, both of China and of Ceylon, Cassia bark and buds, the Malabathrum leaf of the ancients, with the less known Culilawan and Sintoc barks, as well as the American Persea, Pichurim, and Sassafras. Most of these are however now placed in distinct genera by the latest authors who have paid attention to the subject, as Nees von Esenbeck and Blume.

L. camphorifera of Kæmpfer, now the *Camphora officinarum* of Nees, is a native of Japan and of the province of Fokien in China, and also of the island of Formosa, whence, according to Mr. Reeves, the chief portion of the camphor of commerce is brought to Canton. As the wood is said to be valuable, the root, refuse wood, and smaller branches are cut into chips, covered with a little water, and the camphor separated by sublimation. [CAMPHORA.] It is necessary to distinguish this camphor from that produced in Borneo and Sumatra by *Dipterocarpus*, or *Dryobalanops Camphora*. [DRYOBALANOPS.]

The kinds of cinnamon are not so clearly settled, as there is both a Ceylon and a Chinese cinnamon. The former however is no doubt produced by *Cinnamomum Zeylanicum*, and the latter by the *C. aromaticum* of Nees. This cinnamon is of superior quality, at least some of it, and is preferred by the Chinese to that of Ceylon, and said to be produced in Cochin China chiefly in the dry sandy districts lying north-west of the town of Faifoe, between 15° and 16° N. lat. Mr. Crawfurd ('Embassy to Siam,' p. 478) informs us that there are 10 varieties of it, and that it is not cured, like that of Ceylon, by freeing it from the epidermis. Dr. A. T. Thomson gives this as one of the characters by which cassia may be distinguished from cinnamon. It is possible therefore that some of it may be imported into Europe and sold as cassia, though Mr. Marshall states that the cassia-bark of the shops is only a coarse cinnamon obtained from the thick roots or large branches of the cinnamon tree.

Cassia-Buds, or *Flores Lauri Cassiæ*, are the dried receptacles of some species of this family, by some supposed to be the above *C. aromaticum*; but it has been pointed out by Loureiro, and is named *C. Loureirii* by Nees. It is a native of Cochin China towards Laos, and of Japan. [CASSIA-BUDS.]

It has sometimes been doubted whether the substances we now call Cinnamon and Cassia are exactly the same things as those to which the ancients applied these names. It is very certain that the substances which formed such highly-esteemed articles of commerce must have possessed some remarkable physical and sensible properties not common in products beyond the tropics. The aromatic principle is that which is most conspicuous in the products of the tropical zone, and is found probably in most of the substances which the ancients obtained from the east—at least Dioscorides has described them all together. It would be difficult even with our present knowledge to find any other substances which would equally well answer the ancient descriptions, without going still farther east. The Greek name of cinnamon is *Κιννάμωμον*, which Herodotus says his countrymen learnt from the Phœnicians; and the Hebrew name, we know, is Kinnemon. It is remarkable that the Malay name is Kayu-Manis, which Mr. Marshall says is sometimes pronounced as if written Kaina-Manis. By the Hindoos cinnamon is called Dar-Cheenee, indicating that they obtained it from the Chinese; and Professor Wilson has lately proved that there was commerce by sea with China at a very early period, and, what is still more remarkable, that the navigators were Hindoos.

The Culilawan Bark, often written Culihaban, or Culitlawan, said to be derived from 'kulit,' bark, and 'lawan,' clove, in some measure resembles Cassia. It is one of those which has been known in Europe since the 17th century, but it has been little used in modern times, though Blume describes it as possessed of remarkable properties in curing diseases. Analyzed by M. Schloss, it was found to yield a resin, a volatile oil, and a bitter extractive substance. A volatile oil obtained from it in Amboyna is used as a stimulant, according to Labillardière. It was formerly employed in Europe as an aromatic stimulant, and must be useful in cases where such remedies are indicated. The tree yielding it is a native of Amboyna, and is called Cinnamomum Culilawan by Blume.

L. nobilis of Linnæus, the Laurel, or Sweet Bay, now alone remains in the genus *Laurus*. It is a native of the north of Africa and south of Europe, and of Asia; at least it has been so long naturalised in these countries that it would be difficult to ascertain whence it was originally introduced. It is the *Δάφνη* of the Greeks, and is known to the Arabs by the name Ghar, with Zafne as its Greek synonyme. The berries are even found in Indian bazaars by the name Hubal-Ghar.

It attains a height of 20 or 30 feet, and is cultivated in gardens, not only on account of its elegant appearance, but also for the aromatic fragrance of its leaves, which are evergreen, lanceolate, wavy at the margin, and quite smooth. The flowers are small, four or five clustered together in the axils of the leaves, of a yellowish-white colour, and dotted. The fruit is small, ovate, dark-purple coloured, and a little succulent. It is endowed with aromatic properties as well as the leaves, whence both have long been used in medicine as stimulants and carminatives, as well as a fatty oil expressed from the seed, which however, retaining a portion of the volatile oil, has a fragrant smell. The term 'bachelor' has by some been supposed to be derived from the former practice of crowning candidates for honours with bay-leaves and berries, whence the terms Baccalaureus and Laureate

1, a flowering branch of *Laurus nobilis*; 2, one of the flowers, much magnified; 3, a stamen, with a pair of glands on its filament, and the anther opening by two recurved valves; 4, a seed; 5, a section of the same, exhibiting a minute embryo.

LAVA, in Geology, the most general designation of the mineral substances which are erupted in a melted state from volcanic vents. The situation of volcanoes now extinct may often be recognised by their solidified products, even when the characteristic conical figure of volcanic mounds has been destroyed by time; and it is commonly supposed that 'volcanic rocks' may be distinguished from 'trap rocks,' the effects of heat in ancient geological periods, by some peculiarities of aggregation, which appear due rather to the dissimilar circumstances under which the lava was solidified than to any essential difference in the chemical constitution or mineral components.

Dr. Daubeny presents the following general view of the appearance and heat of lava:—"When observed as near as possible to the point from whence it issues, it is for the most part a semifluid mass of the consistence of honey, but sometimes so liquid as to penetrate the fibre of wood. It soon cools externally, and therefore exhibits a rough unequal surface, but, as it is a bad conductor of heat, the internal mass remains liquid long after the portion exposed to the air has become solidified. The temperature at which it continues fluid is considerable enough to melt glass and silver, and has been found to render a certain mass of lead fluid in four minutes, which, placed on red-hot iron, required double that time to enter into fusion." ('On Volcanoes.')

Lavas vary so much in chemical composition and mineralogical aspect, that it might seem impossible to reduce them to a general rule. Yet as among the older products of heat we distinguish two principal groups depending on the relative abundance of felspar and hornblende (or augite), so among the products of modern volcanoes a similar consideration clears away much of the perplexity which belongs to this subject.

According to Von Buch, almost all lavas are to be viewed as a modification of trachyte, consisting essentially of felspar and united with titaniferous iron, to which they owe their colour and their power of attracting iron; they generally contain glassy felspar; and often inclose augite, leucite, hornblende, mica, olivine, specular iron, and many other minerals, developed by crystallisation from the fused mass. Trachyte, one of the most prevalent of all volcanic products, consists chiefly of felspar (90 per cent.), and includes almost every conceivable modification between porphyry and obsidian.

Basalt, another of the characteristic volcanic rocks, contains, besides much felspar, a considerable admixture of augite or hornblende, and is rich in oxide of iron, sometimes titaniferous.

If lava were wholly felspathic it would consist principally of silica, alumina, and potash, as in column 1, the average of seven analyses of felspar: if wholly hornblendic, as in column 2, which expresses the composition of hornblende from the Vogelsberg, according to Bonsdorff; if wholly augitic, as in column 3, which is the analysis of black augite from Ætna by Vauquelin.

	(1.)	(2.)	(3.)	(4.)
Silica	64·0	42·2	52·0	51·0
Alumina	18·9	13·9	3·3	19·0
Lime	0·8	12·2	13·2	9·5
Magnesia	—	13·7	10·0	—
Potash	13·7	—	—	—
Soda	—	—	—	4·0
Oxide of Iron	0·8	14.6	14·7	14·5
&c.	—	—	6·8	—

The fourth column gives, for comparison, the result of Dr. Kennedy's examination of the compact lava from Catania. Soda, an ingredient of compact felspar, appears more frequent in lavas than potash, which belongs to common felspar: magnesia is not common, its place in the chemical aggregate being probably occupied by oxide of iron. [AUGITE.]

Trachyte is conjectured by Dr. Daubeny to be derived from granite; and some volcanic products present in their chemical composition a remarkable analogy to that of granite. Obsidian, of which a specimen from Hecla yielded to Vauquelin—

Silica	78·0
Alumina	10·0
Potash	6·0
Lime	0·1
Soda	1·6
Oxide of Iron	1·0
	96·7

is by the same writer spoken of as derived from trachyte.

In comparison with this we may place the composition of granite as calculated by Sir Henry de la Beche from its constituents, namely:—

Silica	74·8
Alumina	12·8
Potash	7·5
Lime	0·4
Magnesia	1·0
Oxide of Iron	1·9
&c.	0·3
	98·7

The certainty with which the mineral ingredients of lava can be identified depends principally on the degree of crystallisation which circumstances have permitted, and this on the rate of cooling and pressure to which the melted masses have been subjected. There is in lava every degree of variation, some specimens being of granitic, and others of earthy, compact, resinous, or vitreous texture. Yet in most cases the method of mechanical analysis proposed by Cordier will determine, what very often a lens detects, the real mixture of various minerals in what seems a homogeneous mass. According as felspar or augite predominates, volcanic rocks have been classed, by Cordier and most writers, as trachytic and basaltic. Mr. Scrope ('Journal of the Royal Institution,' vol. xxi.) has proposed an intermediate group to be called graystone. He states that in trachyte, felspar (or its substitute) exists in the proportion of 90 per cent. and upwards, in graystone more than 75 per cent., and in basalt less than 75 per cent. The specific gravity of trachyte is about 2·7, of graystone 3·0, of basalt even 3·5; differences which correspond with their chemical composition. The colours yielded by these rocks, when melted by the blow-pipe, afford a good test for the fine-grained sorts. The glass from trachyte is light-coloured and nearly transparent; graystone gives a darker glass with green or black spots; basalt is changed to a dark green or black enamel. According to conditions of solidification,—in water, in air, or in fissures of the earth,—the minerals which occur in lava are variously distributed so as to give it porphyritic, amygdaloidal, or concretionary characters; and the masses appear compact, porous, cellular, vesicular, cavernous, spumous, or filamentous—and all these circumstances are observable in glass and other products of artificial heat, which are subject to unequal rates of cooling and under different circumstances. [VOLCANO.]

LAVANDULA, a genus of Plants belonging to the natural order *Lamiaceæ*. It has a tubular calyx nearly equal, 13- or rarely 15-ribbed, shortly 5-toothed, with the 4 lower teeth nearly equal, or the 2 lower narrower, the upper either but a little broader than the lateral ones, or expanded into a dilated appendage; the upper lip of the corolla 2-lobed, lower 3-lobed, all the divisions nearly equal, the throat somewhat dilated; stamens didynamous, diclinate.

L. spica is a native of the south of Europe, of which there are two varieties, if not distinct species, termed *L. latifolia* and *L. angustifolia*. The former is also called Spike Lavender, or simply Spike, and the oil which it yields differs considerably from the oil of *L. angustifolia*, or *L. vera*, and is termed oil of spike, or foreign oil of lavender. This sort is much less fragrant, of a deeper green colour than the oil of the true lavender, and is merely used in painting, or to adulterate the genuine oil, which is so extensively employed in the preparation of perfumes.

The flowers of the *L. angustifolia* are the parts employed in medicine. They should be collected before they are expanded, as they are then possessed of a more powerful aromatic odour and a hot bitterish taste. By distillation they yield an oil, which is yellowish, but by rectification becomes nearly white. It has the agreeable strong odour of lavender, and a burning bitterish taste. It is very limpid, but becomes thicker by time. The specific gravity is variable; that of the rectified oil is about 0·872. The freshly-rectified oil of lavender acts on litmus paper, reddening it more powerfully than when a year old. In the cold it deposits a lavender-camphor, or stearopten. It is often adulterated by oil of turpentine and oil of spike. The oil dropped on sugar relieves slight spasms of the stomach; when diffused by alcohol in water it constitutes the spirits of lavender. The compound tincture of lavender is useful in similar cases, and is the best means of covering the disagreeable taste of aloes.

LAVATE'RA (in honour of the two Lavaters), a genus of Plants belonging to the natural order *Malvaceæ*. It has numerous styles, a double calyx, the outer one being 3-leaved, the inner 5-leaved; the capsules orbicular and many-celled; the cells circularly arranged, and 1-seeded.

L. arborea, Tree Mallow, has a wooded stem, the leaves 7-angled, plaited, and downy; the pedicels aggregate, axillary, 1-flowered, and much shorter than the petiole. It is a native of Italy, Spain, Portugal, the north of Africa, and the Canary Islands, on maritime rocks; also in Britain, in the Isle of Wight, on Portland Island, in Cornwall, and Devonshire. It is the Μαλάχη of Theophrastus ('Hist. Pl.,' i. 5; i. 14).

L. Neapolitana has an herbaceous scabrous erect stem, with roundish 7-nerved leaves, and 7 blunt crenated lobes: the pedicels axillary and aggregate, the involucel shorter than the calyx, the lobes of the calyx acuminated. The flowers are blue with obcordate petals. This species is a native of Naples, by the sea-side, and is much cultivated in our own gardens as an ornamental plant.

L. Olbia has a shrubby stem, rather scabrous, from distant fascicles of hairs; the leaves are soft, woolly, 5-lobed, the upper ones 3-lobed, with the middle lobe elongated; the uppermost leaves are oblong, almost undivided, the flowers solitary and sessile. It is a native of Provence, in hedges about D'Hières.

None of the species of *Lavatera* are of any importance or value, excepting as ornamental plants. Many of them are hardy, easily cultivated, and well adapted for shrubberies. The greenhouse and frame species will thrive well in a mixture of loam and peat, or any light soil; they may be planted out during the summer against a south wall, and if protected in the winter by a mat, will generally survive throughout the year. The perennial species grow in any kind of soil, and may be propagated either by dividing the plants at the root or by seeds. The annual and biennial kinds should be sown in the open border during the spring. The species chiefly worth cultivation in gardens are *L. Olbia*, *L. flava*, *L. unguiculata*, *L. Neapolitana*, *L. Cretica*, *L. Lusitanica*, and *L. trimestris*.

(Don, *Dichlamydeous Plants*; Babington, *Manual Brit. Bot.*; Fraas, *Synopsis Plantarum Floræ Classicæ*.)

LAVENDER. [LAVANDULA.]

LAVENDULAN, a Mineral which occurs amorphous. Colour lavender blue. Streak paler blue. Lustre greasy, inclining to vitreous. Hardness 2·5 to 3·0. Occurs at Annaberg in Saxony, with cobalt and iron-ores. Accorning to Plattner, it contains arsenic, and the oxides of cobalt, copper and nickel, and water.

LAVER, a substance sometimes used as food, consists of the fronds of marine plants belonging to the genera *Porphyra* and *Ulva*.

Purple Laver is furnished by *Porphyra laciniata* and *P. vulgaris*, two species common on rocks and stones in the sea on many parts of the British coast. They derive their botanical name from their beautiful purple or violet colour, which is produced entirely by the multitudes of spores, arranged in twos, threes, or fours, with which the whole frond is filled.

Green Laver is the *Ulva latissima*, a very common plant in the sea on rocks and stones, not only in Great Britain, but also on the coasts of India, Australia, the Cape of Good Hope, and South America. According to Lightfoot, the Scottish Islanders ascribe to it anodyne properties, and bind it about the temples to assuage the pain of headache in fevers, and to procure sleep.

In the Western Isles of Scotland, we are informed by the same authority, the inhabitants gather it in the month of March; and after pounding and stewing it with a little water, eat it with pepper, vinegar, and butter; others stew it with leeks and onions. In England Laver is usually stewed and rendered palatable with lemon-juice; to many persons it is however nauseous, and it has been suggested that its introduction to fashionable tables was the sly contrivance of some medical practitioner who wished to prescribe it for the benefit of his scrofulous patients. [ALGÆ.]

(Greville, *Algæ Britannicæ*.)

LAWSO'NIA, a genus of Plants belonging to the natural order *Lythraceæ*, which, consisting of only one or two species, may be found in most Oriental regions in gardens or in field cultivation. The genus is characterised by having a 4-partite calyx, 4 unguiculate petals, 8 stamens, a sessile ovary, the capsule scarcely dehiscent, or rather forming a globular membranaceous 4-celled berry, with several angular seeds in each cell.

It is disputed among botanists whether this genus consists of one or of two species; in the latter case, one species being armed with thorns, was called *L. spinosa*, and the other being without any, was named *L. inermis*, by Linnæus. De Candolle has followed Lamarck in uniting them together under the name *L. alba*, stating that when young the plant is unarmed, but when older becomes thorny from the hardening of the smaller branches.

The natives of North India distinguished the unarmed species by the name Phoolke, or flowering Mhendee. It is a much smaller plant, but flowers most abundantly. The thorny species is called Mhendee; this, besides being a larger plant, contains a greater proportion of colouring matter, and is extensively cultivated in the vicinity of Sidonra, near the north-west bank of the Jumna. The flowers of both are corymbose, white, and powerfully fragrant; the leaves smooth, opposite, oval, lanceolate. To the latter species or variety the Arabic name Hinna or Henna is more especially applied, which, in many of their medical works, as in that of Serapion, is described under that of Al Kanna, where it is interesting to observe he quotes the description by Dioscorides of Κύπρος, as applicable to this plant. This Kupros, or Cyprus, is moreover supposed to be the Copher of Scripture. ('Canticl.,' i. 12). Besides the similarity of name, no plant is more likely to have been alluded to in the above passage, as no other is more highly esteemed or more frequently employed than the Hinna, and it would appear to have been applied to the same purposes from very remote antiquity. All oriental travellers describe the use of this plant by Asiatic women in dyeing their nails and the tips of their fingers, as well as the soles of their feet, of an orange hue with the leaves of the Hinna. It is also used by the men for dyeing their beards, the orange colour being afterwards converted to a deep black by the application of indigo. That this plant was similarly used from very early times is highly probable from the allusions to it by poets, as well as from some of the Egyptian mummies appearing as if the nails had been similarly dyed.

LA'ZULITE, LAPIS LA'ZULI, a Mineral which occurs crystalline and massive. Primary form of the crystal a cube, but occurs in imbedded rhombic dodecahedrons. Cleavage parallel to the planes of the dodecahedron. Fracture uneven. Hardness 5·5 to 6·0. Colour azure and different shades of blue; streak paler blue. Lustre vitreous, translucent, opaque. Specific gravity 2·76 to 2·94. It intumesces before the blow-pipe without fusing. It occurs at Salzberg and in Styria, also in the United States.

Massive variety amorphous, sometimes in grains, imbedded. It fuses on charcoal, when pure, into a white glass. It is brought from Persia and China, and is employed in the manufacture of ultramarine. The following are analyses by Gmelin and Fuchs:—

Gmelin.		Fuchs.	
Silica	49·0	Phosphoric Acid	41·81
Alumina	11·0	Alumina	35·73
Lime	16·0	Magnesia	9·34
Soda and Potash	8·0	Silica	2·10
Oxide of Iron	4·0	Protoxide of Iron	2·64
Magnesia	2·0	Water	6·06
Sulphuric Acid	2·0		
	92·0		97·68

It seems improbable that so different results should be obtained from the same mineral. Dr. Thomson admits the presence of phosphoric acid; the analysis by Fuchs is therefore most probably the correct one.

LEAD. The properties of this metal are, that it has a bluish-gray colour, and is of considerable brilliancy when fresh surfaces are formed by cutting; if it has not been cooled too rapidly, it is so soft, that even when in pieces of considerable thickness it may be easily bent. It soils slightly, and leaves on paper or cloth a mark after friction resembling that of plumbago. Its specific gravity is 11·445, but when impure not greater than 11·352. Lead may be reduced to thin laminæ, but its tenacity is extremely slight; so that a wire about one-tenth of an inch in diameter breaks with a weight of 30 lbs. It fuses at about 612°, and when slowly cooled crystallises in octahedrons. It is not a volatile metal, for in close vessels it may be heated to whiteness without subliming. When exposed to the air it absorbs oxygen and carbonic acid slowly, and acquires a superficial coating of carbonate of lead. In distilled water which has been freed from and kept from the contact of the air, it undergoes no change; but if it be exposed to air and water, it is oxidised and converted into carbonate of lead with considerable rapidity; this carbonate has the appearance of minute shining brilliant scales.

The ores of lead, strictly speaking, are few in number; indeed the only one which can properly be considered as a working ore is the Sulphuret, but there are various combinations of lead occurring in nature, of which we shall give a brief account.

Native lead is of very rare occurrence, and in some cases of very questionable origin. It has been found in small masses in the lava of Madeira, and also in the neighbourhood of Alston in Cumberland; it is in small globular masses, imbedded in galena, or sulphuret of lead, and a slaggy substance, accompanied with blende and crystals of quartz.

Protoxide of Lead: Native Massicot.—This occurs in amorphous masses. Fracture earthy. Brittle. Specific gravity 8·0. Colour yellow. Opaque. Externally dull, internally of a semi-metallic lustre.

It melts readily by the blow-pipe, and, according to Dr. John, it consists of—

Protoxide of Lead	87·382
Carbonic Acid	3·846
Lime and Oxide of Iron	0·481
Silica (ferruginous)	2·404
	94·113

Deutoxide, or *Sesquioxide of Lead: Native Red Lead: Native Minium.*—It occurs amorphous and pulverulent; colour carmine red. Hardness 2·0 to 2·5. Specific gravity variously stated. Dull. By the blow-pipe on charcoal it is reduced to the metallic state. It is supposed to arise from the decomposition of sulphuret of lead and the oxidation of the metal. It occurs in Yorkshire, Suabia, Siberia, and some other places. When used in the arts red lead is artificially prepared.

Chloride of Lead: Cotunnia: Cotunnite.—It occurs in small flat colourless crystals in Cornwall, and at Vesuvius in acicular crystals of an adamantine lustre inclining sometimes to pearly or silky. Specific gravity of the chloride from Vesuvius 1·897.

It fuses by the blow-pipe, and is soluble in a large quantity of water, and, according to Berzelius, consists of—

Chlorine	25·48
Lead	74·52
	100

Di-chloride of Lead: Berzelite.—It occurs in crystalline masses, with a fibrous and radiated structure, on earthy black ore of manganese. Hardness 2·5 to 3·0. Specific gravity 7·0 to 7·1. It is found in the Mendip Hills in Somersetshire. According to Berzelius it consists of—

Lead	83·20
Chlorine	13·77
Carbonic Acid	1·03
Lead	1·46
Water	0·54
	100

Sulphuret of Lead: Galena.—This almost universally diffused ore occurs in attached crystals and massive. Primary form the cube; the cleavage easy, parallel to its faces. Fracture conchoidal. Hardness 2·5 to 2·7. Scratched by carbonate of lime. Colour lead-gray. Lustre metallic. Opaque. Specific gravity 7·568. The massive varieties are amorphous, the structure granular, and compact.

By nitric acid it is converted into white insoluble sulphate of lead. By the blow-pipe on charcoal the sulphur is first dissipated, and then metallic lead is obtained.

In Cornwall and Scotland the veins of this ore traverse primary rocks. In Derbyshire it occurs in veins or beds in transition rocks. It very commonly contains a considerable portion of silver, and is often mixed with small quantities of some other metals. Galena is very commonly associated with calcareous spar and fluor spar, blende, calamine, carbonate and sulphate of barytes, and in Greenland with cryolite and spathose iron.

The deposits of this ore are remarkable for their extent in the United States. They abound in what is called the 'cliff limestone' of the states of Missouri, Illinois, Iowa, and Wisconsin. The lead of commerce is obtained from this ore, and it is often worked for the silver it contains. The following is its analysis by two eminent chemists:—

Dr. Thompson.		Beudant.	
Lead	85·13	Lead	79·6
Sulphur	13·02	Sulphur	13·4
Iron	0·50	Silver	7·0
	98·65		100·0

Seleniuret of Lead, or *Clausthalite.*—It occurs massive. Structure granular. Colour lead-gray; resembles fine-grained sulphuret of lead, but is softer, and rather more blue. Lustre metallic, but rather dull. Opaque. Specific gravity from 7·187 to 7·697. When heated in a tube selenium sublimes; by the blow-pipe on charcoal it burns with a blue flame, and the peculiar odour of selenium. It occurs in the Harz. According to the analysis of Rose, it consists of:—

Selenium	25·59
Lead	74·81
	99·40

The above are the principal native binary compounds of lead. We proceed to notice those which are composed of an acid and oxide of lead, remarking that it is the protoxide only which combines with acids.

Carbonate of Lead: White Lead: Ceruse.—It occurs crystallised and massive. Primary form a right rhombic prism; cleaves parallel to the primary planes. Fracture conchoidal. Hardness 3·0 to 3·5. Brittle. Colour white, yellow, gray, and grayish-black, sometimes tinged green or blue by ores of copper. Lustre on the cleavage planes adamantine, on the fracture surfaces resinous. Translucent, transparent, and doubly refractive. Specific gravity 6·3 to 6·6. Phosphoresces when powdered and thrown on hot coals. Soluble in nitric acid with effervescence. By the blow-pipe on charcoal decrepitates, becomes yellow, and is reduced. Massive varieties amorphous; structure columnar, granular, compact. The following is its analysis by Dr. John :—

Carbonic acid	15·5
Oxide of lead	84·5
	100

It occurs in most lead-mines and is sometimes used as an ore of lead. The white lead which is used in paint is made artificially. *Caledonite* is a compound of the carbonates of lead and copper.

Sulphate of Lead: Anglesite.—Occurs crystallised and massive. Primary form a right rhombic prism. Cleaves parallel to the primary planes. Fracture conchoidal. Hardness 2·5 to 3·0. Colourless generally, but has sometimes shades of yellow, green, gray, brown, and black. Lustre nearly adamantine. Transparent, translucent. Specific gravity 6·23 to 6·31. It occurs in Anglesey, Cornwall, the Harz, &c. The following is an analysis by Klaproth;—

Sulphuric Acid	24·8
Oxide of Lead	71·0
Water	2·0
	97·8

Dioxylite is a compound of carbonate and sulphate of lead, so also *Leadhillite.*

Phosphate of Lead: Pyromorphite.—The primary form is a rhomboid. It commonly occurs in hexagonal prisms, and cleaves parallel to its planes, and to the truncations on its terminal edges. Fracture imperfect, conchoidal, uneven. Hardness 3·5 to 4·0. Colour various shades of green, yellow, brown, and gray. Lustre resinous. Transparent, translucent. Specific gravity 6·911 to 7·098. It occurs also botryoidal and reniform. It occurs in most lead-mines, especially in those of Saxony and the United States. The following is an analysis by Wöhler.

Phosphoric Acid	15·72
Oxide of Lead	82·30
Muriatic Acid	1·98
	100

Hedyphane is an arseno-phosphate of lead and lime.

Oxide of Lead also occurs in combination with certain acids whose bases are metallic.

Arseniate of Lead: Gorlandite.—Occurs in crystals and massive. Primary form a rhomboid; usual form an hexagonal prism, which cleaves parallel to its lateral planes. Hardness 3·5 to 4·0. Colour pale-yellow, yellowish and reddish-brown. Lustre resinous. Transparent, translucent. Specific gravity uncertain, stated variously from 5·0 to 6·4, and 6·9 to 7·3. It is found in Cornwall and in France. The following is the analysis by Wöhler :—

Arsenic Acid	21·20
Phosphoric Acid	1·32
Oxide of Lead	75·59
Muriatic Acid	1·89
	100

It also occurs reniform. Structure compact, opaque. Lustre resinous. Colour brownish-red. Found in Siberia.

Chromate of Lead: Crocoisite.—Primary form an oblique rhombic prism. Cleavage parallel to the lateral planes of the primary form. Fracture conchoidal. Hardness 2·5. Colour aurora-red. Lustre adamantine. Translucent. Specific gravity 6·004. It occurs also massive :—Amorphous. Structure columnar, granular. It is found in Siberia and Brazil. The following is the analysis by Pfaff :—

Chromic Acid	32
Oxide of Lead	68
	100

It is the chrome-yellow of artists, and is made for their purposes artificially.

Vauquelinite is a chromate of lead and copper, of a dark-green colour.

Molybdate of Lead: Carinthite.—Primary form a square prism. Cleavage parallel to the primary planes. Fracture slightly undulating. Hardness 3·0. Colour different shades of yellow, greenish, and red. Lustre resinous. Translucent. Specific gravity 6·69 to 6·76. It rarely occurs massive. It is found chiefly in Carinthia, but also in North America, &c. The following is an analysis by Berzelius :—

Molybdic Acid	39·14
Oxide of Lead	60·86
	100

Tungstate of Lead: Scheelate of Lead.—Primary form a square prism. Cleavage parallel to the planes of the primary form. Fracture conchoidal and shining. Hardness 3·0. Colour yellowish-white and brownish. Lustre resinous. Translucent. Specific gravity 8·0. It is found in Bohemia and Carinthia. The following is the analysis by Lampadius :—

Tungstic Acid	51·72
Oxide of Lead	41·28
	100

Vanadiate of Lead: Johnstonite: Vanadurite.—Occurs crystallised and in small globular concretions. Primary form a rhomboid. Fracture conchoidal. Brittle. Colour straw-yellow to reddish-brown. Dull, opaque. Specific gravity 6·99 to 7·23. It is found at Tampico in Mexico, and Wanlockhead in Scotland. The following is the analysis by Berzelius :—

Vanadiate of Lead	74·00
Chloride of Lead	25·33
Oxide of Iron	0·63
	99·96

Chloride of Lead: Cerasite.—Has a white, yellowish, or reddish colour, nearly opaque. A pearly lustre. Its specific gravity is 7 to 71. *Cotunnite* is another chloride of lead. It occurs at Vesuvius in white acicular crystals.

Corneous Lead is a chloro-carbonate of lead occurring in whitish adamantine crystals, and found in Derbyshire and Germany.

Plumbo-Resinite is a protoxide of lead, alumina, and water. It is found at Huelgot in Brittany, and in a lead-mine in Beaujeu, also in the mines of Missouri.

LEAD, BLACK. [GRAPHITE.]

LEAD, RED. [CHROMIUM.]

LEAD, WHITE. [LEAD.]

LEADHILLITE. [LEAD.]

LEAF. Amongst the higher plants, the whole of their parts can be traced to modifications of the Leaf or Axis. What is not axis is leaf, and what is not leaf is axis. In the lower plants no such distinctions exist, as the tissues are not formed into leaves and their homologues. Although so common an organ, the leaf is not easily defined, and those who are inclined to enter on the subject would do well to consult Schleiden in his 'Principles of Scientific Botany.' We shall here follow Schleiden in our description of the structure of this most important organ.

Leaves (Folia) may be divided into Annual (Folia Annua) and Perennial (Folia Perennia); the former again into Deciduous (Folia Decidua), which live only in the early part of the period of vegetation; Yearling Leaves (Folia Annua sensu stricto), which live through the whole period; and Late Leaves (Folia Serotina), which are not perfected till toward the close of the period. With few exceptions every plant has temporary leaves, namely, the cotyledons and frequently those next following them. The *Orchidaceæ*, some species of *Cuscuta*, and some *Cactaceæ* are the only plants at present known with certainty to be destitute of cotyledons. Others, for instance the *Rhizantheæ*, have not yet been sufficiently investigated. Many plants are wholly destitute of leaves between the cotyledons and the peduncles of the flowers, as, for instance, all the *Cactaceæ*, excepting *Peireskia*, and some species of *Opuntia;* in others these are annual, as in *Alnus*, or perennial, as in *Pinus*. The floral parts, the leaves last perfected, exist in all Phanerogamous Plants.

When the leaf emerges from the axis it is a little conical body, the base of which gradually comes to occupy the entire circumference of the axis, a stem-embracing or Amplexicaul Leaf (Folium Amplexicaule); or it shares the circumference of the axis with one or more other leaves, which have originated with it on the axis in the same plane, Whorled Leaves (Folia Verticillata); or, lastly, it is confined to a small portion of the circumference, without any other leaves arising from the axis in the same plane, Scattered Leaves (Folia Sparsa). These three positions of the leaves upon the axis are, most undoubtedly, the primary ones occurring in the plant. We find the first in the cotyledon of the Monocotyledons; the second in the cotyledons of the Dicotyledons. But if we disregard, in the Monocotyledons, the character of embracing the stem, only looking to the fact that one leaf alone is formed at one level on the stem —if we trace the further development of the leaves of Monocotyledons, and of those of most Dicotyledons, since in the latter it is only in a few groups that the later leaves are formed in whorls—we find that the great majority of plants have scattered leaves. If every vegetable axis be regarded as a cylinder, the bases of the leaves must admit of being connected by a spiral line. More minute investigation, then, shows that the distances of the bases of the leaves on this spiral are not without law; but a certain regularity may be observed, and, in fact, the angle (angle of divergence) made by two planes, passing through the middle of the axis and the bases of two adjacent leaves, which angle therefore is the measure of the distance of these leaves from each other, is on an average 137° 30′ 28″, consequently a number bearing no ratio to the circumference of the stem (360°); so that no two leaves ever can be exactly in the same vertical line. In the course of the entire axis the distances of the turns of the spiral alter, but always regularly, sometimes even on account of accidental influences; and thus from the simplest fundamental condition proceeds an infinite multiplicity of modes of manifestation, even when the various forms of the axis do not interfere. Compare but the rosette of leaves of *Sempervivum tectorum*, the stalk of *Lilium Martagon*, a shoot of *Populus dilatata*, a cone of *Abies excelsa*, and the fruit peduncle of *Helianthus annuus*, which latter exhibits the regular position of the leaves even through its fruit which originate from axillary buds.

On this subject the student should consult the following works:—

Dr. Schimper, 'Description of Symphytum Zeyheri,' &c., in 'Geiger's Mag. für Pharmacie,' b. xxix. p. l. et. seq.

Dr. Schimper, 'Essays on the Possibility of a Scientific Comprehension of the Position of Leaves,' &c. Published by Dr. A. Braun, 'Flora Jahrg.' xviii., No. 10, 11, 12 (1835).

L. and A. Bravais, 'Mémoires sur la Disposition géométrique des Feuilles et des Inflorescences, précédés d'un Résumé des Travaux des MM. Schimper et Braun sur le même Sujet, par Ch. Martins et A. Bravais.' Paris, 1838.

The primary form in which the leaf makes its appearance is, as above stated, always that of a little conical body which is pushed out from the axis; its ulterior form depending entirely upon the arrangement of the new cells, and the expansion of already existing cells, and the leaf is as little confined to a definite circle of forms as any other of the organs, except the ovule or seed-bud. It may be globular, ovate, elliptical, and prismatic, as well as filiform, strap-like, and flattened in its expansion, and, by the greater accumulation of the cells in the middle than on the borders, or more flattened mode of expansion in the middle than on the borders, the plane surface may also produce concave forms. The most striking forms of this kind are called Pouches (Asci), as in *Sarracenia*, *Cephalotus*, and *Utricularia*. One of the most frequent forms, which is usually laid down as the normal form, is this—the upper part is developed into a plane, the Blade of the Leaf (Lamina), the lower into a filiform part, the Petiole or Leaf Stalk (Petiolus), and in the latter may frequently be distinguished, still lower down, a somewhat thickened or expanded portion, a Sheathing Portion (Pars Vaginalis), with which the leaf partly or wholly embraces the axis. This latter portion is frequently, especially in compound leaves, swollen into a greater thickness (fleshy), and is then called the Cushion (Pulvinus) of the leaf or petiole. As a general rule, the flat leaf is so developed that its surfaces look more or less upward and downward, rarely so that its borders have these directions, so that the axis lies in the plane of the leaf, as, for instance, in many Australian *Myrtaceæ*. It is very different from this when a flat leaf of the usual development makes a half turn on its base, so that its surfaces are thus also placed vertically, as, for example, in *Lactuca Scariola*. One condition, which has already been mentioned when speaking of the axis, occurs also in the leaf, and here becomes of much greater importance. A Joint (Articulatio) is formed rarely (or never?) in the Monocotyledons, frequently in the Dicotyledons, between the leaf and the axis, in consequence of which the leaf is, after a certain time, thrown off from the axis, while in other cases it gradually dies and decays on the axis itself. This true articulation is often repeated in the continuity of one and the same leaf, either only so that a joint is formed between the petiole and the lamina (for example, in *Citrus*, *Dionæa*), or in such a manner that in the flat Subdivided Leaves (Folia Pinnatisecta, Palmatisecta, &c.), every lobe is connected to the main body by a joint. These latter are called Compound Leaves (Folia Composita), and, according to the subdivision, Digitate, or Pinnate (Folia Digitata, Pinnata, &c.). The separate parts are named Leaflets (Foliola), and the part connecting all these is the Common Petiole (Petiolus Communis). The leaflets can of course assume all the forms of the leaf, in particular they may be again separated into lamina, petiole, and pulvinus. In some Australian acacias (for instance, *Acacia heterophylla*) the first leaves are compound; they gradually form fewer and fewer leaflets, till at last the part corresponding to the common petiole alone remains, which then appears as a perpendicular plate, and is called a Phyllodium, to distinguish it from the other perfect leaves of the same plant.

The pouches or pitchers which occur in *Nepenthes*, *Sarracenia*, *Cephalotus*, *Dischidia Rafflesiana* and *D. clavata*, *Marcgravia*, *Norantea*, *Utricularia*, &c., are not yet perfectly understood. The pouches apparently present three different types:—1. In *Sarracenia* it is the lower part of the leaf which exhibits a form resembling a cornucopia, while at the upper border runs out a flat expansion (the lamina of the leaf), separated from the pouch by a deep incision on each side. The lower half of the internal surface of the pouch is clothed with hairs directed downwards; the upper part is smooth. In *Nepenthes* a pitcher-shaped structure is borne upon a long petiole, winged below, then often tendril-like, and carries upon its upper border an articulated (?) lamina, which originally closes the pitcher like a lid. The inner surface is clothed in the lower part with little papillæ of very delicate succulent cellular tissue, while above the epidermis projects down over these like the eaves of a house. In both the cavity is formed from the leaf in such a manner that the closed base of the pouch corresponds to the base of the leaf (*Sarracenia*), or lies quite close to it (*Nepenthes*). In *Dischidia Rafflesiana* and *D. clavata*, on the contrary, the opening of the pouch is turned towards the base of the leaf. *Cephalotus* appears to possess a structure similar to that of *Sarracenia*. In all the plants mentioned the pouch constitutes the main body of the leaf. 2. In *Marcgravia* and *Norantea*, on the other hand, according to Lindley, the pouches are formed by the stipules. 3. In *Utricularia* many separate portions of the divided leaf unite to assume a very complicated form of pouch. Originally these form a little shortly-stalked somewhat cornet-shaped body in the angles of the divisions of the leaves. In this little body are especially developed the under side and the inner border of the orifice (which does not increase much in size), so that the full-grown pouch presents itself as a roundish and somewhat laterally-compressed body, which above is continuous by one angle with the stem, while the other exhibits an orifice, which forms a little funnel projecting inwards. The external orifice of this funnel is closed by a kind of beard growing on the upper border; the lower part of the internal surface of the funnel is clothed with elegant hairs of various forms, but very regularly arranged, while the internal surface of the pouch exhibits peculiar hairs, consisting of two cells, each running out into a longer or shorter arm.

In leaves, as in plants in general, all forms are possible, and almost all actually existing—strict stereometric forms excepted. The terminology depends either on comparison with mathematical figures, or with objects presupposed to be familiar in common life. There is no scientific rule for this; æsthetic tact alone must be our guide. But within the limits of certain vegetable groups certain circles of forms do exclusively occur; and under the guidance of accurate observation we can here establish more definite modes of nomenclature, which however are only valid for these definite groups.

If the Cotyledon of most Monocotyledons is examined we find that in its gradual development it completely incloses the Terminal Bud (Plumula); indeed that the exceedingly delicate soft cells of the two borders of it become in part so firmly united that they may be regarded as grown together, only a little fissure, which exists in all Monocotyledons, remaining. In germination the developing bud has not room to protrude through the little fissure, so that it pushes the borders of it more or less forward, and then these appear as a peculiar appendage on the middle of the Cotyledon, as a membranous expansion of the border of the lower part of the leaf, or as lobes on its base. Similar conditions also occur frequently in the later leaves. In the Dicotyledons a like condition presents itself not unfrequently; either the borders become expanded like a membrane on the base of a petiole or stalk-like leaf, or the emerging bud lifts up a longer or shorter membranous sheath, or peculiar lobules are formed on the base of the petiole, sometimes assuming the form of leaflets, and even connected with the petiole by an articulation. In all cases, without exception, they are, from the course of the development, parts of a leaf developed principally at its base, and in their essential nature wholly identical structures throughout all the *Phanerogamia*, though they may vary most abundantly in their appearance. They have acquired very different names. In the Grasses these parts are called the Ligule (Ligula): in other Monocotyledons, sometimes Vagina Stipularis, if large and rising free from the lowest part of the leaf; Vagina Petiolaris, if small and showing itself first higher up the leaf: in the Dicotyledons, 'Petiolus Alatus, Stipulæ Adnatæ,' if on the margins of the leaf-stalk; Ochrea, if sheathing, as in the *Polygonaceæ*; or Stipules (Stipulæ), if appearing like special leaflets stationed beside the base of the petiole: lastly, in the floral leaves, Fornix, Corona, Nectarium, &c., as in *Lychnis*, *Boraginaceæ*, *Narcissus*, &c. They occur as stipules, especially in compound leaves, where sometimes they alone are developed into a flat surface, while the leaf itself merely forms a filiform process—for example, in *Lathyrus Aphaca*. At the base of the leaflets of compound leaves also little lobes sometimes occur, which, perhaps originating in the same manner, are called Stipelles (Stipellæ).

Every leaf, as already observed, originates as a little conical papilla at a definite point on the circumference of the axis. Even the sheathing leaves are produced in this manner, and at the point which corresponds to the middle line (the mid-rib) of the future leaf by degrees, and as it is pushed up further from the axis the parts of its circumference take part more and more in the development, and thus the base of the leaf gradually becomes broader, until it completely surrounds the axis. If the development of cells, or the expansion of existing ones, continues on the borders of the base of the leaf beyond the degree required to surround the axis, the newly-formed, still soft, and almost gelatinous cells of the two borders of the base of the leaf become applied to one another, and become united as firmly as the cells of a continuous tissue; in this way the lower part of a leaf then becomes a closed undivided whole surrounding the axis. If the lateral production of cells is small, and the union takes place relatively early, this closed portion forms a longer or shorter sheath, closely embracing the axis (vagina clausa), as in many Grasses. If, on the contrary, the lateral cell-production or expansion is considerable, and occurs relatively late, so that merely the base of the leaf forms a flat projecting border round the axis, the leaf is said to have the stem growing through it (folium perfoliatum)—*Bupleurum perfoliatum*, for example. When the axis is angular, and produces thin more or less projecting plates upon these angles (the so-called winged axis, 'axis alatus'), a similar process may enter into the bud in such a way that a flat leaf is connected at its base with the simultaneously-developed wing or angle of the axis, so that the full-grown leaf appears to be directly continuous with this. Such a leaf is said to run down the axis (folium decurrens), as in *Carduus*, or, by a wholly unfounded fiction, a leaf blended by growth with the axis (axis folio adnatus). Where several leaves arise simultaneously, or almost simultaneously, at about the same height upon the axis, the bases of the leaves become gradually approximated during development; and here it may readily happen that they approach so close that the same process occurs between the bases of two different leaves, as has been already described in the two borders of one and the same leaf. Thus it happens, that leaves, which in their origin and at their summits are free and isolated, in their ulterior development and at their bases form an undivided whole (leaves grown together, 'folia connata'). The leaves of *Lonicera Caprifolium* afford an example simplest and easiest to trace. Two foliaceous organs which originate one above the other on the same axis (as the petal and stamen), or a leaf and the bud developed in its axil (as the bract with the flower-stalk in the Lime) may grow together one above the other in the same way.

A process almost diametrically opposite to this may occur, where a leaf is developed, but becomes suddenly arrested in its development in a way as yet unknown, whether through mere mechanical pressure or some other cause, by the more rapid and powerful development of the contiguous leaves; so that either the little original papilla escapes notice, on account of its relatively minute size in the full-grown part, or the little prominence actually becomes effaced by the subsequent development of the part, or, finally, the little rudiment of a leaf dies and gradually decays. In this case the leaf is said to be abortive: an instance easily traced is afforded by the third perigonal leaf of *Carex*, which aborts in this way, while the two others form the so-called Utriculus; and not only may whole leaves become abortive in this way, but even individual portions of a leaf of which the rudiments already exist: thus it is not at all rare for the so-called stipules to become disproportionately developed in the rudimentary leaf, while the proper leaf, restrained in its growth, gradually disappears from sight. The Bud-Scales (Ramenta) on the perennial buds of *Corylus avellana* may serve as examples, being in fact nothing else than the stipules of an abortive leaf.

The same influence to which the parts closely crowded in the bud are subject, may merely cause the unsymmetrical development of the two halves of a particular foliar organ, so that one side, or that part of the leaf lying on one side of the midrib, assumes a form different from that of the other half, of which the species of *Begonia* afford a striking example.

The nascent leaf consists, like all nascent parts of vegetables, of cellular tissue; determinate cords of cellular tissue are first gradually organised into vascular bundles; and in fact this process proceeds from the vascular bundles of the axis, and advances gradually into the leaf. In many foliar organs, especially the parts of the flower, no vascular bundles are ever formed. The vascular bundles of the leaves are distinguished by the most inconveniently chosen expressions, Nerves or Veins (Nervi, Venæ). Ribs (Costæ) is a more correct expression. In Monocotyledons with undeveloped internodes, the whole of the vascular bundles together (?) of the internode, bounded above by the leaf, pass into the leaf. In all other plants, many at least of the vascular bundles entering the leaf are minor twigs of the vascular bundles of the axis; in the Dicotyledons proceeding exclusively, in great part, from the borders of the loop of the vascular bundles of the axis. The course of the vascular bundles in the leaf depends essentially on the form of the latter. In flat leaves, petioles, or vaginal portions, the vascular bundles lie in one plane; in relatively thick leaves, &c., they lie scattered (Palms) or in a circle (species of *Aloë*, *Mesembryanthemum*). The vascular bundles rarely run separately through the whole leaf (as in the last-named): they mostly anastomose in various ways with each other by lateral branches; frequently in the petiole, in such a manner that all the vascular bundles entering it unite into a single one, and then separate again in the blade of the leaf. The form of the combinations is very varied: in many Monocotyledons the branches are short, going off at right angles; in others, and in most Dicotyledons, more varied, so that a net with polygonal meshes is formed.

The vascular bundles of the leaves are progressive bundles, and they are so formed that (regarding the leaf as passing off horizontally from the axis) the oldest parts lie above, the youngest below. In the lower part also a cambium layer exists in the Dicotyledons: in the lower part liber-bundles accompany the vascular bundles, and in the under part the vascular bundles, in relatively thin and flat leaves, project above the surface (probably in consequence of gradual development), while the upper part of the leaf appears level.

The parenchyma of the leaf is developed in the most varied manner; in general, in thick solid leaves, it is composed externally of small crowded cells containing more chlorophyll, internally, of larger and looser cells filled with aqueous juices. Very often the outer layer passes into a tissue, the cells of which are elongated in a direction vertical to the surface of the leaf, are applied closely, almost without trace of intercellular passages, and thus are pretty sharply distinguished from the rest of the parenchyma, and occur in the whole of the periphery of the leaf, not only in round and triangular leaves, but also in flat ones, as in many Australian *Myrtaceæ*. In flat leaves, especially of Dicotyledons, there is very often a separation into two layers, the upper of which has the cells elongated perpendicularly to the surface, as just mentioned, filled with much chlorophyll, while the lower is composed of looser, globular, or, still more frequently, spongiform parenchyma containing little chlorophyll. In thick coriaceous or fleshy leaves, for instance in species of *Ficus* and *Peperomia*, one or more layers of cells containing little but watery juices, often lie between the upper layer and the epidermis; more rarely, in like manner, at the under surface of the leaf.

Besides these there appear at given places, or dispersed in the parenchyma, according to special peculiarities of the plant, spiral fibrous cells, very thick, and closely porous cells, and cells containing peculiar juices and crystals. Milk-vessels and passages, receptacles for gum, oil, and resin, are also found, and isolated liber-bundles, the last especially in the thin elongated leaves of Monocotyledons. Air-canals and air-cavities are found in the leaves; the last very regularly and beautifully arranged.

All foliar organs, soon after their origin, exhibit a delicate epithelium, which, in plants vegetating under earth or under water, is converted in time into epiblema, and in those vegetating above the surface is converted into epidermis. Some parts of flowers are clothed with a peculiar sort of covering, holding an intermediate station between epithelium and epidermis. [FLOWER.] To the epiblema stomata are wanting. The epidermis is commonly provided with them. [STOMATES.] In flat horizontal leaves they are very frequently wanting on the epidermis of the upper side, and they are usually only found where a thin or spongiform cellular tissue is present beneath the epidermis; in floating leaves, on the contrary, the upper epidermis only has stomata, and through the upper layer of condensed elongated parenchyma air-canals pass into the under and thinner layer of parenchyma; as occurs also in leaves that are surrounded with dense elongated cellular tissue. All parts usually known as appendages to the epidermis are also found occasionally on the leaves: even the cork structure is sometimes found on the petioles of long-enduring leaves, as, for example, in some species of *Pothos* and *Ficus*, as well as on the leaves of *Crassula*, *Bryophyllum*, &c.

The cells of the epidermis are usually filled with a clear watery fluid, which on the under surface of the leaf is sometimes coloured (red). They more rarely present crystals, and yet more seldom offer any peculiar matter, as resin, or the like. The form of the epidermis-cells is determined by the form of the leaf; long slender leaves usually present their epidermis-cells elongated in the same direction. The lateral walls of the epidermis-cells are often curved in the form of waves, but this peculiarity has been too little investigated to be explained at present.

The following is a complete view of the foliar organs:—The floral parts of a plant are distinguished from the other foliar organs, and are termed Flower-Leaves (Phylla), whilst other leaves are termed True Leaves (Folia sensu stricto).

1. True Leaves (Folia).

A. Seed-Leaves (Cotyledons), generally round or flat, fleshy, little divided, and never compound.

B. Stalk, or Stem-Leaves (Folia Caulina). Their forms are very various, as has been shown in the foregoing paragraphs. Those immediately following the Cotyledons are usually simple; the next more perfect; and again, as they rise into the vicinity of the blossoms, they become again more simple. Filiform leaves, or parts of leaves, when they twine around foreign objects, are termed Tendrils (Cirrhi), as in *Pisum*, *Clematis*, &c.; those which are stiff and pointed are termed Spines (Spinæ); very concave leaves that exhibit the form of a cup or pitcher are termed Pouches (Asci), as in *Nepenthes*, *Sarracenia*, *Utricularia*, &c. According to their various positions they are again distinguished from the True Leaves generally:—

a. Leaves of the Inflorescence (Folia Floralia). Indistinguishable from the stem-leaves, but bearing in their axils a blossom or a simple inflorescence.

b. Bracts (Bracteæ). Leaves different from the stem-leaves, and bearing in their axils a blossom or a simple inflorescence; for instance, the scarlet-red leaves of the *Salvia Horminum*. To these belong the Glumæ of Grasses, which are simply two bracts (which have commonly no blossoms in their axils), and the leaves which surround the capitula of the *Compositæ*. A number of bracts, inclosing an inflorescence, are also termed an Involucre (Involucrum). The quickly-drying bracteæ of the *Compositæ* are termed Scales, or Chaff (Paleæ), a word altogether superfluous.

c. Bracteoles (Bracteolæ), distinct from the stem-leaves, and standing beneath the blossom, but upon its axis; for example, the two leaves under the blossom of the *Aconitum*, &c.

C. Bud-Scales (Tegmenta). The very simple, mostly membranous, and quickly-falling outer leaves of a bud which remains for a length of time unexpanded. (See hereafter, under the *Bud*.)

2. Flower-Leaves (Phylla).

A. Perigonial Leaves (Phylla Perigonii).

B. Sepals of the Epi-Calyx (Phylla Epicalycis).

C. Sepals (Sepala).

D. Petals (Petala).

E. Pseudo-Petals (Parapetala).

F. Stamens (Stamina).

G. Pseudo-Stamens (Parastemones).

H. Carpels (Carpella).

In connection with the Leaf we may speak of the Bud, the organ from which the Leaf is developed.

The Bud is the end of a main or secondary axis, as yet undeveloped, but capable of development. We may distinguish—1. The Terminal Bud (Gemma Terminalis), the end of a developed axis, itself capable of development. 2. The Axillary Bud (Gemma Axillaris), the end, capable of development, of a secondary axis newly arising, according to law, in the axil of a leaf; since several buds may arise, without irregularity, in one axil, that which develops most vigorously is termed the main bud, the others accessory buds (gemma axillaris primaria and accessoria). 3. Lastly, the Adventitious Buds (Gemmæ Adventitiæ), formed at the end of any (secondary) axis capable of development, arising irregularly on the plant. In all these we distinguish buds continually progressing in development (gemma vegetatione continua) from buds whose vegetating activity rests for a time after their development into a bud (gemma vegetatione interrupta). Again, buds are distinguished into those which, in the natural course of vegetation, separate themselves from the parent plant and become independent plants (gemmæ plantiparæ), and those which always remain in connection with the parent plant (gemmæ ramiparæ). Finally, buds are distinguished according to their contents: there are the Flower-Buds (Gemmæ Floriparæ, alabastrus); the Leaf-Buds (Gemmæ Foliiparæ); and Mixed-Buds (Gemmæ Mixtæ).

With the exception of the true tuber in *Solanum* and *Helianthus* (?), and of the Tuber-Buds (Tubercula), all buds have a determinate number of rudimentary foliar organs. These foliar organs are folded in specific ways (vernatio), and have a definite position in relation to each other. From the origin of the foliar organs, it follows that when several arise at the same height, they will always be at some time in such a position that their edges will be in contact (vernatio simplex, foliatio valvata). This position often persists during the whole period of the bud remaining as such; it is however changed by various circumstances, not yet clearly understood, but which appear to be caused by the individual development of the separate leaves. In the vernation the following main forms may be distinguished: the foliar organs are either curled up in the direction of their length or their breadth, or they are compressed together in irregular folds (vernatio corrugativa). In those leaves that are curled up lengthways we distinguish sharp folds from those which make rounder curves.

Schleiden gives the following nomenclature of the kinds of Vernation and Foliation:—

A. With sharp folds.

a. Vernatio Duplicativa. Simply folded together (forwards) upon the upper surface of the leaf, as in *Quercus*, *Tilia*, and the lamina of *Liriodendron*.

b. Vernatio Replicativa. Folded in the same way backward upon the under surface of the leaf.

c. Vernatio Implicativa. The two borders folded in sharply forwards, as in the perigone of *Clematis*.

d. Vernatio Plicativa. Many longitudinal folds, as is seen, though not quite perfectly, in *Fagus* and *Carpinus*, but better in *Alchemilla*, and best of all in *Panicum plicatum*.

B. With rounded folds.

a. Vernatio Convolutiva. Simply rolled up, as in *Calla* and *Prunus*.

b. Vernatio Involutiva. With both edges equally rolled up forwards, as in *Alisma* and *Populus*.

c. Vernatio Revolutiva. Rolled backwards in a similar manner, as seen in *Salix* and *Nerium*.

In leaves curled and folded together the cross way, the most important distinctions occur.

a. Vernatio Inclinativa. Incurved forwards, as in the petiole of *Liriodendron* and *Hepatica*.

b. Vernatio Reclinativa. Recurved backwards, as in *Aconitum*.

c. Vernatio Circinata. Rolled up forwards from the point to the base, as in *Cycas*.

In the Foliation we distinguish the position of the foliar organs in relation to one another, in general, from the position of individual circles of foliar organs with respect to each other. With regard to the first of these, the conditions have been pointed out.

A. Foliatio Valvata. When the leaves only touch without covering each other with their borders.

a. Foliatio Valvata sensu stricto, in Vernatio Simplex. Flower in *Stapelia*.

b. Foliatio Induplicativa (?), in Vernatio Duplicativa.

c. Foliatio Implicativa, in Vernatio Implicativa, as in the perigone of *Clematis*.

B. Foliatio Amplexa. When each leaf embraces all those within it.

a. Foliatio Convolutiva, in Vernatio Convolutiva, as in *Prunus Armeniaca*.

b. Foliatio Equitans, in Vernatio Duplicativa, as in *Iris*.

C. Foliatio Semiamplexa. When each leaf embraces with one edge, and is embraced on the other.

a. Foliatio Contorta, in Vernatio Simplex (more than three leaves), as in the flower of *Dianthus* and *Linum*.

b. Foliatio Obvolutiva, in Vernatio Duplicativa, as in *Lychnis*.

D. Foliatio Quincuncialis. When five leaves so lie that between two external quite uncovered ones, and two inner quite covered ones, the fifth is so interposed as to cover one of the inner leaves with one edge, and to be covered at its other edge by one of the external leaves, as in the flower of *Rosa*.

E. Foliatio Connata. When the leaves of a circle are so perfectly and intimately grown together that on the full development they become ruptured from their common basis, and fall away like a cap, as in some calices, for instance, *Eucalyptus*, *Eschscholtzia*; and bracts, as in *Aponogeton distachyon*, &c.

Some of the above forms are given in the following wood-cut.

1. Applicative, or appressed (*Viscum album*). 2. Conduplicate (*Cerasus communis*). 3. Imbricate (*Syringa vulgaris*). 4. Equitant-Terete (*Vaccinium Myrtillus*). 5. Equitant-Ancipital (*Iris germanica*). 6. Equitant-Triquetrous (*Carex paludosa*). 7. Obvolute, or Semi-Amplexal (*Saponaria officinalis*). 8. Gyrate, or Circinate (*Drosera anglica*). 9. Involute (*Viola odorata*). 10. Equitant-Tetraquetral (Some *Carexes*). 11. Plicate (*Vitis vinifera*). 12. Involute (a variation) (*Pyrus Malus*). 13. Revolute (*Polygonum Persicaria*). 14. Convolute, or supervolute (*Prunus Armeniaca*).

Finally, in respect to the position of individual circles of foliar organs with respect to one another, the following have been distinguished:—

A. Foliatio Alternativa. When the members of the one circle stand before the interspaces occurring between the members of another circle, as in the calyx, corolla, and stamina of *Lysimachia*.

B. Foliatio Oppositiva. When the members of one circle stand before the members of another circle.

We may now speak of the particular Forms of Buds.

A. Buds developing in uninterrupted vegetation. These may also be termed open buds, because they seldom or never exhibit a closed form, since in these the leaves are gradually developed to the perfect form and size, from the perfect rudiments contained in the bud. Yet in these buds the foliation is always such, that the youngest and tenderest parts are defended from the influence of the atmosphere, and almost wholly inclosed.

B. Buds with vegetation dormant for a certain time.

I. Buds of Shoots.

a. Terminal and axillary buds of perennial plants, with periodically dormant vegetation. Of these we are only intimately acquainted with the native trees of our woods and forests. It is characteristic of these, that the young leaves, which subsequently come to perfection in the more developed axis, are enveloped whilst in the bud by stipules, which soon after the development of their leaf fall away (stipulæ deciduæ), as in *Liriodendron*, or in leaves or stipules of simple structure, of which the laminar portion is ahortive (tegmenta): and there are varieties amongst these, so far that either only the external or inferior leaves, or stipules, appear as coverings of the huds, as in *Fagus;* or the coverings of the hud seem to he continued into the interior of the hud, hut alternate with leaves capahle of perfect development, which lie hetween and are covered hy them, as in *Acer.* The coverings of the hud are for the most part tough, and almost leathery; they are often filled and coated over with resinous juices, and then mostly fall off in the development of the hud, hut they also occur thin and herhaceous in texture, and even change quickly into dry thin memhranes, which mostly remain upon the plant; these last are seen in *Pinus.*

b. Adventitious huds of perennial plants, with vegetation periodically dormant. They are only distinguished from the foregoing hy the mode of development. Each stem, whether a common one or a root stem, can develop a hud. These buds are caused, not only hy accidental and intentional wounding of the stem, hut also hy the inclination of plants to develop huds at certain places. Many plants exhibit upon their bark peculiar little groups of lax roundish cells, which originally lie under the epidermis, which however is soon destroyed ahove them, leaving them bare (lenticellæ). The result of this exposure is, that at these places the hark is rent hy the distension of the bough or stem; hence the newly vegetating part of the hark comes in contact with the air. It is principally at the edges of the rent hark that the adventitious buds are found.

2. Propagative Buds.

a. Bulhs (Bulbi) are monocotyledonous stems, with undeveloped nternodes, which gradually die away from helow upwards, and therefore remain always very short, with perennial leaves, whose vaginal parts die away and inclose thin memhranes, the sheaths of the inner leaves still living, and always fleshy and thick (hulb-scales); or more rarely die away speedily, and leave hare the latter, as in *Lilium.* They are formed either immediately from the emhryo, and then the sheathing part of the cotyledonary leaf hecomes the first hulh-scale; or they are formed from the axillary huds of the hulb, or from the axillary huds of the stems which have sprung from the hulhs, as in *Lilium bulbiferum:* less frequently they are from adventitious huds on leaves or other parts. We distinguish:—

A. The Leafy Bulh (Bulhus Foliosus).

1. The Tunicated Bulb (Bulhus Tunicatus), where many sheathing parts are closed round, or emhrace the axis pretty hroadly, as in *Hyacinthus orientalis.*

2. The Scaly Bulb (Bulhus Squamosus), where many sheathing parts, relatively slender and short, are seated on the axis, as in *Lilium candidum.*

B. The Solid Bulb (Bulhus Solidus), when the hulh is formed of one single living sheathing part.

b. Bulbels (Bulhilli). To plants not perennial hy means of a hulh (only Dicotyledonous?), the axillary buds are sometimes developed into hulb-like forms, in which the leaves are only developed as thickened sheathing parts, and the huds separate from the parent plant by the dying away of the supporting stem or stalk, and hecome independent plants, as with *Dentaria bulbifera.*

c. Tuhers (Tubera). On underground stems the axillary huds (of attenuated scaly leaves) are sometimes developed in such fashion that the entire axis of the hud hecomes thickened, fleshy, and of a knohhy form; the leaves are quite in rudimentary condition, or scarcely to he recognised, whilst the axillary and terminal huds remain capahle of development, and after the dying away of the stems of the parent plant form new stems, as in *Solanum tuberosum.*

d. Tuber-Buds, Tuhercles (Tubercula). Many plants form small tubers above the earth; seldom (if ever) indeed as axillary huds, hut frequently as adventitious huds, and especially on foliaceous organs, from which new independent plants develop as soon as they are separated from the parent plants: sometimes this is a specific peculiarity, as, for instance, the tuhers of the species of *Amorphophallus* and other *Aroideæ;* sometimes they arise in certain plants particularly readily in consequence of injuries, as, for instance, in the *Gesneriaceæ,* on the hroken surface, after cutting a leaf-nervo at the edge or the point of the leaf.

e. Pseudo-Tubers (Tuheridia). In somo plants a single, frequently an axillary, hud is transformed in a peculiar manner. The parenchyma of the axis of the bud, which is situated over the vascular surface, suddenly becomes exceedingly expanded in a solid and tuberculated form, by means of the sudden commencement of new formation of cells in isolated groups of cells; in the axillary hud this only occurs on one sido (as in our native *Orchideæ*), since, on the other side, the pressure of the stem prevents such distension. In *Aponogeton distachyon,* the thick fleshy cotyledon with the end of the root proves a corresponding ohstruction; hence here also the development of tho pseudo-tuber is only one-sided. In tho Dahlias, on the contrary, the tuhercular development is equal on hoth sides. The mass of cells enters between the hase of the cotyledon and the new adventitious roots, arising at a very early period almost immediately under the cotyledon, and which, through the formation of the pseudo-tuhers, hecome gradually removed far away from the ootyledou.

We may now add a few words on the function of the leaves. Works on hotany are full of speculations on the functions performed hy these organs. Without entering on this history we may say that the whole of the functions performed hy the leaves may he summed up in the word exhalation. The sap is hrought up from the soil hy the loss of water from the leaves. Hence this function of the leaves is necessary to the nutrition of the whole plant. It does not however follow as a consequence of this fact that the leaves send down nourishing materials into the stem and hranches.

It is also frequently stated that the leaves take up carhonic acid. Under certain circumstauces there can he no douht that leaves absorh as well as exhale, hut this is not their constant function. It depends on the condition of the atmosphere; when dry and the sun is shining the leaves exhale water, but if these conditions are not present, if the atmosphere is moist, and there is little or no heat and light, then the leaves absorh.

The following extract from Schleiden's 'Principles of Scientific Botany' supplies some of the data on which recent physiologists hase their view of the leaf heing simply an organ of exhalation.

"From those parts of plants which are exposed to an atmosphere which is not already perfectly saturated with moisture, a continual evaporation of water goes on. The process is purely physical, and, according to accurate investigations, it appears to proceed uninterruptedly, according to the dryness and motion of the atmosphere, with the temperature, and the amount of surface exposed to evaporation. It is highly prohahle that the epidermis permits of no passage to the evaporating water, hut that, the evaporation occurring in the neighhouring intercellular spaces, it escapes through the stomates when they are not closed by too strong evaporation and consequent relaxation. From this circumstance the exhaled water is never quite pure, hut it contains always a small admixture of vegetable suhstances which cannot he accurately analysed.

"Besides this evaporation of water, we sometimes find in a very damp atmosphere, and especially in the case of plants that have already exhaled very much, a taking up of moisture, especially through their green parts; hut our observations on this fact have heen too little accurate and purposeless to admit of a precise explanation of the process.

"The study of vegetable exhalation in general requires a repetition and improvement of the experiments made upon it. We need a set of experiments which should show, with the greatest exactitude, the difference hetween the quantity of water absorhed and exhaled, from which we might decide the quantity used for the nourishment of the plant. If the amount of oxygen exhaled with the water was also obtained, we should prohahly he ahle to arrive at conclusions respecting the nature of the chemical processes carried on within the plant. We have yet to ascertain the relation of the exhalation of the water to its absorption. The fact of its ahsorption (hy other means than the root) has heen estahlished hy Hales, hut we are still quite in the dark as to the manner. An accurate knowledge of these relations is so much the more to be desired, as the evaporation and ahsorption of water with the tension of the vapour must exert an influence upon the ahsorption or exhalation of the several kinds of gases. Yet in the experiments made upon the so-called respiration of plants, this has heen lost sight of.

"We know nothing of the precise types through which exhalation is effected. To myself it appears improhahle that the living epidermis should be permeable to water and the vapour of water, except through the stomates.

"It is an estahlished fact, that all evaporating water carries with it some portion of the matter which it held in solution. This is seen in the vapour of the ocean. It is prohahle that no water exhaled from plants is ahsolutely pure. But no accurate analyses havo heen made on this point.

"The natural consequence of this exhalation of water from the green parts of plants which are exposed to the air, is the continual concentration of the juices in the cells which lie next the evaporating surfaces. By this the endosmose of the cells which do not exhale undergoes a change, of which we shall have to speak hereafter.

"The information which we possess respecting the exhalation of plants is chiefly found in the experiments of Hales, Guettard, Seunehier, Schübler, and Neuffer.

"The strange tendency always to attrihute to vitality something different from the physical powers, has introduced into the doctrine of the transpiration of plants a distinction hetween evaporation and exhalation; the first heing supposed to take place in dead plants and the last in living ones. I can find no distinction in this case in the facts, hut merely in tho words.

"I will here add some facts upon the quantity of water exhaled hy plants.

"According to Hales, a sunflower evaporated daily 1·25 lhs. of water: now let us allow to each of these plants 4 □′ space of soil; then upon the old Hessian acre there would stand 10,000 plants, which in 120 days would exhale 1,500,000 lbs. of water.

"A cabhage exhaled in twelve hours of the day 1 lb. 6 oz. of water;

now if, according to Block, each plant occupies 5 □′ of soil, and if we reckon an inferior expenditure for the night, yet the plants on an acre would exhale 1,200,000 lbs. of water in 120 days.

"A dwarf pear-tree, according to Hales, exhaled in 10 hours of the day 15 lbs. of water. Allowing for each such tree 20 □′ of soil, the trees of an acre would exhale 3,600,000 lbs. of water, and probably another third of the quantity might be added for the grass between the trees, which would make for the acre almost 5,000,000 lbs. of water.

"An acre of 40,000 square feet, planted with hops, exhaled in 120 days 4,250,000 lbs. of water through the hops alone.

"A square foot of soil covered with *Poa annua* exhaled, according to Schübler, daily, on an average, during the summer, 33·12 cubic inches of water: thus an acre of meadow-land would exhale about 6,000,000 lbs."

The subject of the food of plants and the general processes of nutrition in the vegetable kingdom is described under the article SAP.

LECANORA. [LICHENS.]

LECYTHIDA'CEÆ, *Lecythis*, an important but small natural order of Plants with singular fruits, and very large fleshy flowers, inhabiting the woods of South America. They are regarded by De Candolle as a section of *Myrtaceæ*, from which they differ in their leaves being alternate, and not dotted, the stamens monadelphous, and extended on one side, in an unusual manner, into a broad lobe, which covers over the centre of the flower like a hood. They are natives of the hottest parts of South America, especially of Guyana.

Among the plants belonging to this order are the following, which deserve particular notice :—

Lecythis ollaria, a tree inhabiting the forests of Cumana and Brazil, with a hard woody fruit as large as a child's head, and opening by a lid like that of a jar or urn. It contains numerous large seeds, which are eatable.

L. Zapucaje, a large Guyana tree, with alternate oval leaves 12 inches long, and racemes of large fleshy red and white flowers. The fruit is hard, woody, urn-shaped, and about 4 inches broad by 6 inches high; it contains numerous seeds as large as almonds, and quito as agreeable when fresh. They are sometimes seen in the fruiterers' shops in London, where they are called Sapucaya Nuts.

Bertholletia excelsa, already described. [BERTHOLLETIA.]

Couroupita Guianensis, or Cannon-Ball Tree. This plant takes its name from its large heavy woody fruit, which, according to Aublet, is about the size of a 36-pound shot, and although urn-shaped like the others, does not open by its lid, but is broken by its fall, or lies on the ground till it rots, before the seeds can extricate themselves. The flowers are very large and handsome, deep rose-colour and white; the tree is of great size, with a trunk often more than 2 feet in diameter. The shells of the fruit are used as drinking vessels.

Flower of Cannon-Ball Tree (*Couroupita Guianensis*).

Fruit of Cannon-Ball Tree (*Couroupita Guianensis*).

LEDERERITE. [CHABAZITE.]

LEDERITE. [TITANIUM.]

LEDUM, a genus of Plants belonging to the natural order *Ericaceæ*. It has a minute 4-toothed calyx, 5 spreading petals, from 5 to 10 stamens, anthers opening by two pores at the apex. The capsules are subovate, 5-celled, 5-valved, stalked, and dehiscent at the base. The seeds are furnished with a membranous wing at each extremity.

L. latifolium is a small evergreen shrub, with an irregularly branched stem. The branches and under surface of the leaves are woolly; the calyx is very minute; the corolla white, with obovate obtuse petals. It has been commended as a stomachic; but an infusion of the leaves in beer renders it unusually heady, and produces headache, nausea, and even delirium. Pallas however says that they have been used with advantage in tertian agues, dysentery, and diarrhœa. They have an aromatic bitter flavour. This species is a native of the swamps around Hudson's Bay, Labrador, Greenland, and various parts of the United States.

L. palustre has linear leaves, with revolute margins, clothed with rusty tomentum beneath; it has 10 stamens, longer than the corolla. It is a native of North America, in the swamps of Canada and New York, also the North of Europe, Denmark, Silesia, &c. *L. palustre* has somewhat similar properties to those ascribed to the former species. In Germany a kind of beer is made from its leaves, and it has also been recommended as a febrifuge. This species was formerly admitted into the catalogue of British plants; but Mr. Babington considers that it has no claim to appear there, and has omitted it accordingly.

L. Canadense has ovate petiolate leaves, white beneath; the flowers disposed in terminal large umbellate corymbs of a white hue. It is a native of the swamps of Canada. A peat soil or a very sandy loam answers best for the cultivation of the species of Ledum, and they are readily propagated by layers or by seeds. The seeds should be sown, and the seedlings afterwards managed in the same manner as the *Rhododendron*.

(Don, *Dichlamydeous Plants*; Burnett, *Outlines*; Babington, *Manual of British Botany*.)

LEECH. [ANNELIDA.]

LEEK. [ALLIUM.]

LEERSIA, a genus of Grasses belonging to the tribe *Oryzeæ*. It has 2 paleæ compressed, keeled, and awnless, the lower one much broader; stigmas protruding from the side of the florets; nut inclosed in the paleæ.

L. oryzoides has a patent panicle with wavy branches, spikelets triandrous, half oval, ciliated on the back. It is a creeping plant with a stem one to two feet high, never procumbent, and rooting at the joints. The leaves are broad and rough-edged, the uppermost horizontal at the flowering season; panicle rarely, if ever, protruded in this country, mostly inclosed in the sheath of the uppermost leaf. It is found in marsh ditches in Sussex and Hampshire.

LEGUMINOSÆ, or FABACEÆ, a very extensive natural order of Plants, consisting of herbaceous plants, shrubs, or vast trees, extremely variable in appearance. The leaves are alternate, most commonly compound, occasionally marked with transparent dots; petiole tumid at the base; stipules 2 at the base of the petiole, and 2 at the base of each leaflet; pedicels usually articulated, with 2 bractlets under the flower; calyx 5-parted, toothed, or cleft, inferior, with the odd segment anterior, the segments often unequal and variously combined; petals 5, or by abortion 4, 3, 2, 1, or none, inserted into the base of the calyx, either papilionaceous or regularly spreading; the odd petal, if any, posterior; stamens definite or indefinite, perigynous, rarely hypogynous, either distinct, or monadelphous, or diadelphous, very rarely triadelphous; anthers versatile; pistil simple, superior, 1-celled, 1- or many-seeded, commonly consisting of a single carpel, but occasionally of 2 or even of 5 carpels; style simple, proceeding from the upper margin; stigma simple; fruit either a legume or a drupe; seeds attached to the upper suture, solitary or several, occasionally with an aril; embryo with or without albumen, either straight, or with the radicle bent upon the cotyledons; cotyledons either remaining underground in germination or elevated above the ground, and becoming green like leaves, always very large in proportion to the radicle, and very often amygdaloid.

The most common feature of Leguminous Plants is to have what are called papilionaceous flowers, and when these exist no difficulty is experienced in recognising them, for papilionaceous flowers are found nowhere else. Another character is to have a leguminous fruit: and by one of these two characters all the plants of the order are known. It is remarkable however that one or other of these distinctions disappears in a great many cases. *Cæsalpinieæ* have an irregular flower with spreading petals and stamens adhering to the calyx; others have no petals at all, or some number less than five, while *Mimoseæ* have perfectly regular flowers and indefinite hypogynous stamens. *Detarium*, *Dipteryx*, and others, instead of a legume have a fruit not distinguishable from a drupe. This last circumstance is easily to be understood if we bear in mind that a legume and a drupe differ more in name than reality, the latter being formed on precisely the same plan as the former, but with this modification, that its pericarp is thickened, more or less fleshy on the outside and stony on the inside, 1-seeded, and indehiscent. Hence some of the regular flowered genera with distinct stamens may be said to be rosaceous in flower and leguminous in fruit. Simple therefore as the diagnosis of this order usually is, Brown is perfectly correct in asserting that, until he indicated the difference of the position of the odd lobe of the calyx in Leguminous Plants and Roseworts, no positive character had been discovered to distinguish the one order from the other. Very few double flowers are known in this order; those of *Spartium junceum* and *Ulex Europæa* are the most remarkable. Two ovaries are common in *Wistaria Sinensis*, and the same phenomenon is to be seen, according to De Candolle, in *Gleditschia*. On account of these and other circumstances, De Candolle assumes the carpel of Leguminous Plants to be solitary by abortion, and that a whorl of 5 is that which is necessary to complete the symmetry of the flowers.

In consequence of the highly irritable nature of the leaves of many of the plants of this order, and of the tendency to irritability discoverable in them all, some botanists have placed them at the extremity of their system, in contact with the limits of the animal kingdom. For observations upon the nature of this irritability see Dutrochet, 'Sur la Motilité,' Paris 1824, in which the author endeavours to show that the motion is the effect of galvanic agency; and the same writer's 'Nouvelles Recherches sur l'Exosmose,' in which he alters the explanation of the manner in which galvanism produces the motion, adhering however to his opinion of that subtle principle being the real agent. It is more probable however that these movements are connected with the inherent irritability of the protein common to all plants.

In many respects this order is one of the most important which the botanist can study; more especially as it serves to show how little real importance ought to be attached to dehiscence of fruit in determining the limits of natural orders. What may be called the normal fruit of Leguminous Plants is a legume, that is to say, a dry simple carpel, with a suture running along both its margins, so that at maturity it separates through the line of each suture into two valves; but every conceivable degree of deviation from this type occurs. *Arachis* and many more are indehiscent; in *Carmichælia* the valves separate from the suture, which remains entire, like the replum of *Cruciferæ*; in all Lomentaceous genera, such as *Ornithopus*, the valves are indehiscent in the line of the suture, but separate transversely; in *Entada* a combination of the peculiarities of *Carmichælia* and *Lomentaceæ* occurs; in *Hæmatoxylon* the valves adhere by the suture and split along the axis; and finally, *Detariun*, *Dipteryx*, and others, are true drupes, in no respect different from those of *Amygdaleæ*.

The geographical distribution of this order has been considered with great care by De Candolle, from whom the substance of what follows is borrowed. One of the first things that strikes the observer is, that if a number of genera of Leguminous Plants have as extensive a range as those of other orders there is a considerable number of which the geographical limits are clearly defined. Thus, the genera of Australia are in most cases unknown beyond that vast island; the same may be said of north and South America, and the Cape of Good Hope; and there are 14 or 15 genera unknown beyond the limits of Europe and the neighbouring borders of Asia and Africa. About 92 genera out of 280 are what are called 'sporadic,' or dispersed over different and widely-separated regions, such as *Tephrosia*, *Acacia*, *Glycine*, and *Sophora*. The species are found more or less in every part of the known world, with the exception of the islands of Tristan d'Acugna and St. Helena, neither of which do they inhabit; but they are distributed in extremely unequal proportions. In general they diminish sensibly in approaching the pole. This will be apparent from the following table :—

Europe, with the exception of the Mediterranean	184
Siberia	129
United States	183
China, Japan, and Cochin China	77
Levant	250
Basin of the Mediterranean	463
Canaries	21
Arabia and Egypt	87
Mexico	152
West Indies	221
East Indies	452
Equinoctial America	605
Equinoctial Africa	130
Australia	229
Isles of Southern Africa	42
South America beyond the tropics	29
Cape of Good Hope	353
South Sea Islands	13

This distribution, if condensed, will give the following results :—

Equinoctial Zone	1602
Beyond the Tropics to the North	1312
Beyond the Tropics to the South	524

Since the time this calculation was made the order has been prodigiously enlarged and a very considerable number of species has been added to those from the tropical parts of America, Australia, and the Cape of Good Hope. Nevertheless the calculation, with these exceptions, is instructive as a general sketch of the statistics of this branch of Geographical Botany. The Leguminous order is not only among the most extensive that are known, but also one of the most important to man, whether we consider the beauty of the numerous species, which are among the gayest-coloured and most graceful plants of every region, or their applicability to a thousand useful purposes. The properties of the order are very various: some are nutritious, others tonic and astringent, others purgative, and some poisonous. The plants supply timber, fibres, gum, dyes, and various other economical articles. There is however to be borne in mind, in regarding the qualities of this order in a general point of view, that upon the whole it must be considered poisonous, and that those species which are used for food by man and animals are exceptions to the general rule.

The species amount to some thousands, and are conveniently divided into three sub-orders, *Papilionaceæ*, *Cæsalpinieæ*, and *Mimoseæ*.

Papilionaceæ, Pulse section, have what are called papilionaceous flowers, that is, of the five petals one is large, broad, spread open, and called the standard; two others are parallel, convex, or slightly spreading, and called wings; and the two remaining ones are also parallel, but united by their anterior edge so as to form a body not unlike the keel of a boat, after which it is named. In all these plants the stamens are definite in number, and inserted with tolerable distinctness into the calyx; but while many are diadelphous, others are monadelphous or decandrous; the fruit is either a legume, a lomentum, or a drupe, or some form intermediate between the first and last. It is here that the great mass of the order occurs, especially in the colder parts of the world. Peas, beans, clover, saintfoin, lucern, liquorice, indigo, medicks, and trefoils, lupines, and numerous other common European genera, belong to *Papilionaceæ*.

Indigofera Anil.

1, Standard; 2, wings; 3, keel of the flower; 4, calyx; 5, diadelphous stamens; 6, legume.

Many species are tonics and astringents, and others yield a kind of gum, and among those that yield dyes is the *Baptisea tinctoria*, the Wild Indigo of America.

In a very large number of species narcotic properties have been discovered.

The descriptions of the useful genera will be found under their respective heads, such as ASTRAGALUS, BUTEA, COLUTEA, CYTISUS, INDIGOFERA, ERVUM, GLYCYRRHIZA, GEOFFROYA, MAVIA, CROTALARIA, MELILOTUS, TRIPTOLOMEA, &c., &c.

The sub-order *Cæsalpinieæ* have the petals spread out, and nearly equal-sized, with distinct unequal stamens; they may be considered the regular form of the order, while *Papilionaceæ* are the irregular form. Their fruit is usually a legume, but not always. The *Cassia*, which furnishes the senna-leaves of the shops, is the most interesting among them; to this sub-order also belong the Tamarind and Algaroba fruits, the trees yielding logwood, Brazil-wood, Sappan-wood, &c., and *Hymenæa*, from which gum anime is procured.

Purgative properties are the great characteristic of this sub-order. Senna is their most remarkable product. Some of them yield dyes. The Locust-Trees of North America belong to this order, and are celebrated for their gigantic stature. The principal species are described under CASSIA, CERATONIA, COPAIFERA, HÆMATOXYLON, HYMENÆA, ROBINIA, TAMARINDUS, &c.

Cassia elongata.

The sub-order *Mimoseæ* have small regular flowers collected into heads, numerous often indefinite stamens, usually hypogynous, and a legume. They are unknown in cold countries in a wild state, but in the hotter parts of the world they form a strikingly beautiful portion of the vegetation. From the much greater length of their stamens, their petals, and the clustered compact arrangement of their flowers, the latter often resemble tassels of silk, of the most vivid colours, intermingled among the leaves. Their bark is usually astringent, with a frequent intermixture of gum. The gums Arabic, Senegal, Sassa, and others, are produced by different species; catechu is the extract of the astringent bark of *Acacia Catechu*, and rose-wood is said to be the timber of some *Mimosa* inhabiting the interior of Brazil. One of the most striking phenomena among the plants of this order is the excessive irritability observable in the leaves of certain species of *Mimosæ*, such as *M. pudica*, *M. sensitiva*, &c., which are hence called Sensitive Plants. It is however a special peculiarity, and not one of general occurrence; unless the folding up at night of the leaves of the whole sub-order be regarded as an instance of the same irritable quality in a low degree.

The species of this order are described under ACACIA, ENTADA, MIMOSA, &c.

Mimosa pudica.

1, a flower, much magnified; 2, a legume.

In 1845 Mr. Bentham made the following estimate of the numbers of genera and species belonging to the order *Leguminosæ*.

	Genera.	Species.
Papilionaceæ:—		
Podalyrieæ	33	350
Loteæ	133	3000
Hedysareæ	52	500
Phaseoleæ	70	650
Dalbergieæ	41	250
Sophoreæ	21	50
Cæsalpinieæ	88	700
Mimoseæ	29	1000
	467	6500

LEGUMINOSITES, a genus of Fossil Fruits, from the Isle of Sheppey. (Bowerbank.)

LEHUNTITE, a Mineral consisting of silicate of alumina and soda. It occurs massive. Its colour is flesh-red, the mass when broken exhibiting two parallel white lines near the centre. Under the microscope it appears to be composed of minute scales. Hardness 3·75. Translucent on the edges. Specific gravity 1·953. Before the blowpipe it fuses into a white enamel. It is found at Glenarm, county of Antrim, in an amygdaloidal rock. Analysis by Dr. R. D. Thomson:—

Silica	47·33	
Alumina	24·00	
Soda	13·20	
Lime	1·52	
Water	13·60	
		99·65

LEIOCEPHALUS. [IGUANIDÆ.]

LEIODERA. [IGUANIDÆ.]

LEIODON. [SAURIA.]

LEIOLÆMUS. [IGUANIDÆ.]

LEIOLEPIS. [AGAMA; DRACONINA.]

LEIOSAURUS. [IGUANIDÆ.]

LEI'OTHRIX, a genus of Birds established by Mr. Swainson, with the following generic characters:—Bill much compressed; culmen gradually curved; nostrils large, membranaceous; tail moderate, deeply forked.

L. furcatus ('Pl. Col.,' 287, f. 1.: India). The genus belongs to Mr. Swainson's sub-family *Leiotrichanæ* (Silky Chatterers?), being the first of his family *Ampelidæ* (Fruit-Eaters, or Chatterers). [LEIOTRICHANÆ.]

LEIOTRICHA'NÆ (Swainson), a sub-family of the *Ampelidæ*, a family of Birds. It is thus defined by Mr. Swainson:—Legs large, robust, syndactyle; hind toe longer than the outer; wings short and rounded; bill strong; the gonys ascending.

The only other genus besides *Leiothrix* placed in this sub-family by Mr. Swainson is *Pteruthius* (Sw.), to which that author gives the following generic characters:—Bill short, compressed, thick; the tip shrike-like, hooked; culmen arched; gonys ascending; nostrils basal; the aperture round; gape wide; rictus slightly bristled; wings very short, rounded; tail short, broad, rounded; the tips obtuse; tarsi smooth, pale. *P. erythropterus*, Gould's 'Century of Himalaya Birds,' pl. 11 (*Lanius erythropterus*), India, is an example.

LEMMING. [MURIDÆ.]

LEMMUS. [MURIDÆ.]

LEMNA, a genus of Plants belonging to the natural order *Araceæ*, and the sub-order *Lemneæ*. It has a 2-flowered membraneous urceolate spathe; the male flowers consist of 2 stamens; the fruit is reticular and indehiscent; the fronds are without distinction of stems or leaves; the flowers appear just below the margiu of the frond. Several species have been described. They are all inhabitants of stagnant waters, and are known familiarly by the name of Duck-Weeds. The following are the British species:—*L. trisulca*, with lanceolate fronds; *L. minor*, with compressed obovate fronds; *L. polyrhiza*, with roundish-obovate compressed fronds; *L. gibba*, with obovate hemispherical fronds. (Babington, *Manual of British Botany*.)

LEMNIAN EARTH, occurs in the Isle of Lemnos, whence its name. It is found massive. Fracture earthy. Dull. Has a meagre feel. Soft. Opaque. Colour grayish or yellowish-white. Falls to pieces when put into water. It was formerly used in medicine under the name of *Terra Sigillata*. According to Klaproth it consists of—

Silica	66·0
Alumina	14·5
Oxide of Iron	6·0
Soda	3·5
Water	8·5
Traces of Lime, Magnesia, and Loss	1·5
	100·0

LEMON. [CITRUS.]

LEMUR. [LEMURIDÆ.]

LEMU'RIDÆ, a family of Animals belonging to the *Quadrumana*. Linnæus, in his 'Characteres Mammalium,' defines *Lemur*, the third genus of his *Primates*, thus—"Dentes primores inferiores 6." In the body of the work ('Syst. Nat.') he characterises the genus as follows:—Upper incisors (primores) 4; the intermediate ones remote; lower incisors 6, longer, prominent (porrecti), compressed, parallel, and approximate. Canines (laniarii) solitary, approximate. Molars numerous (plures), sublobate, the anterior ones longer and more acute. The genus consists of *Lemur tardigradus*, *L. Mongoz*, *L. Macaco*, *L. Catta*, and *L. volans*. To these species Gmelin added *L. Indri*, *L. Potto*, *L. murinus*, *L. bicolor*, aud *L. laniger*.

Cuvier remarks that the Makis (*Lemur*, Linn.) comprehend, according to Linnæus, all the *Quadrumana* which have, in the one or the other jaw, incisors which differ in number from four, or at least otherwise directed than in the Monkeys (Singes). This negative character, Cuvier observes, could not fail of embracing considerably different beings, and did not even collect all those which ought to be together. He goes on to notice that M. Geoffroy has established in this genus many divisions much better characterised. These animals have all the four thumbs well developed and opposable, and the first hind finger or toe armed with a pointed and raised nail or claw, whilst all the other nails are flat. Their fur is woolly; their teeth begin to exhibit pointed tubercles fitting into each other (engrenant les uns dans les autres), as in the *Insectivora*. The following groups are adopted by Cuvier:—

1. The Makis, or Macancos, properly so called, *Lemur*.
2. The Indris, *Lichanotus*, Illiger.
3. The Loris group (Slow Lemurs, *Stenops*, Illiger).
4. The Galagos, *Otolicnus*, Illiger.
5. The Tarsiers. *Tarsius*.

Dr. J. E. Gray arranges the *Lemuridæ* as the third family (Quadrupedoid) of the order *Primates* (Linn.), and he thus characterises the family:—

Grinders 6—6 above, 5—5 below; nostrils terminal; extremities free; first finger of the hind feet armed with recurved claws.

† Head long; grinders blunt.

1. *Lemurina:* genus *Lemur*, Linn. 2. *Lichanotina:* genera *Indris*, Lacép.; *Lichanotis* (*Lichanotus*), Ill.

†† Head round.

3. *Loridina:* genera *Loris*, Geoff.; *Nyaticebus* (*Nycticebus*), Geoff. 4. *Galagonina:* genera *Otolicnus* (*Otolicnus*), Ill.; *Galago*, Adams; *Cheirogallus* (*Cheirogaleus*), Geoff. 5. *Tarsina:* genus *Tarsius*. 6. *Cheiromina:* genus *Cheiromys*, Cuv.

Mr. Swainson makes the *Lemuridæ* his third family of *Quadrumana*, with the following characters:—

Form approaching that of quadrupeds; cutting teeth, $\frac{4}{4}$ or $\frac{4}{6}$; canine, $\frac{1-1}{1-1}$; grinders, $\frac{5-5}{5-5}$ or $\frac{5-5}{4-4}$, obtusely tubercular; head long, triangular; nostrils terminal; ears generally concealed, very small.

The following genera are comprised by the author last mentioned under this family:—*Lemur*, Linn.; *Indris*, Lacép.; *Lichanotus*, Ill.; *Scartes*, Sw.; *Stenops*, Ill.; *Otolicnus*, Geoff.; *Cephalopachus* (*Tarsius Bancanus*, Horsf.); *Tarsius*, Storr; *Aötes*, Humboldt; *Galeopithecus*, Pallas; *Cheirogaleus*, Geoff.

The author of 'The Natural History of Monkeys, Lemurs, and Opossums' ('Library of Entertaining Knowledge,' vol. xlii.) divides the Mammals with opposable thumbs into three sections, like Storr; and the author's arrangement is almost the same, differing only in the removal of the *Simiadæ* or *Prosimia*, as Storr calls them, from the second to the third section in consequence of observations made since Storr's time. The author observes that the coincidence is the more remarkable inasmuch as the arrangement of Storr was unknown to him till long after the publication of his own views. [CHEIROPODA.] The author makes his second section of Cheiropeds consist of the *Quadrumana*, or those which have opposable thumbs on both fore and hind hands; and he divides the section into two sub-divisions, the first consisting of the *Simiæ* (with anthropoid teeth), and the second of the *Lemuridæ* (with abnormal teeth). The genera arranged by him under this last sub-division are *Lichanotus*, *Propithecus*, *Lemur*, *Otolicnus*, *Cheirogaleus*, *Stenops*, *Tarsius*, *Cheiromys* and *Galeopithecus*.

Dr. J. E. Gray's sub-family *Lemurina* contains the true Lemurs, or Macaucos.

The genus *Lemur*, properly so called, is thus characterised:—

$$\text{Incisors, } \frac{4}{6}; \text{ canines, } \frac{1-1}{1-1}; \text{ molars, } \frac{5-5}{4-4} = 32.$$

Teeth of *Lemur*, more than one-third larger than nature. F. Cuvier.

M. Geoffroy maintains that the number of incisors in both jaws is equal, coinciding with the number in the Monkeys, the two outermost of the six, which are larger than the rest, being, according to him, the true canines; while the teeth commonly called canines are, in his opinion, only the first series of molars. "This conjecture," says Mr. Bennett, "unquestionably derives considerable strength from the fact that when the animal closes its mouth the supposed canines of the lower jaw pass behind those of the upper, a position directly contrary to that which they uniformly assume in every other animal that is furnished with that kind of teeth."

The muzzle is very pointed; the tail very long, the fur woolly and soft, and there are two pectoral mammæ. The structure of the hands and nails is mentioned above. (Cuvier's description of the Makis.)

"The whole of the genus thus characterised," writes Mr. Bennett in his 'Tower Menagerie,' "are natives of Madagascar, and of two or three of the smaller islands in its immediate vicinity. They appear to occupy in that remarkable and very imperfectly-known country the place of the Monkeys, none of which have yet been detected within its precincts. They are said to live in numerous troops upon the trees, and to feed upon fruit and insects; but their habits in a state of nature have not yet been observed with sufficient accuracy to enable us to form any clear idea of their mode of existence. In captivity they are particularly tame and good-tempered, fond of being noticed, delighting in motion, and leaping with surprising agility. They are however in some degree nocturnal, and when undisturbed pass a considerable portion of the day in sleep. If alone they roll themselves up in the form of a ball, and wind their long tail in a very curious manner round their body, apparently for the purpose of keeping themselves warm, for they are naturally chilly, and delight in basking in the rays of the sun, or in keeping as close as possible to the fire. When two of them are confined together they interlace their limbs and tails after a singular fashion, and placing their heads in such a position as that each may, if disturbed, see what is going on behind the other's back, fall comfortably asleep."

There are several species, and all that we have seen, some of them very beautiful, and exhibited in the Zoological Society's Collection at the Regent's Park, have been very mild.

L. albifrons, the White-Fronted Lemur, may be taken as an example.

The fur is ruddy or bronzed-gray above, whitish below; male with the front white; female with the same part of a deep gray and a black longitudinal line on the top of the head. M. Lesson remarks that the female is the Maki d'Anjouan of M. Geoffroy St.-Hilaire, and the Maki aux Pieds Fauves of Brisson.

White-Fronted Lemur (*Lemur albifrons*).

The bounding elasticity of this species, when familiar and quite at its ease, is wonderful. It pitches, after a leap of many yards, so lightly as hardly to attract the notice of the ear when it alights. If it take a leap from a table to the back of a distant chair, or even to the upper angle of an open door, it never misses its hold. Under the points of the fingers are elastic cushions, which no doubt assist it in performing these feats. It is a very affectionate animal, and a most amusing companion. Our limits will not permit us to indulge in an account of one which we kept, and which was suffered to go at large. When tired with playing about in the evening, its favourite perch was on the instep of the uppermost leg of his master, as he sat cross-legged before the fire. Having obtained leave, he used to take his seat, wrap his boa-like tail round his shoulders and back, and enjoy his nap.

In the catalogue of the 'Specimens of Mammalia,' in the collection of the British Museum, the following species of *Lemuridæ* are found:—

L. Macaco, the Ruffed Lemur. A native of Madagascar.
L. Catta, the Ring-Tailed Macauco. Also a native of Madagascar.
L. ruber, the Red Lemur. From Madagascar.
L. albifrons, the species described above.
L. nigrifrons, the Black-Fronted Macauco. Madagascar.
L. coronatus, the Crowned Macauco. Madagascar.

All these species of *Lemur* were living in the gardens of the Zoological Society in Regent's Park in 1852. In addition to these the following species are given in the Society's list:—

L. albimanus, the White-Handed Lemur. Madagascar.
L. rubrifrons, the Red-Fronted Lemur. Madagascar.
L. Mongoz, Mongozheim. Madagascar.
L. Anjuanensis, Anjouan Lemur. Madagascar.
L. niger, Black Lemur. Madagascar.

Stenops is Illiger's name for a genus of *Prosimii*, his third family of his second order, *Pollicata*, of *Mammalia* including the genera *Loris* and *Nycticebus* of Geoffroy.

Mr. Bennett, in his 'Gardens and Menagerie of the Zoological Society,' observes that in an early memoir on the family to which the Slow-Paced Lemur belongs, M. Geoffroy St.-Hilaire divided it for the first time into those minor groups of which it was most obviously composed. But Mr. Bennett remarks that M. Geoffroy has since carried the principle of subdivision to a still greater extent by separating the Slow-Paced Lemur from the slender *Loris*, with which he had previously associated it, in order to form from it and some other doubtful species the genus *Nycticebus*. Mr. Bennett cannot perceive any sufficient grounds for thus disuniting two animals so intimately allied to each other, and differing in no more essential characters than the somewhat greater length of the nose and of the limbs in the one than in the other. For this reason Mr. Bennett prefers M. Geoffroy's older arrangement, and proceeds, in accordance therewith, to describe the Slow-Paced Lemur as a species of *Loris*, which he considers to be a well-marked and circumscribed natural genus, differing from the Lemurs of the same author in many highly important characters. Mr. Bennett adds, that it is to be regretted that M. Geoffroy should not have applied the latter name to the species to which it was originally given by Linnæus, and to which alone it is, in Mr. Bennett's opinion, in any degree applicable; the Madagascar animals at present comprehended under it not presenting, he observes, even one of those characters on which Linnæus himself states that his generic name is founded.

"In common with the latter group," says Mr. Bennett in continuation, "the genus *Loris* forms part of that division of the Quadrumanous order which is essentially distinguished by an unequal number or irregular disposition of the incisor teeth in the two jaws; terminal nostrils with sinuous openings; and a long subulate or sickle-shaped claw upon the fore-finger of the hinder hands, all the rest of the nails being flat and rounded like those of the greater part of the monkeys and of man. The *Loris* differs from the other genera of this family in having four incisors in the upper jaw, placed in pairs with a vacant space between, and six in the lower, directed obliquely forwards; canines of moderate size; twelve molars above and ten below; a short rounded head and little or no tail. Sometimes, it would appear, the lateral incisors of the upper jaw, which are always smaller than the others, are either entirely wanting or so minute as not to be easily seen. But M. Geoffroy was enabled to detect them in the identical specimen which Vosmaer had declared not to possess them: and it is by no means improbable that future investigators may ascertain their existence in the stuffed individuals sent from Java by M. Leschenhault, of which M. Geoffroy has made a new species, principally on account of the supposed absence of these teeth. In addition to these primary characters, the *Loris* are distinguished by large prominent eyes, placed in front of the head and at no great distance from each other; short ears, scarcely rising through the hair with which they are invested; a rough tongue; nostrils projecting beyond the mouth and surrounded by a naked muzzle; and thumbs widely separated from the fingers, both on the fore and hinder hands."

Cuvier states that the *Loris* have the teeth of the *Makis*, only that the points of the molars are sharper; a short muzzle (museau court d'un doguin); a slender body; no tail; great approximated eyes; and a rough tongue. Their nourishment, he says, consists of insects, small birds or quadrupeds; sometimes their progression is excessively slow, and their habits nocturnal. Sir Anthony Carlisle, he adds, found at the base of the arteries of the limbs the same division into small branches as exists in the true sloths. To this part of their organisation we shall presently allude more at large. Cuvier remarks that two species are known, both from the East Indies—Le Loris Paresseux, on Le Paresseux de Bengale (*Lemur tardigradus*, Linn.), and Le Loris Grêle (*L. gracilis*); the latter, he remarks, has the nose more raised by a projection of the intermaxillary bones, and upon this difference of the nose M. Geoffroy has made of the first-named species his genus *Nycticebus*, and of the second his genus *Loris*.

M. F. Cuvier assigns the following dentition (that of the Great Galago)—

$$\text{Incisors, } \frac{4}{6}\text{; canines, } \frac{2}{2}\text{; molars, } \frac{6-6}{5-5} = 36$$

—to the Small Galago, the Slender Loris, the Cingalese Loris, the Slow-Paced Loris or Lemur, and the Dwarf Lemur, with hardly more than very slight exceptions, which are only manifested in the incisors and false molars.

The following are the generic characters of *Loris* and *Nycticebus*, Geoffroy:—

Loris.—Four upper incisors; six lower incisors inclining forwards; head round, eyes very large, limbs very slender, no tail; four mammæ coming from two mammary glands only. The tibia longer than the femur; ears short and hairy.

$$\text{Incisors, } \frac{4}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{6-6}{5-5} = 36.$$

Species.—1. Loris Grêle, *Loris gracilis*, Geoff.; Le Loris, Buffon; Le Tardigradus, Seba. 2. Loris de Ceylon; *Loris Ceylonicus*, Fisch.

The locality assigned to both these species is Ceylon; but, according to M. Lesson, neither Geoffroy, Desmarest, nor F. Cuvier admit the second species, regarding it as a simple variety differing hardly at all from *Loris gracilis*.

Nycticebus.—Head round; muzzle short; eyes very large; ears short and hairy; a tail more or less long; extremities strong and robust.

$$\text{Incisors, } \frac{6}{2\text{ or }4}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{6-6}{5-5} = 34\text{ or }36.$$

The species are—*N. Bengalensis*; *N. Javanicus*; and *N. Ceylonicus*. All from the East Indies.

We here adopt Mr. Bennett's view of the subject, and take the Slender Loris and the Slow-Paced Loris, or Slow-Paced Lemur, both of which are confounded by Linnæus under the name of *Lemur tardigradus*, as examples of the genus *Loris*.

Loris gracilis, the Slender Loris, has the visage produced and dog-like; forehead high above the nose; ears large, thin, and rounded; body slender and weak; limbs very long and slender; thumb on each foot more distinct, and separate from the toes; on that and the three outmost toes are flat nails; on the interior toe of every foot a crooked claw; no tail; the hair on the body universally short and delicately soft; the colour on the upper part tawny, beneath whitish, space round the eyes dusky; on the head is a dark-shaped spot with the end pointing to the interval between the eyes. Length from the tip of the nose to the anus only eight inches.

Pennant, whose description we have given, states that notwithstanding the epithet (tardigradum) given in Seba, who has figured the animal (male and female) in the 35th plate of his first volume, the Slender Lemur is very active, ascending trees most nimbly, and having the actions of an ape. "If," says Pennant, "we credit Seba, the male climbs the trees and tastes the fruits before it presents them to its mate." Seba himself observes that the epithet 'tardigradum' is misapplied. Others say that it is a melancholy animal, silent and very slow, sleeping in the day and only awaking in the evening, and living on insects, fruits, and eggs. There is a living specimen in the gardens of the Zoological Society, Regent's Park, London.

Slender Loris (*Loris gracilis*).

L. tardigradus, the Slow-Paced Lemur.—The most accurate description known to us is that given by Mr. Bennett:—"The Slow-Paced Lemur," he says, "is an animal of small size, scarcely equal to that of a cat. The largest individual yet noticed appears to be that seen by Pennant, who states its length at no less than 16 inches from the nose to the extremity of its back. Its proportions are short and thick-set; and the apparent clumsiness of its form is much increased by the manner in which it usually contracts itself into a kind of ball. Its head is broad, flat, and rounded, with a slightly projecting and pointed muzzle, in which the nostrils are perforated laterally. Its eyes are large and perfectly orbicular, and furnished with transverse pupils capable of being entirely closed during the day, and of being very largely dilated at night; their inner canthus is situated so low towards the nose that the motion of the eyelids appears to take place in a diagonal instead of a horizontal direction. The ears are short, round, widely open, but buried in the fur; and the tail is merely a rudiment of a few lines in length. The hinder limbs are considerably longer than the fore. The whole of the body, with the exception of the muzzle and hands, is thickly invested with long close woolly hair of a deep ashy gray with something of a brownish tinge. A deep brown or chestnut band passes along the middle line of the back, and is accompanied on either side by a faint grayish stripe, expanding on the back of the head into a still lighter patch. The dark middle stripe divides on the head into two branches, each of which is again subdivided, the posterior division passing transversely across the forehead and inclosing the ear, the anterior crossing the eye obliquely and extending to the angle of the mouth. Between the two, above the outer angle of the eye, is a large white spot. Each of the eyes is surrounded by a ring of dusky black, between which a narrow white line passes from the back part of the head to the tip of the nose, which, with the exception of the naked muzzle, is also white. The latter, together with the naked parts of the hands, is of a livid flesh-colour with a tinge of black. On the under surface the fur is of a lighter gray than above."

There are some parts of the organisation of this animal that require more particular notice.

Sir Anthony Carlisle injected the arterial system of a *Lemur tardigradus*, and upon tracing the course of the vessels, so as to make a dried preparation, which is now in the Museum of the Royal College of Surgeons in London, he found that an unusual appearance of distribution was exhibited by the large trunks of the subclavian and external iliac arteries. He shows that immediately after the subclavian has penetrated the axilla, it is divided into 23 equal-sized cylinders, which surround the principal trunk of the artery, here diminished in size to an inconsiderable vessel. These cylindrical arteries, he observes, accompany each other, and divide with the ulnar and radial branches, being distributed in their route upon the muscles, each of which has one of these cylinders. The other branches, for example the radial and ulnar, proceed like the arteries in general, dispersing themselves upon the skin, the membranes, joints, bones, &c., in an arborescent form. The iliac artery, he tells us, divides upon the margin of the pelvis into upwards of 20 equal-sized cylinders, surrounding the main trunk, as described in the axillary artery; these vessels are also finally distributed as in the upper extremity; the cylinders wholly upon the muscles, and the arborescent branches on all the other parts. The cylindrical arteries, he adds, do not divide into equal-sized cylinders, but are distributed as in the generality of animals.

Slow-Paced Lemur (*Loris* (*Nycticebus*) *tardigradus*).

Sir Anthony concludes by observing that it would be of some importance in physiology to ascertain whether the other slow-moving quadrupeds have any peculiar arrangement of the arteries of those limbs. This solitary fact, he remarks, is hardly sufficient for the foundation of any theoretical explanation of the slow movement of these muscles: if however it should be corroborated by similar circumstances in other animals, he thinks that a new light may be thrown upon muscular motion, by tracing a connection between the kind of action produced in a muscle, and the condition of its vascularity or supply of blood.

Mr. Baird, in his interesting paper in the 'Magazine of Nat. Hist.,' vol. i., 1829, remarks that all the known *Mammalia* close their eyelids in a direction upwards and downwards, and in general the upper eyelid is the one possessing the greatest degree of motion. He found however that in his Slow-Paced Lemur the eyelids were brought together in a diagonal direction, or outwards and inwards, which gave the animal at the moment of shutting its eyes a most peculiar look. It was the under or outer eyelid that had the greatest degree of motion, the upper or inner one being almost fixed; and he concludes that the orbicularis oculi must be very powerful. After the death of the animal, and when Mr. Baird had left this country on a second voyage to India, the eye was dissected by Dr. Knox, who found that the peculiar movement of the eyelids above described did not depend on any peculiar structure, but merely on the greater degree of strength of the orbicularis muscle.

Mr. Baird also observed another peculiarity in the species. "Beneath the tongue proper," says he, "if I may so call it, which is somewhat like that of the cat, though not rough, is another tongue, white-coloured, narrow, and very sharp-pointed, which he projects along with the other one when he eats or drinks, though he has the power of retaining it within his mouth at pleasure." Mr. Baird however had not been able to see any particular purpose to which he applied it; but he saw him use this double tongue when eating flies, of which he was exceedingly fond, snapping them up most eagerly when presented to him, and catching them himself when they were reposing in the evening upon the walls of the room.

Little or nothing certain appears to be known of the habits of the Slow Lemur of Bengal in a state of nature, except as they may be inferred from those which it exhibits in captivity. In this latter state many good observers have narrowly watched it, and have recorded their observations.

Vosmaer received one in June 1768, and kept it in his chamber. It slept all day till the evening, not waking (it being summer) till half-past eight. It was shut up in an oblong cage, secured with iron bars, and constantly slept sitting on its hinder parts close to the bars, with its head brought forwards between its fore-feet, which were bent against its belly. In this attitude it held on strongly to the wires with its hind feet, and often by one of the anterior feet as well, which induced Vosmaer to think that the animal ordinarily slept in trees attached to the branches. When awakened it moved very slowly, and always the same from the commencement to the end, dragging itself from bar to bar, grasping one above with its fore foot or rather hand, and not quitting its hold till it had slowly but very powerfully seized another with one of its anterior feet or hands. The same slowness marked its creeping on the ground, along which it dragged one foot after the other, as if it had been paralytic. In this mode of progression it raised its body but very little, so little, that as it dragged itself forward the belly was frequently not more than the breadth of a finger from the ground. It was vain to attempt to drive it by putting a stick through the bars; for it would not quit its hold, and if pushed too roughly, its only defence was biting the stick. As the evening approached it awaked by degrees, like one whose sleep is broken after long watching. Its first care was to eat, for the day had been dedicated to repose. After its repast, which it dispatched with comparative celerity, the remains of its former meal were evacuated. The fæces were in small pellets like sheep's dung, and the urine had a strong disagreeable odour. The sea-captain who brought it over stated that it fed on rice boiled very thick, and that it had never been seen to drink.

Vosmaer, impressed with the belief that his animal would not refuse a different sort of food, gave it a leafy lime-tree sprig: this it rejected. Fruits, such as pears and cherries, were more to its taste. It willingly ate dry bread and biscuit; but if dipped in water would touch neither. When offered water it smelt it, but drank not. Eggs were a favourite diet. "Il aimoit à la fureur les œufs," are the words of Vosmaer, who, concluding from its appetite for eggs that it would eat birds, gave it a live sparrow, which it instantly killed with a bite, and ate the whole very greedily. He gave it a live cockchafer, to try whether it would eat insects: it took the offering in its paw, and devoured it completely. Vosmaer afterwards gave it a chaffinch (pinçon), which it ate with much relish, and afterwards slept for the remainder of the day. He often saw it still awake at two hours past midnight; but from half-past six in the morning its sleep was so sound that its cage might be cleaned without disturbance to its repose. If forcibly awaked during the day in order to teize it, it was vexed and bit the stick; but with a very slow motion, repeating the cry 'ai, ai, ai,' drawing out the ai each time into a plaintive, languid, and trembling note, in the same manner as is reported of the American Sloths. When it was thus harassed for a long time, and thoroughly roused, it crawled two or three times round its cage, and then slept again.

The specimen observed by Sir William Jones was a male, as Vosmaer's appears to have been; and Sir William thus gracefully describes its habits:—"In his manners he was for the most part gentle, except in the cold season, when his temper seemed wholly changed; and his creator, who made him so sensible of cold, to which he must often have been exposed even in his native forests, gave him, probably for that reason, his thick fur, which we rarely see on animals in these tropical climates: to me, who not only constantly fed him, but bathed him twice a week in water accommodated to the seasons, and whom he clearly distinguished from others, he was at all times grateful; but when I disturbed him in winter, he was usually indignant, and seemed to reproach me with the uneasiness which he felt, though no possible precautions had been omitted to keep him in a proper degree of warmth. At all times he was pleased with being stroked on the head and throat, and frequently suffered me to touch his extremely sharp teeth; but at all times his temper was quick; and when he was unseasonably disturbed, he expressed a little resentment by an obscure murmur, like that of a squirrel, or a greater degree of displeasure by a peevish cry, especially in winter, when he was often as fierce, on being much importuned, as any beast of the woods. From half an hour after sunrise to half an hour before sunset he slept without intermission, rolled up like a hedgehog; and, as soon as he awoke, he began to prepare himself for the labours of his approaching day, licking and dressing himself like a cat, an operation which the flexibility of his neck and limbs enabled him to perform very completely; he was then ready for a slight breakfast, after which he commonly took a short nap; but when the sun was quite set, he recovered all his vivacity. His ordinary food was the sweet fruit of this country; plantains always, and mangoes during the season; but he refused peaches, and was not fond of mulberries, or even of guaiavas: milk he lapped eagerly, but was contented with plain water. In general he was not voracious, but never appeared satiated with grasshoppers, and passed the whole night, while the hot season lasted, in prowling for them: when a grasshopper, or any insect, alighted within his reach, his eyes, which he fixed on his prey, glowed with uncommon fire; and having drawn himself back, to spring on it with greater force, he seized his victim with both his fore paws, but held it in one of them while he devoured it. For other purposes, and sometimes even for that of holding his food, he used all his paws, indifferently, as hands, and frequently grasped with one of them the higher part of his ample cage, while his three others were severally engaged at the bottom of it; but the posture of which he seemed fondest was to cling with all four of them to the upper wires, his body being inverted; and in the evening he usually stood erect for many minutes, playing on the wires with his fingers, and rapidly moving his body from side to side, as if he had found the utility of exercise in his unnatural state of confinement. A little before day-break, when my early hours gave me frequent opportunities of observing him, he seemed to solicit my attention; and if I presented my finger to him, he licked or nibbled it with great gentleness, but eagerly took fruit when I offered it, though he seldom ate much at his morning repast: when the day brought back the night, his eyes lost their lustre and strength, and he composed himself for a slumber of 10 or 11 hours. . . . . My little friend was, upon the whole, very engaging; and when he was found lifeless in the same posture in which he would naturally have slept, I consoled myself with believing that he had died without pain, and lived with as much pleasure as he could have enjoyed in a state of captivity."

Mr. Baird, in the paper above quoted, gives an account of one of these Loris (loeris, a clown, Dutch; name in Ceylon, according to that gentleman). Mr. Baird's specimen was a male, and was obtained at Pulo-Penang (Prince of Wales's Island). When Mr. Baird wrote, he had been in possession of the animal upwards of nine months. Its food consisted of fruit and small animals, such as birds and mice. The plantain was the fruit of which he was the most fond, and was the only food Mr. Baird saw him eat when he first got him into his possession. The necks of fresh-killed fowls formed the major part of its sustenance during the voyage. It was particularly fond of small birds: these, when put into his cage, he killed speedily, and, stripping off the feathers, soon devoured them, eating the bones as well as the flesh. Veal was preferred to all other butcher's meat, and it was fond of eggs; meat boiled, or otherwise cooked, it would not touch. Sugar appeared to be grateful to its palate, and it ate gum-arabic. "As flesh is not always to be had quite fresh (the only state in which it is acceptable to him), he has for some time past been fed upon bread sopped in water, and sprinkled with sugar; this he eats readily, and seems to relish it much. M. Vosmaer mentions that his animal eat dry biscuit, but refused it if moistened with water; neither would it ever taste water. This is completely at variance with the habits of my animal, for he not only eats moistened bread, but laps water like a cat. When food is presented to him, if hungry, he seizes it with both hands, and letting go with his right, holds it with his left all the time he is eating. Frequently, when feeding, he grasps the bars in the upper part of his cage with his hind paws and hangs inverted, appearing exceedingly intent upon the food he holds fast in the left hand. He is exceedingly fond of oranges;"—in this the animal resembled a domesticated *Lemur albifrons* once in our possession;—"but when they are at all hard, he seems very much puzzled how to extract the juice. I have, upon such an occasion, seen him lie all his length upon his back, in the bottom of his cage, and, firmly grasping the piece of orange with both hands, squeeze the juice into his mouth." Mr. Baird, after noticing the cry mentioned by Vosmaer and Sir W. Jones, says, "When the cat annoys him, which she does very frequently by leaping over him, he repeats the cry nearly a dozen times: it is always however expressive of anger. He has also another sort of cry expressive of eagerness to obtain anything: this is much gruffer in sound, not shrill nor loud, but apparently made by forcing the air out of his nostrils. He likes much to be stroked under the chin and throat, and also under the arms, turning his head round to the hand like a cat, and lifting his arm, stretching it out beyond his head. Though not a very sensible animal, he is still evidently capable of feeling kindness and showing resentment. He allows his throat and fore arms to be stroked, but refuses to let the same liberty be taken with his lower limbs. For some time while in China, a little Chinese dog was his companion, sleeping in the same cage with him; and, with the exception of a few occasional jars, they lived very comfortably together. As the dog grew up however they were separated. A cat, the only animal in the house besides himself, has made many overtures to him, and when he is allowed to get out of his cage, he is followed up and down the room by his feline companion, who evidently wishes to make him her playfellow. Any undue familiarities however on her part are met with an immediate repulse from him; and, one time, when patting him rather incautiously with her foot, he bit her so severely, that she now, though evidently wishing to be on good terms with him, keeps at a safe distance. This same cat has, since this, become more familiar. Though not daring to approach him, she follows him wherever he goes, to his great annoyance, and renders herself an object of his abhorrence. He cries out on her approach, and is sadly tantalised by her playful trick of leaping over him. He seems to be rather a social animal notwithstanding. A large japanned tray attracts a good deal of his attention. Seeing his image reflected in it, he walks before it, and tries to grasp his own image. Finding his efforts ineffectual, he imitates the action of the child, by peeping behind it, with xpectation to see the object there. Before a looking-glass he shows the same regard and curiosity." In most respects, the rest of Mr. Baird's description agrees with those of Vosmaer and Sir W. Jones.

M. D'Obsonville's memoir is very interesting, but offers no differences sufficient to justify the insertion of his account of his specimen at length. The little animal, which enjoyed comparative liberty, being suffered to go at large, appeared to him to be very much attached. He used to caress it after giving it food; and the marks of sensibility upon the part of his favourite were, taking the end of his hand and pressing it to its bosom, fixing, at the same time, its half-opened eyes upon his.

One that Pennant saw in London, slept holding fast to the wires of its cage with its claws, as above described, and he states that the inhabitants of Bengal call the animal Chirmundi Billi, or Bashful Billy. Sir W. Jones says of it, "The Pandits know little or nothing of the animal: the lower Hindoos of this province generally call it Lajjábánar, or the Bashful Ape; and the Mussulmans, retaining the sense of the epithet, give it the absurd appellation of a cat; but it is neither a cat nor bashful; for though a Pandit, who saw my Lemur by day-light, remarked that he was Lajjàlu, or modest (a word which the Hindoos apply to all sensitive plants), yet he only seemed bashful, while in fact he was dimsighted and drowsy; for at night, as you see by his figure, he had open eyes, and as much boldness as any of the *Lemures* poetical or Linnean."

In a state of nature there can be no doubt that its habits are, for the most part, arboreal; and that it takes its prey by night, seizing that which is living, such as small birds, mice, and insects, by surprise, probably whilst they are sleeping; and varying its diet by having recourse to fruits.

"As to his country," says the author last quoted, "the first of the species that I saw in India was in the district of Tipra, properly Tripura, whither it had been brought, like mine, from the Garrow Mountains; and Dr. Anderson informs me that it is found in the woods on the coast of Coromandel: another has been sent to a member of our society from one of the eastern isles; and though the Loris may be a native of Silán, yet I cannot agree with M. de Buffon that it is the minute, sociable, and docile animal mentioned by Thevenot, which it resembles neither in size nor disposition."

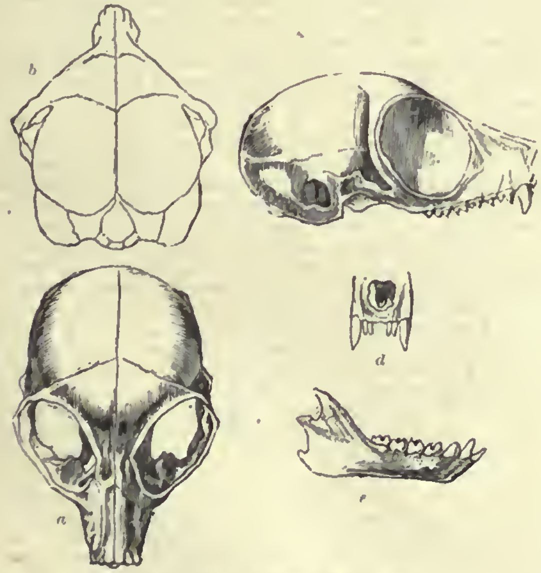
It has been found in other parts of the peninsula of Hindustan; and in Java, Penang, and Ceylon.

The genus *Galago*, Geoffroy, has the following dental formula, which is generally given by authors thus:—

Incisors, $\frac{2}{6}$ or $\frac{4}{6}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{6-6}{5-5}$.

In the species which we select to illustrate the form, Dr. Andrew Smith found the dentition as follows:—

Incisors, $\frac{4}{6}$; canines, $\frac{1-1}{1-1}$; false molars, $\frac{2-2}{1-1}$; true molars, $\frac{4-4}{4-4} = 18$ in each jaw.



Skull and Teeth of *Galago Moholi*. Smith.

a, front view of skull; *b*, back view of same; *c*, lateral view; *d*, front view of the anterior portion of upper jaw; *e*, lateral view of lower jaw. All the figures natural size. Smith.

The head is rounded, muzzle short, eyes very large, ears very large. Feet pentadactyle; all the nails flat with the exception of the first digit of the hind feet, which is armed with a sharp subulate claw; two teats; tail very long, loose, and villous. The species are found in Africa, to which Mr. Swainson adds India.

a, Basal view of skull, exhibiting the teeth; *b*, lower jaw. Both figures double the natural size. Smith.

The habits of these creatures are arboreal. The great size of the orbits will at once strike every observer. The large development of the eyes requires such spacious receptacles; and this development is necessary on account of the nocturnal habits of the genus. The food of these animals consists of soft fruits, and, from the structure of the teeth, probably of insects also. They are fond of vegetable gum, and their large ears are said to be closed when they sleep, but to be opened upon their hearing the least noise.

G. Moholi, Smith.—The upper parts of the head and neck, the back, the sides of the body, and the outer and hinder surfaces of the extremities are intermediate between a pearl and yellowish-gray colour; the back is finely brindled, from the dark colour of the basal portion of the fur being here and there seen through the surface tints; the extremities are of a lighter hue than the other parts enumerated, and their outer and hinder surfaces are distinctly tinted with yellow; the middle of the face, the lips, the sides of the head, below and behind the eyes, the chin, throat, abdomen, and the upper surface of the fingers, white; inner surfaces of extremities white, tinged with yellow. Tail glossy; the colour intermediate between yellowish-brown and cochineal red; the fur is througbout of the same colour; that of the other parts is a dark slate-colour except at and near its surface. Ears flesh-coloured; and the down, which is very sparingly scattered over their outer surface, is pure white. Eyes deep topaz yellow; the palms of the hands and under surface of the fingers are of a flesh-colour tinged with brown. Figure slender and elegant. Head broad, subglobular, and anteriorly terminated by a short, high, and almost pointed nose. Ears large, bare, and patulous, their tips rather narrow and slightly rounded; the outer margin of each ear has two faint emarginations, and the internal or anterior surface of each is distinctly marked with four or more transverse ridges; the eyeballs and the pupils large; anterior extremities short and slender; posterior ones long, rather robust, and each is terminated by four fingers and an opposable thumb, the tips of which are dilated and depressed; the nail of the forefinger of each of the hinder extremities is narrow, convex, considerably elongated beyond the soft parts, and obtusely pointed; all the other nails both of the anterior and posterior extremities small, thin, flat, roundish or ovate in form, and not extended to the points of the fingers. Tail cylindrical, slender towards the base, much thicker towards and at the tip, which arises from the fur being longer on those parts. On the head, body, and extremities, the covering consists of a very fine short woolly fur, which on the tail and the upper surface of the fingers is rather harsher. Palm of the hands and under surface of the fingers naked. (Smith.) Length from nose to tip of the tail, 16 inches. It is found in Southern Africa, and probably Western Africa.

The first specimens observed by Dr. Smith were upon trees close to the Limpopo River, in about 25° S. lat., and from that parallel he continued to observe others as the expedition travelled. They were very active, springing from branch to branch and tree to tree with extraordinary facility, and always seized the branch on which they intended to rest. In their manners they considerably resembled the monkeys, particularly in grimaces and gesticulations. According to the natives, the species is entirely nocturnal, and rarely to be seen during the day, which the animal spends in the nest which it has formed in the forks of branches or in cavities of decayed trees; and in these nests, constructed of soft grass, the females bring forth and rear their young (generally two at a birth). Dr. Smith states that the food of the *Moholi* consists principally of pulpy fruits, though there is reason to believe it also consumes insects, as remains of the latter were discovered in the stomachs of several individuals which he examined.

Moholi (*Galago Moholi*).

Dr. Smith for the reasons stated in his work, considers this animal different from *G. Senegalensis*. He gives an elaborate anatomical description and good figures of the more important and interesting parts of this animal.

In the 'British Museum Catalogue' the following species of *Galago* are found:—

G. Senegalensis, the Senegal Galago. From Gambia, Western Africa.
G. Alleni, the Black Galago. From Fernando Po.
G. minor, the Little Galago. From Madagascar.

Perodicticus (Bennett).—Face somewhat lengthened. Limbs subequal. Tail moderate. Index very short, the ungueal phalanx alone exserted.

$$\text{Incisors, } \frac{4}{6}\text{; canines, } \frac{1-1}{1-1}\text{; molars, } \frac{4-4}{3-3}\ (?).$$

The upper incisors are subequal, and the lower slender and sloping (declives); the canines conic, compressed, with the anterior and posterior margins acute; the first upper molar smallest, the second larger, and both conic; the third acutely tuberculate, the tubercles being two externally and one internally; the fourth like the preceding, its internal tubercle rather larger than the rest (absent in the young specimen); the lower molars consist of two, conic and equal, and a third externally acutely bituberculated, and one internal tubercle; the rest absent.

P. Geoffroyi (Bennett) is of a chestnut colour, paler below, with a few ash-coloured hairs interspersed; fleece woolly. It is a native of Sierra Leone. A live specimen of this animal exists in the Gardens of the Zoological Society of London.

Mr. Bennett gives the following as the synonyms of this highly-interesting animal:—Potto, Bosman ('Guin.,' li. 35, No. 4 l); *Lemur Potto*, Gmel. (Linn., 'Syst. Nat.,' 42 ?); *Nycticebus Potto*, Geoff. ('Ann. Mus.,' xix. 165 ?); *Galago Guineensis* (Desm., 'Mamm.,' 104, No. 127 ?); and describes the head as rounded, with a projecting muzzle; the nostrils lateral, small, sinuous, with an intermediate groove extending to the upper lip; the tongue rough with minute papillæ, rather large, thin, and rounded at the tip, and furnished beneath with a tongue-like appendage, which is shorter than the tongue itself, and terminates in about six rather long lanceolate processes, forming a pectinated tip. The eyes are small, round, somewhat lateral, and oblique; the ears moderate, open, and slightly hairy both within and without; the body rather slender, and the fingers moderately long. The index on the forehands is excessively short, the first phalanx being concealed, and the ungueal phalanx (the only phalanx free) being barely large enough to support a rounded nail, which did not exist on the specimen, but of which there was an apparent cicatrix; nails of all the other anterior fingers flat and rounded; those of the hinder hands similar, except that of the fore finger, which, as in the Lemurs generally, is long, subulate, and curved. Tail of moderate length, covered with hairs resembling those of the body. Hairs generally long, soft, and woolly, each of them mouse-coloured at the base, rufous in the middle, and paler at the tip; some few tipped with white. This arrangement produces on the upper surface and on the outside of the limbs a chestnut hue, slightly mixed with gray; the under surface is paler. Muzzle and chin almost naked, and having only a few scattered whitish hairs. Length of the head two inches and two-tenths; of the body six inches; of the tail one inch and six-tenths, or, including the hairs, two inches and three-tenths. Breadth of the head in front of the ears one inch and four-tenths; distance between the eyes four-tenths; from the anterior angle of the eye to the end of the nose seven-tenths; from the eye to the ear fifteen-twentieths; length of ears behind five-tenths, of their aperture eight-tenths, breadth five-tenths. Elaborate measurements of the anterior and posterior limbs are given by the author, to which we refer the reader.

The animal is described as slothful and retiring, seldom making its appearance except in the night-time, when it feeds upon vegetables, chiefly the *Cassada*. It is known to the colonists of Sierra Leone as the Bush-Dog.

Mr. Bennett remarks that the genus is readily distinguishable from the other *Lemuridæ* by the comparative length of the tail. In this, he observes, in the moderate elongation of the face, in the moderate size of the ears, in the equality of the limbs, and especially in the extreme shortness of the index of the anterior hands, reside its essential characters. The latter character is regarded by Mr. Bennett as especially important, and he considers it as indicating its typical station in a family, all of which are distinguished from the neighbouring groups by a variation in the form of the index or of its appendages. "In the *Lemuridæ* generally," says Mr. Bennett in conclusion, "the nail of the index of the hinder hands is elongated and claw-shaped, and unlike those of the other fingers, which are flat, as in the Monkeys. This is frequently accompanied by an abbreviation of the index of the fore hands, which becomes in *Loris* (Geoff.) very considerable, and is in *Perodicticus* carried to its maximum, that organ being here almost obsolete." ('Zool. Proc.,' 1831.)

Of *Cheirogaleus* but little is known. M. Geoffroy characterised the genus from the drawings and manuscript of Commerson. He gives the following generic characters:—Head round; nose and muzzle short; whiskers long; eyes large and prominent; ears short and oval; tail long, full (touffue), cylindrical, and curled (euroulée); nails of the thumbs flat, and all the other nails subulate; fur short.

The three species mentioned in Commerson's manuscript notes are —*Cheirogaleus major*, *C. medius*, and *C. minor*, all from Madagascar. M. Geoffroy thinks that the species last-named is *Galago Madagascariensis*.

Two species are named in 'the British Museum Catalogue,' *C. Smithii* and *C. typicus*, both from Madagascar. [LICHANOTUS.]

LENTIBULARIA'CEÆ, *Butter-Worts*, a small monopetalous order of Exogenous Plants, resembling *Scrophulariaceæ* very much in all respects, except that their seeds are arranged upon a free central placenta. They are natives of marshes or rivulets or fountains, in all parts of the world, especially within the tropics. *Pinguicula vulgaris* has the property of giving consistence to milk and of preventing its separating either into whey or cream. It is by the use of the leaves of this plant that the solid milk of the Laplanders is prepared. There are 4 genera and 175 species of this genus, all of which are herbaceous plants, living in water or marshes, chiefly within the tropics. The species of *Genlisea* are exclusively Brazilian.

LENTIL. [ERVUM.]

LENZINITE, a Mineral consisting of silicate of alumina. It occurs massive. Fracture earthy. Sometimes slightly conchoidal. Hardness 1·5; easily scratched by the point of a knife. Colour white. Lustre rather greasy. Translucent, transparent on the edges. Specific gravity 1·8 to 2·10. When put into water it divides into numerous small translucent bits, which, when touched, fall into grains of great hardness; by heat loses 25 per cent. in weight, and becomes hard enough to scratch glass. It is found at Eifeld in Prussia. Dr. John's analysis gives—

Silica	37·5
Alumina	37·5
Water	25·0
	100

LEO. [FELIDÆ.]

LEO'DICE. [ANNELIDA.]

LEONHARDITE, a Mineral occurring crystallised. Primary form

Pinguicula vulgaris.

1, an anther; 2, the glandular ovary, with a two-lobed stigma, of which one of the lobes is much larger than the other.

an oblique rhombic prism. Cleavage very perfect, parallel to the lateral planes. Colour white, yellowish, and more rarely brownish. Streak white. Fracture uneven. Frequently coated with brownish or black powder. Hardness 3·0 to 3·5. Lustre pearly, especially on perfect cleavage planes; on the fractured surface vitreous. Translucent on the edges. Specific gravity 2.25. Found near Wolfstein in Rhenish Bavaria. The following is its analysis by Dr. Delf:—

Silica	56·128
Alumina	22·980
Lime	9·251
Water and Loss	11·641
	100

LEONTICE, a genus of Plants belonging to the natural order *Berberidaceæ*, the root of one species of which is used at Aleppo as a substitute for soap, and is regarded by the Turks as a corrective of overdoses of opium.

LEONTODON, a genus of Plants belonging to the natural order *Compositæ*. The heads are many-flowered; involucre double, the inner row erect, outer of few short lax or adpressed imbricated phyllaries; fruit sub-compressed, muricated, and suddenly contracted above, produced into a filiform beak.

L. Taraxacum, Dandelion, is a well-known plant found in dry places, in bogs or damp places. It has runcinate toothed leaves; fruit linear, obovate, blunt, and squamosely muricated at the summit, longitudinally striated with a long beak; stalks single-headed, radical; florets yellow; leaves all radical, very variable, glabrous or slightly hispid.

The following varieties are considered as species by De Candolle, but are described merely as varieties by Babington. *L. Taraxacum* of Smith is known by the outer scales being linear, deflexed. *T. lævigatum* has its outer scales erect, patent, ovate. *T. erythrospermum* has the outer scales lanceolate, depressed, or patent. *L. palustre* with the outer scales ovate, acuminate.

The root, leaves, and flower stem (scape) of the Dandelion contain much milky juice; but the root only is employed in medicine: though the leaves by blanching can be rendered fit for use as a salad, retaining then only a moderate degree of bitterness. The root of plants which are three or four years old should alone be collected, and at Midsummer; as young plants or roots collected in spring merely contain a reddish mucilaginous juice, while those of older plants taken up in summer have a brown, bitter, and saline juice. Those from rich soil are not so potent as those from a poorer land. The root may either be speedily and carefully dried for preservation, or the expressed juice may be inspissated, and so form what is termed the extract.

The chemical constitution is a peculiar bitter principle, grumous sugar, and inulin, and probably some important salts.

Either an infusion, decoction, or extract possesses sedative, deobstruent, and diuretic properties. In chronic subacute inflammation of the stomach or liver, enlargements of the liver, or spleen, it proves more beneficial than almost any other vegetable remedy. In many cases of dropsy, particularly connected with obstruction of the liver, it has often succeeded when all other diuretics have failed. It is very extensively employed in Holland to obviate the effects of the intermittents or agues common there, and with the greatest advantage. The extract, unless very carefully prepared, soon ferments and spoils.

There are 14 European species of this genus described in Wood's 'Tourist's Flora.'

LEONU'RUS (from λέων, a lion, and οὐρά, a tail), a genus of Plants belonging to the natural order *Labiatæ*. The anthers approximate in pairs, with parallel cells and naked valves. The upper lip of the corolla is nearly flat, the lower one trifid, with the middle lobe obcordate. The calyx is tubular and 5-toothed; the nuts flatly truncate.

L. cardiaca, Mother-Wort, is a bitter herb, with a pungent unpleasant smell. The stems rise from two to three feet in height; they are wand-like, downy, purplish, and quadrangular. The leaves are long-stalked, somewhat downy, and of a dark-green colour. The lower leaves are the broadest, and deeply jagged, the upper ones 3-lobed, and those about the summit lanceolate and undivided. The corolla is of a purple colour, and externally hairy; the calyx rigid and pungent. It is found in hedges and waste places in Great Britain, all over Europe, and the middle of Asia. The reputed tonic powers of this herb as a remedy in palpitations of the heart and cardialgia, or hearthurn, are now disregarded: from being used however in the last complaint it derives its name. It has been extolled by the Russians as an antidote to canine madness, and bees are fond of the honey contained in its flowers.

L. marrubiastrum has elongated pubescent branches, oblong-ovate deeply-toothed leaves, the calyx nearly glabrous, and the corolla small, white or pale-red, and shorter than the calycine teeth, which are subulate, spiny, and diverging. It is found in waste places throughout Europe and Asiatic Russia.

There are 8 species of *Leonurus* described by botanists as growing chiefly in Europe and the north of Asia. None of them are very ornamental, and being biennial plants the seeds only require to be sown in the open ground.

(Don, *Dichlamydeous Plants;* Lindley, *Flora Medica;* Babington, *Manual of British Botany.*)

LEOPARD. [FELIDÆ.]

LEOPARD'S BANE. [ARNICA.]

LEPADITES, one of the many names of the supposed bivalvular opercula of *Ammonites*, found at Solenhofen, termed *Trigonellites* by Parkinson, *Solenites* by Schlottheim, and *Aptychus* by Meyer.

LEPAS. [CIRRIPEDIA.]

LEPEDOLITE, *Lilac Mica*, a Mineral which occurs massive, and is usually composed of small flexible thin scales. The fracture is uneven. Colour pearl-gray, peach-blossom, rose- and purple-red, and greenish. The scales, which are sometimes hexagonal, are translucent. Specific gravity 2·85. Before the blow-pipe it melts into a spongy semi-transparent white globule. It is found in granite near Rosena in Moravia, at Perm in Russia, at the Isle of Uton in Sweden, and in North America.

Analysis by Dr. Turner of the red variety from Moravia:—

Silica	50·35
Alumina	28·30
Potash	9·04
Lithia	4·49
Oxide of Manganese	1·23
Fluoric Acid and Water	5·20
	98·61

LEPI'DIUM (from λεπίς, a scale, in allusion to the form of the pods, which resemble little scales), a genus of Plants belonging to the natural order *Cruciferæ*, and the tribe *Lepidineæ*. It has a roundish or oblong pouch, either notched or entire, compressed valves, keeled or winged at the back. There is but one seed in each cell; the filaments are simple The species consist of herbs, some of which are shrubby, with small white flowers. This genus is divided into seven sections, the first of which, *Cardaria*, is so called from the heart-shaped form of the silicles. To this section belong

L. Draba. It has oblong leaves, entire or toothed, the lower ones narrowed into a foot-stalk, the stem-leaves sagittate and amplexicaule, the style as long as the dissepiment. It is native in the south of Europe from Spain to Tauria, and from Greece to Paris. It was introduced into Great Britain probably by foreign seed, and is now found in the hedges of Kent.

L. sativum, Common Garden Cress, belongs to the section *Cardamom* of this genus. It has orbicular pods, variously cut winged leaves, and smooth branches. It is native of Persia and the island of Cyprus in corn-fields. There are three varieties of the species: the Broad-Leaved Cress, which is cultivated chiefly for rearing young turkeys; the Curled Variety, which is sometimes used as a salad, but is considered preferable as a garnish; and the Common Plain-Leaved Cress, which forms one of our earliest spring salads, and has a peculiarly warm and grateful relish. All the varieties are raised from seed, of which one ounce will serve for a bed 4 feet square. Cress should be raised four or five times a month, so as to have the crops delicately young in succession. When raised in the open garden it should be sown early in March, and if the weather be cold it should be covered either with matting or a frame during the night. Cress is often raised on porous earthenware vessels of a conical form, having small gutters on the sides for retaining the seeds. These are called pyramids: they are somewhat ornamental in winter, and afford repeated gatherings. This species is the Λεπίδιον of Dioscorides, 2, 203.

L. campestris has downy leaves, the upper ones toothed, the lower ones oblong and narrowed into a foot-stalk, the stem-leaves lanceolate, sagittate, and amplexicaule. It is distinguished from the other species by the pouch being ovate, rough, and covered with minute scales, notched and rounded at the end, the style scarcely longer than the notch. It grows on dry gravelly soil in Great Britain.

L. latifolium has ovate lanceolate leaves, serrated or entire; the pouch is oval and downy. It has numerous small flowers in compound leafy panicled clusters. It is a native of Europe, also of Algiers, and of several parts of England, generally near the sea. It has a very hot biting taste, and has been used instead of horse-radish, occasionally as a salad. The poor people are in the habit of eating it as a condiment to their food; hence it has acquired the name of Poor Man's Pepper. An infusion of it acts as an emetic. Fraas believes this to be the Κράμβη ἀγρία of Dioscorides, 2, 147, although it is usually referred to the *Brassica cretica*. It is also the *Lepidium* of Pliny, 20, 17, 19, 5.

The green-house species will thrive well in any kind of light soil, and are readily propagated by cuttings planted under a hand-glass, or by seeds. The hardy perennial species, by dividing at the roots or by seeds, will grow in any kind of soil. The hardy annual kinds only require to be sown in the open ground. None of the species are worth cultivating for ornament.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Fraas, *Synopsis Floræ Classicæ*; Burnett, *Outlines of Botany*.)

LEPIDODENDRON (λεπίς, a scale, and δένδρον, wood), an important genus of Fossil Plants, in the examination of which Sternberg ('Flora der Vorwelt'), Brongniart ('Végétaux Fossiles'), and Lindley ('Fossil Flora') have signalised their abilities, not without success, though some uncertainty yet attaches to the botanical relations of these singular specimens of the flora of earlier nature. M. Brongniart in 1822, and again in his 'Prodrome' (1828), referred the *Lepidodendra* to the natural group of *Lycopodiaceæ*, pointing out however their analogies to *Cycadeæ* and *Coniferæ*, and assigned the following characters:—

Stems dichotomous, covered near the extremities with simple linear or lanceolate leaves, inserted on rhomboidal areolæ; lower part of the stems leafless; the areolæ for their insertion marked in the upper part with a transverse cicatrix, of a deltoid figure, the lateral angles acute, the inferior angle obtuse or wanting. The form of the cicatrix of the leaves is the essential character of the genus; it indicates that the leaves were nearly trigonal at the base, becoming plane at some distance therefrom, with a strong midrib. A rounded cicatrix distinguishes the leaf-base of stigmaria, which was perhaps an aquatic plant of the same natural group as the terrestrial *Lepidodendron*.

Lepidodendron Sternbergii. Brongniart. (From the 'Fossil Flora,' pl. 4.)

The stems thus named and characterised attain the size of 60 or 70 feet in length, with a diameter exceeding 3 feet: their whole surface is covered by rhomboidal eminences, arranged in spiral rows, so as to present a beautiful quincuncial ornament. In the opinion of M. Brongniart the mode of division (dichotomous) of the stem and the form of the leaves determine a great affinity between the *Lepidodendra* and *Lycopodiaceæ*. The growth of the stem he compares to that of *Cycadeæ*, and the form of the reproductive organs (cones) shows analogy to *Coniferæ*, and especially *Araucaria*.

Dr. Lindley, in the first volume of the 'Fossil Flora of Great Britain,' after discussing the botanical relations of *Lepidodendra* as far as the facts then collected allowed, thus expresses his opinion:—"Upon the whole, we are led to conclude that the *Lepidodendron* genus was not exactly like either *Coniferæ* or *Lycopodiaceæ*; but that it occupied an intermediate station between these two orders, approaching more nearly to the latter than the former."

A great addition to the data requisite for determining the problem of the true characters of *Lepidodendron* was made by the Rev. C. V. Harcourt, who discovered a specimen in which the internal structure of a branch was perfectly observable, and which, when cut thin and polished, cleared up many important points. Mr. Witham, the authors of the 'Fossil Flora,' and finally M. Brongniart, have published drawings and descriptions derived from this precious fragment. Dr. Lindley and Mr. W. Hutton ('Fossil Flora,' ii. p. 51) consider their former view entirely confirmed by this discovery. "It had a central pith, a vascular sheath surrounding that pith, and fistular passages in its cortical integument: thus far it was Coniferous. But as no trace can be found of glandular woody fibre, it can scarcely be said to have had any wood, and it is uncertain whether it had any bark. . . . Its vascular system was confined to the middle of the stem and to the curved passages emanating from it: the stem consisted of lax cellular tissue, which became more compact towards the outside, and it had a very powerful communication between the bases of its leaves and the central vascular system: thus far it was Lycopodiaceous." Spiral vessels are stated to be seen round the central cellular tissue; and (tab. 113) it is further said, "the genus was more nearly related to *Coniferæ* than to *Lycopodiaceæ*."

M. Brongniart, renewing his investigations with the aid of these new facts, evidenced by *Lepidodendron Harcourtii*, adopted a different view concerning the vascular system of the stem, for he supposes the central cellular tissue to be entirely surrounded by a narrow zone of large vessels, "rayés transversalement' (by Dr. Lindley considered as a loose cellular tissue), as in *Lycopodiaceæ* and Ferns, without medullary rays, and of which the exterior parts go off in bundles to the leaves.

From the whole discussion he adopts the conclusion that by the interior structure of the stems, as well as by their exterior form, their mode of ramification, and the arrangement of their leaves, the *Lepidodendra* agree almost completely with *Lycopodiaceæ*, and may be regarded as arborescent groups of that family, which contains in the living creation only small and humble plants; nor does it appear that his conviction is weakened by the comparison of these elongated (cylindrical) fossil 'cones' (*Lepidostrobi*), which are by most botanists referred to *Lepidodendron*, with the analogous organs of *Lycopodiaceæ* and *Coniferæ*. [LEPIDOSTROBI; COAL-PLANTS.]

The species are numerous, and confined to the older strata, and specially abundant in the Coal-Formation.

(Brongniart, *Histoire des Végétaux Fossiles*; Lindley and Hutton, *Fossil Flora of Great Britain*.)

LEPIDOGASTER, a genus of Fishes belonging to the Subbrachial *Malacopterygii*, and to the family *Cyclopteridæ*, or *Discoboli*. [DISCOBOLI.] The genus *Lepidogaster* is distinguished by its smooth body without scales; dorsal and anal fins opposite and near the tail; pectoral fins large, descending to the inferior surface of the body, and by an extension of the membrane surrounding an oval disc; ventral fins united by a membrane which extends circularly under the belly, forming a second concave disc.

L. Cornubiensis, the Cornish Sucker, Jura Sucker, and Ocellated Sucker, *Cyclopterus Lepidogaster* of Pennant and *L. biciliatus* of Risso, is occasionally seen on the Cornish coasts, and has been taken on the coasts of Antrim and Clare in Ireland. This fish is small, a specimen described by Mr. Couch not being more than two inches and a half in length. It adheres with its sucker to almost any substance presented to it, and even to the human hand. The general tint of this fish is a pale flesh-colour, with spots and patches of carmine about the upper and under surface of the jaws, around the eyes, on the top of the head, sides of the body, and abdomen.

L. bimaculatus, the Bimaculated Sucker, is a second British species. This fish is rarer than the last. It has been taken on the southern coasts of Great Britain. It seldom exceeds three-quarters of an inch to an inch in length. Its general colour is a carmine red; pale flesh-colour underneath, with a light-coloured patch between the eyes, and otherwise liable to some variation in the markings: the two spots on the sides not always very obvious. It lives in deeper water than the last species.

(Yarrell, *British Fishes*.)

LEPIDOGONYS. [FALCONIDÆ.]

LEPIDOKROKITE. [GÖTHITE.]

LEPIDOLEPRUS, a genus of Fishes belonging to the family *Gadidæ*. It is closely related to the genus *Morrhua*, to which the Common Cod belongs. The suborbitals are united with the nasal bone, and form a depressed muzzle, advancing before the mouth, which however retains its mobility. The head and body have hard spinous scales; the ventrals are a little on the throat; the pectoral of mean size; the first dorsal high; the second dorsal, anal, and caudal united; the jaws short; the teeth fine and short. The species inhabit deep water, and utter a grumbling noise when taken out of the water. Two species are known. They inhabit the Mediterranean and Atlantic.

LEPIDOLITE. [MICA.]

LEPIDOMELANE. [MICA.]

LEPIDOPHYLLUM. Fossil Leaves which occur in the coal formation are thus named by M. Brongniart. They appear to have been sessile, simple, entire, lanceolate or linear, traversed by a single simple midrib, or three parallel nervures, and without secondary nervures. (Some of these belong to *Lepidodendron*, others to *Stigmaria*.)

LEPIDO'PTERA, one of the Orders into which Insects are divided, called *Glossata* by Fabricius.

This order is composed of those insects which are commonly known by the names Butterflies and Moths, and which possess four wings, usually of large size, and covered with a multitude of minute scales, which to the naked eye appear like powder. The nervures of the wings are not very numerous, and are disposed chiefly in a longitudinal direction: a small tippet-like appendage is situated on each side of the thorax at the base of the wings, which appendages are called by Latreillo Pterygoda. The antennæ are almost always distinct, and are composed of numerous minute joints. The parts of the mouth are formed into a proboscis fitted for extracting the nectar from flowers, or conveying other juices to the œsophagus. This proboscis, when not in use, lies spirally folded beneath the head and between two palpi covered with hair, which are usually directed forwards and upwards, and which represent the labial-palpi. The proboscis is called, in these insects, Antlia by Messrs. Kirby and Spence, Spiritrompe by Latreille, and Lingua according to the nomenclature of Fabricius; and is composed of two sub-cylindrical tubes, which vary greatly in length in the different species of Lepidopterous Insects, and between which there is an intermediate one, formed by their junction, which is effected by means of a series of hooks inosculating one with another like the laminæ of a feather. It is through this central tube that the juices are conveyed, the lateral tubes being intended, as it is supposed, for the reception of air; they are called by Messrs. Kirby and Spence Solenaria, a name however which is not wanted, since the two tubes in question represent the maxillæ, and are furnished with minute maxillary-palpi at their base. The mandibles and labrum in these insects are reduced to mere rudiments. The head, thorax, and abdomen are always more or less covered with hair; the former, besides the ordinary compound eyes, is sometimes furnished with simple eyes or stemmata; these however are generally hidden by the hair of the head, and, according to M. Dalman, do not exist in the diurnal *Lepidoptera*. Of the three segments of which the thorax is composed, the first is usually distinct, though small; the others are confluent; the scutellum is triangular, the apex of the triangle pointing towards the head. The abdomen is composed of six or seven distinct segments, and is attached to the thorax only by a small portion of its diameter. There are only two kinds of individuals, males and females.

The principal modifications of the larvæ, or caterpillars, of Lepidopterous insects are noticed in the article INSECTA.

The food of the larvæ almost always consists of vegetable substances, generally the leaves of plants; some live in rotten, or rather, dead wood, upon which they feed; others feed upon animal substances, and are very destructive to furs, woollen goods, feathers, &c.; and the larva of a species of moth (the honeycomb moth, *Galleria cereana*) subsists upon wax, living in bee-hives.*

The pupæ, or chrysalises, are incapable of eating or locomotion, and are termed obtected; they usually approach somewhat to an oval form, but are pointed more or less at the posterior extremity. The shape of the pupæ however varies much according to the species; and those of butterflies often present numerous angular projections, and sometimes exhibit brilliant metallic colours. The parts of the perfect insect, such as the head, thorax, segments of the abdomen, wings, and legs, can be distinctly traced. Various modifications of the pupa state of the present insects are noticed in the separate articles on species which are described.

Latreille divides this order into three principal groups, according with the three Linnæan genera *Papilio*, *Sphinx*, and *Phalæna*. To the first group he applied the name *Diurna; Crepuscularia* is used to designate the second; and the third group, or that corresponding to *Phalæna* of Linnæus, is called by Latreille *Nocturna*.

The group *Lepidoptera Diurna* comprises those species which fly by day, called Butterflies, in which the antennæ are terminated by a knob, or at least somewhat suddenly thicker at the extremity; the anterior margin of the posterior wings is simple; the wings are usually erect when the insect is in a state of repose; the larvæ have 16 legs; the chrysalises are always naked, attached by the posterior extremity, so that the head hangs downwards, and have usually angular projections.

The *Lepidoptera Crepuscularia* are distinguished by the antennæ being gradually thicker from the base towards the extremity, and forming a prismatic or fusiform club; the extreme tip is slender, pointed, and often recurved. The wings are in a horizontal position when at rest, or a little inclined; the posterior wings have a rigid spine at the anterior margin, which is received into a hook on the under surface of the superior wings. The caterpillars have 16 feet, 6 of which are thoracic, 8 abdominal, and 2 anal; and many of them have a horn-like process on the upper side of the last segment. The pupæ are never angular like those of butterflies, but are generally smooth, and sometimes furnished with small spines. The perfect insects generally fly in the morning, evening, or afternoon.

The *Lepidoptera Nocturna* have the antennæ setaceous, or diminishing gradually from the base to the apex, often serrated or pectinated, especially in the male sex: the wings during repose are horizontal or deflexed, and sometimes convoluted and inclosing the body; the posterior wings, as in *L. Crepuscularia*, have a rigid seta on their anterior margin, which hooks into a corresponding groove in the anterior wings. The larvæ differ much in form, and in the number of feet they possess, varying from 10 to 16. They frequently inclose themselves in a cocoon before assuming the pupa state. The pupa is most frequently smooth, but is sometimes furnished with spines, and in some instances it is hairy.

The perfect insect almost always flies by night or after sunset. In some species the females are apterous.

* This larva forms galleries in the honeycomb, which are invariably inclosed by a strong silken web, serving to protect it from the bees; and as the moths increase rapidly in number, the hive is of necessity soon deserted by its proper inhabitants.

LEPIDOPUS. [TÆNIOIDES.]

LEPIDOSTROBI. Detached petrified cones which are scattered through the various strata of the Coal Formation have been thus named. They are obviously organs of fructification, and have therefore belonged to some of the arborescent plants whose remains they accompany. Such of them as are preserved in the nodules of iron-stone, or are otherwise mineralised without pressure, alone offer the means of ascertaining to what existing families of plants they are most nearly allied; for in those that are crushed flat in the shales the internal structure is wholly destroyed. Many of the better-preserved specimens have been sliced, polished, and examined with the greatest care; but this expensive operation has hitherto thrown little light upon the true nature of the objects investigated. This is owing to the fact that the three conditions necessary for their complete illustration have never been displayed by one specimen, and the most important point, the nature of the organs of fructification, has hitherto wholly escaped observation in all. Every one being an aggregation of organs of some kind it becomes necessary to ascertain, not only the arrangement of these organs, but the nature of the tissues composing them, and their contents, before satisfactory conclusions can be drawn as to their relationship to any of the vegetable remains they accompany, or to whatever existing order of plants they are allied. The three necessary conditions are these:—

1. The arrangement of the individual organs of fructification, of which the cone is an aggregation, and the nature of the scales supporting them. These are characters sometimes displayed on the fracture of the specimen by ordinary means, though rarely, from the parts appearing to have suffered partial decay previous to or during petrifaction. The imbricating apices of the scales, which lie over one another like those of a pine cone, are generally removed with the matrix wherein the fossil is embedded.

2. The tissues, or anatomical structure of the various organs composing the cone: namely, of the central axis, which is a continuation of the stem of the plant; of the scales, which being inserted into the axis support the individual male or female organs; and of the latter themselves. These tissues can only be displayed by slicing fossils in the very best state of preservation, and in such as are changed into a more or less transparent mineral. Specimens of this description are exceedingly rare.

3. The two preceding considerations are secondary to the remaining one—the nature of the contents of the cones. There may be stamens or male organs—ovaria or female ones—or, lastly, capsules containing reproductive spores (which are peculiar to plants having no sexual system); for these three kinds of organs all occur arranged in the form of cones, undistinguishable from one another by any external marks. Up to the present time no carboniferous fossil cone has ever been known to supply this great desideratum, without which we can arrive at no exact conclusion as to whether these curious objects are clusters of flowers or fruits, or are the spore-bearing organs of flowerless vegetables, as mentioned above.

Specimens of *Lepidostrobi* are mostly found in seams or nodules of clay iron-stone, and are very highly mineralised, sometimes containing crystals of iron, and the cavities in their substance being filled with white carbonate of lime and magnesia. Those which are most complete always form the nuclei to nodules of clay iron-stone; others again, including all in which the spores are preserved, have occurred as broken frustules within stems of *Lepidodendron elegans* and other species of that genus. Usually the fragments of *Lepidostrobi* are not more than half an inch long, and very frequently are mere discs; so that though there is often the appearance of one several inches long, and traversing the whole length of the fragment of *Lepidodendron*, it will generally be found that this is owing to two being placed each at an extremity of the truncheon, and opposite to one another. [See Figure, COAL PLANTS.] That all were exceedingly brittle cannot be doubted, for no modern cone of any natural order could be broken up into the shallow discs which many of these fossils present. It is difficult to account for the presence of these fragments of *Lepidostrobi* in the stems of *Lepidodendron;* we can but conjecture that the trunks of the latter were erect stumps, whose interior was hollowed out by decay—that these stumps were covered with water in which were fragments of *Lepidostrobi* and other vegetable matter, which were thus washed into the stumps. This supposition is founded on the following considerations :—

1. The stumps of *Lepidodendron* appear to have been rooted and erect, and to have received the cone fragments into their cavity as fern fronds find their way into the axis of *Sigillariæ*. Were the stumps mere prostrate portions of stems it is evident that cones would have lain horizontally in them, and that no washing or drifting could have induced the fragments of these cones to lie with their axes parallel to them, or could have introduced so many into one trunk; and the latter would certainly have been materially compressed had they received on one side the pressure of the superincumbent shales.

2. The stumps must have been submerged, and the fragments quietly deposited from the water. Had the cones fallen from an overhanging forest they would have alighted in all manner of irregular positions, and in some cases overlain one another, which is never the case.

3. The deposit appears to have been effected by the gradual subsidence of the water, and not by a sudden rush or current. This again is proved by the non-interference of the cones, and their uniformly vertical position with respect to the *Lepidodendron*.

It is hard to account for the accession of so large a volume of water as would submerge these stumps and deposit these fragments, and yet exhibit no signs of drifting in its course. The sudden fall of a tropical torrent of rain on a *Lepidodendron* forest, in which were hollow stumps of these trees, must at once suggest itself. This would both carry down the *Lepidostrobi* from the trees and float up the fragments on the ground, depositing them together in the stumps. Another effect of such a fall would be to break down some of the older trees, whose decaying stumps would be prepared to inclose other *Lepidostrobi* on the precipitation of the next similar torrent. The extreme fragility of the *Lepidostrobi* displayed by these specimens is very satisfactory, as the Lepidodendrons of which they are the fruit no doubt partook of this character, which is eminently favourable to a rapid decomposition and intimate union with the silt or mud which is the basis of the clay-ironstone in the one case, and the formation of a homogeneous bed of vegetable matter, such as the coal presents, in another. The extraordinary abundance of the fragments too suggests a most vigorous vegetation, for they must indeed have been profusely scattered to be deposited in such numbers within narrow cylinders into which no current appears to have been directed.

It is worthy of remark that no fern-leaves are contained in any of these *Lepidodendron* stems; and their absence is the more singular from their being commonly deposited along with branches of *Calamites*, &c., in the erect stumps of *Sigillaria* resting on the coal-shales. This is no doubt connected with the well-known fact of the *Sigillaria* stumps being filled with sandstone, or the same materials as those composing the stratum above the shales they root into; whilst the fossil *Lepidodendron* of the clay-ironstone seams is of the same mineral as that wherein it is imbedded. Were the fragments of *Lepidostrobi* washed into their inclosing stumps by any current, that agent would in all probability have transported the remains of other plants to the same spot. The perfect preservation in which these fragments occur must be attributed to the protection afforded them by the surrounding *Lepidodendron* bark. That the circumference of the latter has been subjected to pressure may be inferred from the flattening of the prominences to which the leaves were attached. This pressure was moreover very considerable, as may be proved by comparing the evenness of their surface with that of a piece of *Lepidodendron* bark fossilised without pressure, and imbedded within the stem along with the *Lepidostrobi*.

If these cones be examined with reference to the known contemporaneous fossils which accompany them, it will appear impossible to deny their having the reproductive organs of *Lepidodendron*, not only from their association with the fragments of that genus, because the arrangement of the tissue in the axis of the cone entirely accords with that of the stem of *Lepidodendron*. Just as we find in modern cones of *Lycopodiaceæ* and *Coniferæ* that the axis is a continuation of the branch, which bears leaves modified into organs adapted to support and protect the parts of fructification. The most positive evidence that can be adduced of *Lepidostrobi* belonging to a genus allied to *Lycopodium* is afforded by the spores, the presence of which not only removes them from *Cycadeæ*, *Coniferæ*, or any other order of flowering plants, but directly refers them to the family of *Lycopodiaceæ*. It is well known to botanists not only that cones are far from being peculiar to one natural order of plants, but that their extreme form is no indication either of their contents or of the affinities of the plants which produced them. Accordingly we find that Dr. Lindley, the first English observer who published any extended views on the affinities of these plants, suggests the probability of their being referrible either to *Coniferæ*, *Lycopodiaceæ*, or more probably still to *Cycadeæ*. Dr. Hooker, after describing the nature of spurious cones which have no relation to the reproductive organs of the plant, as in the common cone-bearing willow, the larch, &c., and those produced by the puncture of an insect, as in a genus inhabiting Terra del Fuego, where a cone is formed by this means from a leaf, says :—"Some of the so-called *Lepidostrobi* may be of this nature: witness the *Lepidodendron oöcephalum*, of which it is impossible to say whether it be a *Lepidostrobus* or the apex of a branch crowded with short leaves. Were the Fuegian plant to occur in a fossil state the probability is, that its cones would be regarded as undoubted reproductive organs, and the plants themselves be referred to *Coniferæ*."

(Hooker, *On the Structure and Affinities of Lepidostrobi*, in *Transactions of Geological Survey of Great Britain*.)

LEPIDOSTEUS, a genus of Fishes belonging to the family *Clupeidæ*. The species are natives of tropical America. They are remarkable for their long teeth, which have their anterior surfaces rasp-like; the scales are very hard, like stone. The dorsal and anal fins are opposite, and far back. The intestine has two folds and numerous cæca; the air-bladder is cellular. The species of this genus are interesting, with those of *Polypterus*, as being the only living representatives of the vast numbers of extinct voracious fishes whose remains are found in the various secondary formations. [POLYPTERUS.]

LEPIGONUM, a genus of Plants belonging to the natural order *Paronychiaceæ*. It has 5 flatish sepals; petals 5, entire, as long as the calyx; stamens from 5 to 10; styles 3- or 5; fruit 3- to 5-valved, many-seeded, valves fewer than the sepals, or alternate with them.

L. rubrum is found in sandy fields near the sea in Great Britain. It has a round stem, flat leaves linear-pointed, capsules about equalling the calyx, rather shorter than the slightly declining fruit-stalks; seeds triangular, obovate, with a thickened rough border; stem procumbent.

L. marinum has a compressed stem, fleshy leaves, blunt apiculate, capsules exceeding the calyx, much shorter than the declining fruit-stalks; seeds roundish, usually surrounded by a membranous striated wing; the root is almost woody; stem glabrous or glandular, hairy. It is found on the sea-coast.

(Babington, *Manual of British Botany*.)

LEPIDO'TUS, a genus of Fossil Ganoid Fishes, abundant in the Oolitic strata. (Agassiz.)

LEPISMA. [THYSANURA.]

LEP'ORIDÆ, a family of *Rodentia*, the type of which may be considered as existing in the Common Hare.

Linnæus characterised his genus *Lepus*, the second of his order *Glires*, as having two incisor teeth (dentes primores 2), the upper ones double, the interior being the least, and he placed the following under it, namely, *Lepus timidus*, *L. cuniculus*, *L. Capensis*, and *L. Brasiliensis*. Gmelin added several species, some of which had no claim to a place among the Hares.

Cuvier characterised the Hares as having the proper incisor teeth double; that is to say, each of them has, behind, another smaller one. Their molars, to the number of five, are formed each of two vertical laminæ soldered together. In the upper jaw there is a sixth, which is simple and very small. They have five toes before and four behind, an enormous cæcum, five or six times larger than the stomach, and furnished within with a spiral lamina (lame spirale), which runs throughout its length. The interior of their mouth and the bottom of their feet are furnished with hair, like the rest of their body. He divides the group into—

1. The Hares, properly so called, which have long ears, a short tail, the hind feet much longer than the fore feet, imperfect clavicles, and the suborbital space in the skeleton pierced like net-work (en reseau). The species are, he observes, rather numerous, and so much alike, that it is difficult to define them.

2. Of *Lagomys*, his 2nd division, he says that the species composing it have the ears moderate, the legs not much differing from each other, nearly perfect clavicles and no tail: they have hitherto, he adds, been only found recent in Siberia, and fossil remains of an unknown species have been detected in the Osseous Breccia of Corsica.

Dr. Gray's third family of the order *Glires* is named *Leporidæ*, and is thus defined :—

Cutting teeth two in each jaw, or four in the upper one, lower one subsubulate; grinders numerous, rootless; ears generally large; tongue often hairy: eyes large; clavicles none; fore feet short; hinder ones long; tail none, or very short, hairy; fur soft.

† Cutting-teeth four above.

1. *Leporina*, genus *Lepus* (?). 2. *Lagomina*, genus *Lagomys*.

†† Cutting-teeth, two above.

3. *Caviina*. genera *Kerodon*, F. Cuv. 4. *Hydrocharina* (Hydrochœrina (?), genus *Hydrocharus* (Hydrochœrus), Brisson. 5. *Dasyporcyna* (Dasyproctina ?), genera *Cœlogenys*, Illig., *Dasyporca* (Dasyprocta ?), Illig., *Dolichotis*, Desm.

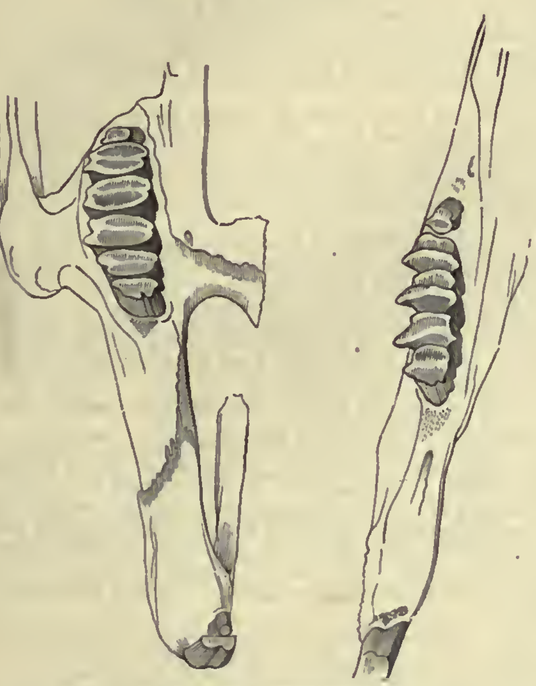
Mr. Swainson defines the genus *Lepus* thus :—Cutting teeth $\frac{4}{2}$, the upper in pairs two in front, large and grooved, and two smaller behind; lower teeth square; grinders $\frac{6-6}{5-5}$, composed of two soldered vertical plates; a sixth, very small, in the upper jaw; soles of the feet hairy; anterior feet with five toes; posterior with four; tail very short, turned upwards.

L. timidus, the Common Hare.

Lagomys, Geoff., Mr. Swainson appears to give as a sub-genus of *Lepus*.

The sub-family *Leporina* seems to be strictly natural, consisting entirely of those species, and they are not few, which are usually known by the name of Hares and Rabbits.

$$\text{Incisors, } \frac{4}{2}; \text{ molars, } \frac{6-6}{5-5} = 28.$$



Teeth of Common Hare (*Lepus timidus*). F. Cuvier.

L. timidus, the Common Hare, which is generally considered as the type, is too well known to need description, and it will suffice to state that it is the Λαγώς of the Greeks; *Lepus* of the Romans; Lepre of the Italians; Liebre of the Spaniards; Lebre of the Portuguese; Lièvre of the French; Hase of the Germans; Haas and Haze of the Danes; Hara of the Swedes, according to Mr. Bell; Hara of the Anglo-Saxons; Ysgyfarnog, Ceinach, of the Welsh; Maukin of the Scotch.

The usual weight of a full-grown Hare is 8 or 9 lbs.; but one is mentioned in 'Loudon's Magazine' of extraordinary size: this weighed 13 lbs. 1½ oz.

L. Hibernicus, the Irish Hare. The Earl of Derby appears to have been the first who drew particular attention to this species, and it was described in the 'Proceedings of the Zoological Society' by Mr. Yarrell in 1833. Mr. Jenyns gives it as a variety of the *L. timidus;* but Mr. Bell ('British Quadrupeds') states that a careful examination of several specimens has assured him that it is not merely a variety of the Common Hare of England, but that it is specifically distinct. He mentions the following differences of character:—The Irish Hare is somewhat larger; the head is rather shorter; the ears are even shorter than the head, while those of the English Hare are fully an inch longer; the limbs are proportionally rather shorter; and the hinder legs do not much exceed the fore legs in length. The fur is also remarkably different: it is composed exclusively of the uniform soft and shorter hair which in the English species is mixed with the black-tipped long hairs that give the peculiar mottled appearance of that animal; it is therefore of a uniform reddish-brown colour on the back and sides. The ears are reddish gray, blackish at the tip with a dark line near the outer margin. The tail is nearly of the same relative length as in the common species.

It further appears that *L. Hibernicus* is the only Hare found in Ireland, which may account for its remaining so long unnoticed; for opportunities of comparison could not have been very frequent. Its fur is considered valueless.

Whether the Irish Hare will take the water willingly does not appear; that the English Hare is, occasionally at least, an accomplished and bold swimmer is manifest from the following account related by Mr. Yarrell in 'Loudon's Magazine' (vol. 5):—"A harbour of great extent on our southern coast has an island near the middle of considerable size, the nearest point of which is a mile distant from the mainland at high water, and with which point there is frequent communication by a ferry. Early one morning in spring two hares were observed to come down from the hills of the mainland towards the sea-side; one of which from time to time left its companion, and proceeding to the very edge of the water, stopped there a minute or two, and then returned to its mate. The tide was rising; and after waiting some time one of them exactly at high water took to the sea, and swam rapidly over in a straight line to the opposite projecting point of land. The observer on this occasion, who was near the spot, but remained unperceived by the hares, had no doubt they were of different sexes, and that it was the male that swam across the water, as he had probably done many times before. It was remarkable that the hares remained on the shore nearly half an hour; one of them occasionally examining, as it would seem, the state of the current, and ultimately taking to the sea at that precise period of the tide called slack-water, when the passage across could be effected without being carried by the force of the stream either above or below the desired point of landing. The other hare then cantered back to the hills."

The female goes thirty days with young, and produces from two to five at a birth; these are born well covered with hair and with their eyes open. The leveret quits the mother and provides for itself in less than a month, and is capable of breeding when it is a year old.

The Common Hare sometimes varies accidentally; there is such a variety in the museum of the Zoological Society of London. All attempts to promote a breed between the hare and rabbit appear to have been hitherto fruitless.

L. variabilis, the Varying Hare, or Alpine Hare, of Pallas, which changes the colour of its coat with the seasons, requires a short notice. The fur, which is full and soft, is in summer gray intermixed with silky hair of a yellowish brown; the ears are tipped with black, and the under parts are light gray. The tail is white beneath and gray above. As the winter approaches the fur gradually becomes white, except that on the lips and the tips of the ears, which remains black. In the 'Edinburgh Philosophical Journal,' vol. ii., is an interesting account of the process as it occurs in Scotland, from which it would seem that the winter change of colour takes place without any removal of the hair, as in the Ermine, and somewhat in the same way that the change is effected on the head of the Black-Headed Gull, *Xema ridibundus*, and in the feathers of other birds. "About the middle of September," says the writer in the 'Journal,' "the gray feet begin to be white, and before the month ends all the four feet are white, and the ears and muzzle are of a brighter colour. The white colour gradually ascends the legs and thighs, and we observe under the gray hairs whitish spots, which continue to increase till the end of October; but still the back continues of a gray colour, while the eyebrows and ears are nearly white. From this period the change of colour advances very rapidly, and by the middle of November the whole fur, with the exception of the tips of the ears, which remain black, is of a fine shining white. The back becomes white within eight days. During the whole of this remarkable change in the fur no hair falls from the animal; hence it appears that the hair actually changes its colour, and that there is no renewal of it. The fur retains its white colour until the month of March, or even later, depending on the temperature of the atmosphere; and by the middle of May it has again a gray colour. But the spring change is different from the winter, as the hair is completely shed."

L. Cuniculus, Linn., the Rabbet, Rabbit, or Coney; Coniglio of the Italians; Conejo of the Spanish; Coelho of the Portuguese; Kaninchen of the Germans; Konyn or Konin of the Dutch and Belgians; Kanin of the Swedes; Kanine of the Danes; and Cwningen of the Welsh, is known to every one.

The fertility of the animal may be imagined when it is remembered that it will begin to breed at the age of six months, and produce several broods in a year, generally from five to seven or eight at a time. Pennant says:—"Rabbits will breed seven times a year, and bring eight young ones each time. On a supposition that this happens regularly during four years, their numbers will amount to 1,274,840." The young are blind at their birth, and nearly naked.

The fur of the Rabbit is in considerable demand, particularly for the hat trade; and at one time the silver-haired varieties, or silver-sprigs, fetched three shillings a piece, for ornamental linings to cloaks, &c.; in Pennant's time however the price had fallen to sixpence.

The following additional species of *Lepus* are found in the 'British Museum Catalogue:'—

L. Altaicus, from the Altai Mountains.
L. arcticus, the Rekalek, or Polar Hare. Labrador.
L. Tolai, the Tolai. Siberia.
L. macrotus, the Indian Hare. Nepaul.
L. diostolus, the Woolly Hare of Thibet. Nepaul.
L. Douglasii, the Marsh Hare. California.
L. kurgosa, the Lasa, or Khargosh.
L. Vermicula, the Irish Rabbit. Ireland.
L. Capensis, the Vlakte Haas. Cape of Good Hope.
L. arenarius, the Barrow Hare. Cape of Good Hope.
L. saxatilis, the Rock Hare. Cape of Good Hope.
L. Bennettii. California.
L. Americanus, the Wawproos, or American Hare. North America.
L. Ægypticus, Egyptian Hare. Egypt.

The subfamily *Lagomina* consists of a single genus, *Lagomys*, which has the muzzle acute, the ears short and somewhat rounded, the soles of the feet hairy, the claws falcular, and no tail.

$$\text{Incisors, } \frac{4}{2}; \text{ molars, } \frac{5-5}{5-5} = 26.$$

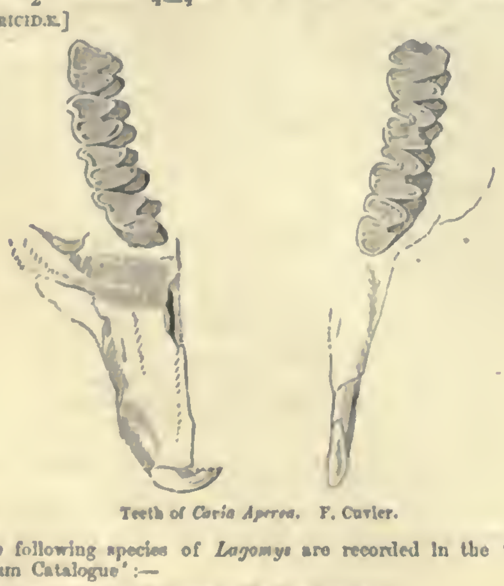
L. pusillus (*Lepus pusillus* of Pallas; Semlanoi Saetshik, or Ground Hare, of the Russians about the Volga; Tschotschot, or Ittsitskan, or the Barking Mouse of the Tartars; Rusla of the Kalmucs; Calling Hare of Pennant) has the head longer than usual with hares, and thickly covered with fur, even to the tip of the nose; numerous hairs in the whiskers; ears large and rounded; legs very short; soles furred beneath; its whole coat very soft, long, and smooth, with a thick long fine down beneath of a brownish-lead colour; the hairs of the same colour, towards the ends of a light gray, and tipt with black; the lower part of the body hoary; the sides and ends of the fur yellowish. Length about 6 inches; weight from 3½ to 4½ ounces; in winter scarcely 2½ ounces. (Pallas; Pennant.)

Calling Hare (*Lagomys pusillus*).

It inhabits the south-eastern parts of Russia, and is found about all the ridges spreading from the Ural Mountains to the south, about the Irtish, and in the western parts of the Altai Mountains, but nowhere in the East beyond the Oby. (Pallas; Pennant.)

It delights in the most sunny valleys and hills, where the herbage is plentiful and delicate. The Calling Hares choose these localities when in the vicinity of a wood, which will afford them a ready refuge in the case of danger or alarm. Their burrows, especially those belonging to the old ones and to females, are curious and intricate, so well concealed amid the shrubs of some dry spot that detection is very difficult; and to increase the difficulty the animal is said to drop its excrements under some bush, that they may not betray its abode, which would almost defy search were it not for their peculiar cry or call. This is described as being like the piping of a quail, but deeper, and so loud as to be heard at the distance of half a German mile. It is repeated at just intervals, thrice, four times, and even six, at night and morning, but seldom in the day, unless the weather be cloudy. Both the male and female emit this note, but the latter is silent for some time after she has given birth (in May) to her young, which are born naked and blind, and are carefully attended to by the mother, who covers them up warm with the cosy materials of her nest.

The sub-family *Caviina*, which has the following dental formula—Incisors, $\frac{2}{2}$; Molars, $\frac{4-4}{4-4} = 20$—is often referred to *Hystricidæ*. [HYSTRICIDÆ.]



Teeth of *Cavia Aperea*. F. Cuvier.

The following species of *Lagomys* are recorded in the 'British Museum Catalogue':—

L. princeps, the Little Chief. North America.
L. alpinus, the Ladajac. Siberia.
L. Roylei, the Indian Sulgan. Himalaya.
L. Nepalensis, the Red-Shouldered Sulgan. Nepaul.
L. rufescens, the Reddish Sulgan. Cabul.

Fossil Leporidæ.

Of the genus *Lepus* the following species are named:—*L. diluvianus*, Hare of the Caverns, Cuvier, Buckland, Pander, and D'Alton; *L. priscus*, Hare of the Osseous Breccias, Cuvier. Fossil Hares and rabbits are also recorded by M. Bourdet, M. D'Orbigny, M. Risso, M. Wagner, Messrs. Croizet and Jobert, and Messrs. Marcel de Serres and Pitorre.

The following fossil species of *Lagomys* are recorded:—*L. Corsicanus* and *L. Sardus*, from the Osseous Breccia of Corsica and Sardinia respectively. Other remains of *Lagomys* are noticed by Cuvier, Wagner, M. de Serres, Risso, Chabriol and Bouillet, Croizet and Jobert, Bravard, Sedgwick (Oeningen beds), and Murchison. All tertiary.

Of the Agouti (*Dasyprocta* of Illiger; *Chloromys* of F. Cuvier) remains are noticed by M. Bravard and M. Eichwald in tertiary beds.

LEPTACANTHUS, a genus of Fossil Placoid Fishes occurring in the Carboniferous and Oolitic strata. (Agassiz.)

LEPTÆNA, a subdivision of the great family of Fossil *Brachiopoda*, proposed by Dalman to include species which Mr. Sowerby named *Producta*. Its use is at present more restricted, and has become rather indefinite. *Leptæna lata*, of the Silurian system, may be regarded as a frequent type. The species are extinct, and are confined to Palæozoic strata.

LEPTIDES, a sub-family of Dipterous Insects of the family *Brachystoma* (Macquart). The family of insects to which the present section belongs is distinguished by the proboscis being short and membranous; the lips terminal and thick; third joint of the antennæ simple, often spatulate; stylet often dorsal; abdomen usually with five distinct segments. The wings have commonly one submarginal and three posterior cells. The family *Brachystoma* is divided by Macquart into four tribes or sub-families—*Xylotomæ*, *Leptides*, *Dolichopoda*, and *Syrphidæ*.

The first, or the *Xylotomæ*, are distinguished by the third joint of the antennæ being conical, by the wing having two submarginal cells, and by the tarsi being furnished with two small cushions.

In the sub-family *Leptides* the antennæ are inserted near the base of the head, and have generally a terminal stylet; the tarsi are furnished with three small cushions; the femora are elongated; the wings have two submarginal and generally five posterior cells. This group contains six genera, of which one (*Clinocera*) is distinguished from all the other Leptides by its possessing only three posterior cells to the wings, the remaining genera having five.

In the genus *Leptis* the head is depressed; the palpi are generally decumbent, with the second joint conical and the third joint short and generally conical. The thorax has a distinct tubercle; body conical and transparent. The species inhabit Europe. The *Leptis vermileo* (*Musca vermileo*, Linn.) has been separated from *Leptis* proper by Macquart, and forms the type of his genus *Vermileo*, distinguished chiefly by the body being elongated and depressed, the first joint of the antennæ elevated, and the last conical and horizontal in its direction.

L. vermileo of Fabricius, or *Vermileo Degeerii*, Macquart. This Fly is about 4 or 5 lines in length, of a yellow colour, having four black streaks on the thorax, and five ranges of black spots on the body; the wings immaculate. The larva somewhat resembles the stick-like caterpillar of the *Geometræ*, and is nearly of a cylindrical form, but narrower towards the anterior extremity of the body; the posterior extremity is furnished with four fleshy tubercles. It lives in sandy districts, forms excavations in the soil, at the bottom of which it secretes itself either wholly or partially. If an insect falls into its trap it rises suddenly, clasps the insect with its body, and having sucked all its juices, bends itself in the form of a bow, and by suddenly relaxing throws away the remains.

The next genus, *Chrysophila* (Macquart), has the body furnished with velvet-like hair, the palpi elevated and with the second joint cylindrical, the third being generally conical; thorax without a distinct tubercle. Several species are found in Europe. The genus *Spania*, which is the next in succession according to Macquart, has but two distinct joints to the antennæ; it contains but one species. The genus *Atherix* has the third joint of the antennæ distinct; the stylet is generally dorsal; the body depressed. All the species of this genus are European.

The third sub-family, *Dolichopoda*, is distinguished by the second joint of the palpi being membranous, depressed, and covering the base of the proboscis. The stylet of the antennæ is sometimes dorsal and sometimes apical; the eyes are generally separated in both sexes; the abdomen is somewhat cylindrical, or approaches a conical form; wings decumbent, without any discoidal cell, and generally possessing four posterior cells.

The *Syrphidæ* are a very extensive group, and although given by Macquart as a division of his family *Brachystoma*, certainly constitute a section of higher value than a sub-family. [SYRPHIDÆ.]

LEPTOCEPHALUS, a remarkable fish of the Eel tribe, discovered on the British coast in Pennant's time, and since observed in the

Mediterranean. The *Leptocephalus Morrisii* is a small, slender, and compressed animal, as thin as a piece of tape, aud at first sight resembling a marine worm. The head is extremely small and short, the eyes large, the jaws furnished with numerous miuute teeth; the pectoral fins and gill-openings very small, and the anal and dorsal fins connected with the tail. The outline of the hody resembles that of the Lancelet (*Branchiostoma*); hut the organisation of the *Leptocephalus* is that of a perfect fish. Mr. Yarrell describes the vertebræ as having no spinous processes. It lives among sea-weed.

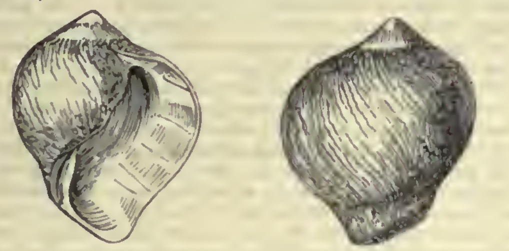
(Montagu, in 2nd vol. of the *Wernerian Memoirs*; Yarrell, *British Fishes*, vol. ii.)

LEPTOCLINUM. [BOTRYLLIDÆ.]

LEPTOCONCHUS (λεπτὸς, thin, and κόγχος, a shell), Rüppell's name for a genus of Pectinihranchiate Gasteropodous *Mollusca*. The genus is thus characterised:—Head of the animal with an elongated proboscis, hut which is entirely retractile; mouth without any apparent armour; tentacles two, flattened, triangular, short, united at their internal base, supporting the eyes at one-half of their length on their external side. Foot moderate, muscular, without any operculum. Mantle with a circular border, without ornament, and with a slight prolongation on the left side. Branchial cavity with a rather large aperture, the gill composed of a single comb formed of triangular laminæ close set one against the other: at the hottom of this cavity is found the orifice of the ovaria, whence (in the month of July) the eggs come forth in numerous hundles (par paquets nombreux), each enveloped in a viscous sac, which is flattened, elliptical, and three lines in length. In the middle of the branchial cavity is the orifice of the anus. On the right side of the neck, a little behind the right tentacle, there is another orifice, which may have some relation to the male organs of generation.

Shell subglobular, delicate, fragile, translucent, with a low spire, which is nearly effaced by the encroachment (surcroissement) of the laminæ of the last whorl. Aperture large, suboval, with its two extremities turned contrariwise, so that the aperture has some resemhlance to the letter S reversed; the two margins not united, the right one delicate at all ages, and a little expanded anteriorly as in adult *Janthinæ*. No columella. No umhilicus.

L. striatus, Rüppell. The shell of this species, which served Rüppell for the type of the genus, is a rather dirty milk white; it is furrowed externally with numerous longitudinal undulated lines very much approximated. Length of adult, 14¾ lines; breadth, 12½: young, 7¼; hreadth, 6.



1 2

Shell of *Leptoconchus striatus*. 1, anterior view; 2, view of the back.

It inhahits the Red Sea, where it is found imbedded in the calcareous mass of *Polyparia*, and having no communication with the water except hy a moderate opening. These corals prove almost always to to be a species of *Meandrina* (*M. Phrygia*) in which *Magilus*, *Venerupis*, &c., occur.

Rüppell is of opinion, from the few words of M. Rang concerning the young of *Magilus*, that the last-named naturalist had before him the genus above described. Rüppell notices the following distinctions hetween *Leptoconchus* and *Magilus*. In the former the margins of the shell are always disunited; in the latter they are always united. The animals of the two genera are distinguished hy the possession of an operculum in the one (*Magilus*) and its absence in the other, and by the difference in the proboscis; nor is the siphou of the *Magilus* present in *Leptoconchus*.

Rüppell suggests that *Leptoconchus* approximates to the *Janthinæ*. The numher of the tentacles, the oval proboscis, the mantle deprived of a siphon, the pectinated branchiæ framed of crowded pyramids, and the ahsence of an operculum, favour this approximation, as well as the analogies of the shell; hut he adds that he is perfectly aware that the difference of the hahitations of the two genera is too great to allow of a reliance on this suggestion. ('Transactions of the Zoological Society of London,' vol. i.; 'Proceedings' of the same Society, 1834.)

LEPTO'LEPIS, a genus of Fossil Ganoid Fishes, occurring in the Liassic strata.

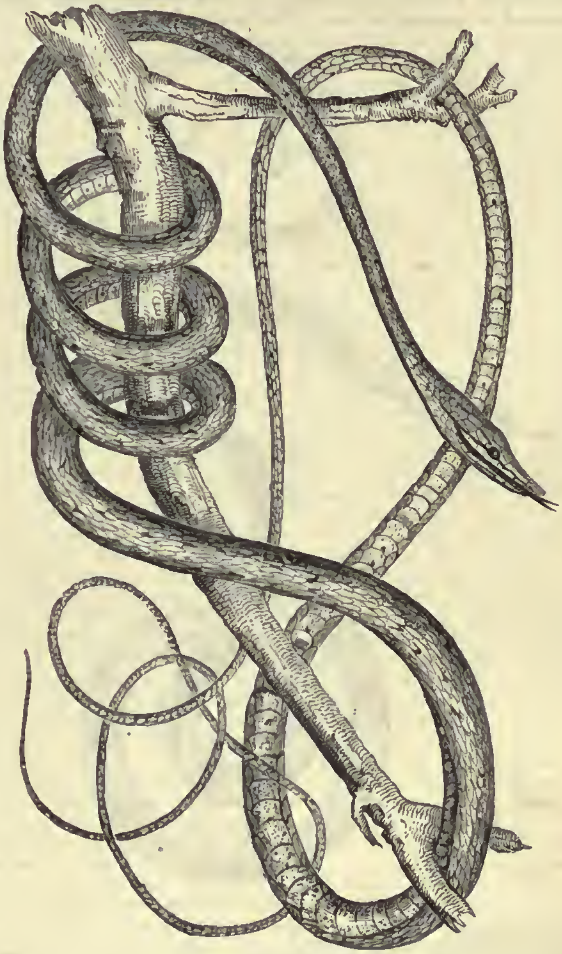
LEPTOMÆRA. [LÆMADIPODA.]

LEPTOMERIA. [SANTALACEÆ.]

LEPTON, a genus of Acephalous Lamellibranchiate *Mollusca*, belonging to the family *Kelliadæ*. This genus is closely allied to *Kellia*. Only three species havo heen described, two of which, *L. squamosum* and *L. convexum*, are British. *L. fabagella* has heen taken on the shores of the United States. The species are all small and rare.

LEPTOPHI'NA, the name given by Professor Bell to a sub-family of Serpents belonging to the family *Colubridæ*. It is thus defined:—Head elongate, hroad behind, narrowed before; the anterior part covered with nine scutæ. Eyes large. Gape wide, somewhat waved. Maxillary and palatine teeth; no poisonous fangs. Body very slender, slightly depressed. Tail very long, slender, the point acute. Dorsal scales oval, elongate, loose; caudal scales very small, closely arranged. Abdominal scuta very long; subcaudal scuta small, indistinct.

The genera *Dryinus* and *Leptophis* are included in this family, of which *Dryinus auratus* and *Leptophis purpurascens* may he regarded as examples.



Dryinus auratus. Bell.

"The whole of the serpents composing these genera live," says Mr. Bell, "in woods, entwining themselves amongst the hrauches of trees, and gliding with great rapidity and elegance from one to another. These hahits, combined with the graceful slenderness of their form, the beautiful metallic reflection from the surface in some species, and the bright and changeable hues in others, place them amongst the most interesting of the serpent trihe. Their food consists of large insects, young hirds, &c., which the extraordinary size of the head, the width of the gape, and the great dilatability of the neck and hody, enahle them to swallow, notwithstanding the small size of these parts in a state of rest. In a specimen in my possession of *Dryinus auratus*, for instance, the lcugth of which is 4 feet 9 inches, the diameter of the neck is hardly 2 lines. When the skin is distended either by food or during inspiration, the scales are separated from each other, and the skin, which is of a different colour, hecomes visible in the interstices, producing a curious reticulated appearance. Notwithstanding the poisonous mark was affixed hy Linnæus to the only species of *Dryinus* known to him (*Coluber mycterizans*, Linn.), it is well ascertained that they are all of them perfectly harmless; and it is asserted of that species that the children are in the hahit of taming and playing with them, twining them round their necks and arms, and that the snakes appear pleased at heing thus caressed."

Dryinus (Merrem).—Upper jaw much longer than the lower. Rostrum very narrow, more or less acute at the apex, which in some species is distinctly mucronate and moveahle. (Bell.)

Mr. Bell records six species, three of which are American, Carolina, Mexico, and Brazil; and the other three Asiatic, two from the East Indies and one from the island of Java.

D. auratus. Yellowish-gray, shining with pale gold-colour, dotted with whitish and black; rostrum subobtuse. It is a native of Mexico.

Leptophis (Bell).—Rostrum obtuse; upper jaw projecting, but very slightly beyond the lower.

Mr. Bell records three species, three from the East Indies, and one from America (Carolina). To these Dr. Gray subsequently added two species, *L. punctulatus* and *L. spilotus* (*Coluber spilotus*, Lacépède), collected by the expedition under Captain Phillip Parker King, R.N. ('Survey of Australia.')

L. purpurascens (*Coluber purpurascens*, Shaw). Violet, changing to green, gilded; a lateral and dorsal line of a paler hue; head obtuse. It is found in the East Indies. ('Zool. Jonrnal,' vol. ii.)

Leptophis purpurascens. Seba.

LEPTOPHIS. [LEPTOPHINA.]

LEPTOPODIA. [MACROPODIDÆ.]

LEPTOSOMA. [CUCULIDÆ.]

LEPTOSO'MUS, a genus of Birds established by Vieillot, and belonging to the family *Cuculidæ.* Example: *Leptosomus afer; Cuculus afer*, Gmel.; Edolian Cuckoo of Shaw, noticed by the late Major James Franklin, F.R.S., &c., in his 'Catalogue of Birds' collected in the Ganges between Calcutta and Benares, and in the Vindhyian Hills between the latter place and Gurrah Mundela on the Nerbudda. ('Zool. Proc.,' 1830-31.) Lieutenant-Colonel Sykes also describes and notices it in his interesting Catalogue as occurring in the Dukhun (Deccan), but as being rare. ('Zool. Proc.,' 1832.)

LEPTOSTOMA. [CUCULIDÆ.]

LEPTURUS, a genus of Grasses having solitary spikelets, imbedded alternately on opposite sides of the rachis of 1 flower and a superior rudiment. Glumes 1 or 2 opposite to the rachis, cartilaginous, covering the flower. Paleæ scarious. Stigmas feathery.

L. incurvatus has a cylindrical subulate spike; 2 glumes equalling or slightly longer than the flowers; stem from 2 to 6 inches long; spike long, curved when dry. In a variety of this species, *L. filiformis*, the spikes are much more slender, filiform, scarcely at all curved. It grows in sandy salt-marshes.

LEPTYNITE, a form of Granite in which mica is absent. It consists of a granular mixture of felspar and quartz. It is also called *Granulite.*

LEPUS. [LEPORIDÆ.]

LERISTA, a genus of Reptiles belonging to the family *Scincidæ*, established by Mr. Bell, and thus characterised by him:—Head scutated; no eyelids; ears hidden under the skin. Body slender; the scales smooth and equal. Feet four; the anterior little, very short, and didactylous; the posterior longer, and tridactylous. Vent simple, semicircular; no præanal or femoral pores.

L. lineata is bronze-green, paler beneath, with two dorsal and two lateral black lines. It is a native of Australia.

Mr. Bell observes that this new genus agrees with *Gymnophthalmus*, Merr., and *Ablepharus*, Fitzing., in the absence of eyelids, but differs from both in the number of its toes. In addition to this difference in the structure of the feet, it is, he adds, remarkably distinguished by the want of external ears, and by its elongated and anguiform body; characters in which it agrees with *Saiphos*, Gray. The last-named genus, he remarks, however, possesses eyelids, and differs also in the number of its toes from *Lerista.* ('Zool. Proc.,' 1833.)

LERNEA. [LERNEADÆ.]

LERNEADÆ, the second order of the legion *Pœcilopoda* amongst the Entomostracous *Crustacea.* [ENTOMOSTRACA.]

This order is characterised by Dr. Baird in his 'History of British Entomostraca' as follows:—Mouth suctorial; thorax not articulated; feet and other organs belonging to thoracic segment nearly rudimentary; no eyes; body very outré in appearance.

The existence of the *Lerneæ* seems to have been known to the ancients. Aristotle informs us, in his 'Historia Animalium,' that the tunny and sword-fish are tormented by a sort of worm which fastens itself under the fin, and causes such irritation to the animal that it often leaps out of the water and falls on board of ships. Pliny repeats the assertion almost in the words of Aristotle. Oppianus, in his poem 'Alieuticon,' describes the sufferings of the poor tunny and sword-fish in moving language, and asserts that the fish are frequently killed by their pigmy assailants. Athenæus repeats what his predecessors had written before him; and Salvianus, in his 'Aquatilium Animalium Historia,' 1554, quotes at length the passages bearing upon the subject from Aristotle, Pliny, Oppianus, and Athenæus. Rondeletius, in his 'Libri de Piscibus Marinis,' 1554, repeats for the sixth time Aristotle's and Pliny's accounts of this parasite of the tunny and sword-fish; and to prove his personal knowledge of the little animal in question gives a figure of a tunny, with the parasite attached, near the pectoral fin. He says it adheres so tenaciously, that it cannot be shaken off by any agitation of the body of its host.

Conrad Gesner, in his 'Historia Animalium — De Aquatilibus,' 1558, enters largely into the history of this parasite.

Boccone, a Sicilian gentleman, in his 'Recherches et Observations Naturelles,' published at Amsterdam in 1674, informs us, that at Messina his attention was called by M. Scilla, a famous painter and antiquary of that town, to the fact that the *Xiphias*, or Sword-Fish, was well known to the fishermen on the coast to be tormented by a parasite which they called Sanguisuca. The only information he received was that the motion of the creature was like that of a gimlet in plunging itself into the flesh of the fish. He succeeded however in obtaining a specimen, which he describes and figures. They bury, he says, their whole head or trunk in the flesh of the sword-fish. They are not generally confined to one part of the body, but always on such places as that the fin of the animal cannot reach them. Boccone refers this species to the *Oistros*, or *Asilus marinus* of Gesner, &c.

In 1746 Linnæus, in his 'Fauna Suecica,' first edition, described a parasitic animal found upon the *Cyprinus Carassius*, "whose blood it sucks." He established from this species the genus *Lernea.* In his 'Iter Wast Gotha,' 1747, he notices another species found on the gills of a species of *Gadus;* and in his second edition of the 'Fauna Suecica,' 1761, he adds a third, as inhabiting the gills of the salmon, which had been figured and described by Gisler, in the 'Act. Holmens.' (Kongl. Vetensk. Handling.) for 1751, under the name of *Pediculus Salmonis.* In the 'Syst. Nat.,' 12th edition, 1766, he adds a fourth species to the list, and up to that time these four constituted all that Linnæus admitted into the genus *Lernea*—a genus which, since his time, notwithstanding the difficulties attending its investigation, has increased a hundredfold, and now constitutes a large family. So bizarre in appearance are these *Lerneæ*, that Linnæus had no idea that they belonged to the *Crustacea;* on the contrary, he places them amongst the worms.

"Of all the curious creatures which the naturalist meets with in his researches," says Dr. Johnston, "there are none more paradoxical than the *Lerneæ;* none which are more at variance with our notions of animal conformation, and which exhibit less of that decent proportion between a body and its members which constitutes what we choose to call symmetry or beauty." It is no wonder then that, with the scanty knowledge he had of their habits and history, Linnæus should have considered their proper place in the system of nature to be amongst his *Mollusca;* animals belonging to his class *Vermes*, and characterised by him, from the softness of their body and the want of a shell.

In 1817 Cuvier adopted the view taken by Bosc, and in his 'Règne Animal' placed the *Lerneæ* amongst the intestinal worms.

There is nothing very instructive in this detail of the difficulties felt by systematic writers in knowing or determining where these curious and at first sight bizarre-looking animals should be placed. Little was known of their habits, manners, or mode of propagation, and though their near relations with the *Caligi* had been observed by several authors, they had not sought to resolve the question by deeper anatomical researches or investigations into their mode of life and habits. Their true position however was soon about to be ascertained. Soon after Cuvier had published the first edition of his celebrated work, the 'Règne Animal,' a French physician at Havre, M. Surriray, made the important discovery that the ova were contained in the long filaments suspended from the abdomen, and that the young when born bore no resemblance to their parent, but on the contrary were extremely similar to the young of the Cyclops. De Blainville recorded the fact in the 'Journal de Physique,' 1822, in his excellent article 'Lernea,' and fully admitted the truth of Surriray's statement. In this article he remarks the near approach of his last genus among the *Lerneadæ* to the last of the *Caligidæ*, and traced the almost insensible gradations by which we are carried from that genus to the *Caligus* itself, thence to *Argulus*, and through it to the *Apus* and other Branchiopods. He still retained them however amongst the *Epizoa*; and Desmarest, in his 'Cons. Gén. sur la Classe des Crust.,' 1825, appears to have been the first to distinctly refer them, as a group, to the class *Crustacea*.

In 1826 Messrs. Audouin and Milne-Edwards discovered a parasite upon the *Astacus*, or lobster, the *Nicothoe*; and in the course of their observations upon the history of this curious Siphonostome they came to the conclusion, reasoning from analogy, that the *Lerneæ* were real *Crustacea* that "became monstrous after they had fixed themselves" upon the animal which was to serve them with nourishment.

Kroyer informs us that several German zoologists, as Nitsch, Leuckart, and Schwegger, had advanced similar opinions, though it would appear, from his references to their observations, upon very insufficient grounds. Zoologists however were gradually coming to the conclusion that these fantastically-formed creatures were in reality crustaceous. But it is to Alexander Von Nordmann, an eminent Prussian naturalist, that we are indebted for a complete and satisfactory solution of our doubts upon the subject. In his work, 'Mikrographische Beitrage zur Naturgeschichte der Wirbellosen Thiere,' Berlin, 1832, he has confirmed the observations of Surriray upon the young when first hatched from the ova, shown the dissimilarity which exists between the male and female, and thrown much light upon the anatomy of this interesting group of animals, especially with regard to the structure of their mouth and feet. Since the publication of his excellent work his observations have received still further confirmation, additions, and corrections by three zoologists of considerable reputation—the well-known entomologist Burmeister; an Austrian naturalist, Vincenz Kollar; and the acute observer Rathke.

The form of the animals belonging to the *Lerneadæ* is very variable. "Respecting this," says Kroyer, "it is not easy to say anything general. The remark only forces itself upon every observer, that the exterior of these animals is often so highly fantastical, that we are disposed to admire the freaks of nature in bringing forth such forms. But it is evident, that when continued observations and investigations have put us in possession of the condition of these forms, we shall see here, as everywhere else, that singularity resolves itself into regularity."

For the most part the skin, or external envelope, is soft and flexible, but there are many species in which it is somewhat of a cartilaginous consistence. Nordmann has discovered that it consists of a threefold structure; an external layer, tolerably firm and elastic; next, a very loose and soft cellular tissue; and finally, a third layer, composed of a number of muscular fibres crossing each other in length and breadth, and having in consequence a reticulated appearance.

We can generally trace, more or less distinctly, a division of the body into two parts; the first of which, the smaller of the two, forms the head, and the other the thorax. This latter is generally of considerable size, whilst the abdomen, in almost all the species, has become very nearly rudimentary. Attached to the head, in the greater number of the *Lerneadæ*, we find one pair of antennæ, and two pairs of foot-jaws, by means of which they attach themselves to their prey. In a few we find no antennæ, and only one pair of foot-jaws. We find no appearance of eyes. The organs corresponding to the thoracic feet of the *Siphonostoma* are variable in form, but in general are almost rudimentary, sometimes indeed altogether wanting. It is this very rudimentary state of the organs of motion and other appendages that forms the principal mark of distinction between the *Lerneadæ* and the *Siphonostoma*. The mouth, according to Kroyer, has generally the shape of a blunt spherical snout, placed on the most advanced portion of the head, and terminating in a roundish opening, though in some of the genera it is in the form of a slight elevation merely, and is placed at a considerable distance from the anterior part of the head.

The manner in which these animals fasten themselves to the fishes upon which they live varies much. In some it is by means of the foot-jaws alone, which in these species are strong and of a hooked form. In others it is by means of two long appendages springing from the upper part of the thorax, one on each side, and uniting at the tip, forming at their junction a sort of round button. In a third set, again, the organs of attachment are a series of horns or appendages proceeding from the side of the head.

The females are generally furnished with large external ovaries, containing numerous ova. The intestinal canal is very distinct, extending through the whole body. It is cylindrical, and widens towards the middle of its length into a stomach. The motion in the living individuals may be plainly seen, a series of rhythmical movements to both sides, occurring to the number of from about 60 to 65 in the minute; besides a sort of peristaltic motion, or an alternate contracting and lengthening itself upwards and downwards.

Nordmann has described what he considers may be the liver and brain, and has pointed out the heart. This latter organ contracts and expands regularly, but no blood-vessels are to be seen, the blood flowing freely about in the hollow of the body and arms. The blood is a clear watery-like fluid, composed of three kinds of globules, differing in form and dimensions. The internal ovaries lie on each side of the intestinal canal, and open by means of a canalis deferens on each side of the inferior portion of the thorax, where the external ovaries take their origin.

In general it is only the adult female of the *Lerneadæ* that we are in the habit of observing, and in an animal whose organs of motion and perception for the most part are merely rudimentary, and whose existence is strictly stationary, the manner of life must be very simple. Immoveably fixed upon the fish which serves it for food, its existence depending upon the life of its host, it requires neither feet to transport it from place to place, nor eyes to guide it in its search for fresh abodes. In fact, the whole of its active existence consists in the two operations of taking food, and propagating its species. We find them in all instances more or less deeply fixed in the tissue of the parts upon which they have taken up their habitation, and often so deeply lodged, that little else but the oviferous tubes are visible externally. There they remain, living at the expense of their host, those that inhabit the branchiæ or are deeply fixed in the soft tissue of the bodies, drinking up the blood; and the others which are fixed less deeply, and take up their abode under the fins and such places, sucking the slimy juices of the skin. As they are never seen to change their place of residence, the question naturally occurs—how did they come there originally? Having no feet to propel them through the water, and no eyes to guide them, even if they possessed the faculty of transporting themselves from one place to another, how is it that we thus find them fixed upon these fishes, mature and possessing ova? Blainville answers this question by saying, "It is difficult to conceive how these animals, which spring from eggs, are fixed upon fishes without admitting that in their young age they possess a little motion." M. Surriray had at that time demonstrated to Blainville the existence of the young when just hatched; but less importance was attached to this discovery than it deserved; and it was not till Nordmann corroborated the fact, and followed it up by his more patient researches, that we were enabled to answer the question fully.

The circumstance that the *Lerneadæ* soon die after being taken from the fish that has served them for nourishment and a habitation, certainly throws great difficulty in our way of observing the development of the young; but we now know that when hatched, and for some time afterwards, the young *Lerneadæ* are nimble and active, and possess both the organs of motion and the faculty of using them. When they first come out of the egg they are of an oval shape, and very much resemble the young of the *Cyclopidæ*. They possess a large eye, situated in the centre of the anterior and upper part of the body, and are provided with two large pairs of swimming-feet, and a pair of jointed antennæ. As in the *Cyclopidæ*, these young *Lerneadæ* cast their skin repeatedly before they arrive at maturity. After the first moulting the body is seen plainly divided into two parts, the anterior of which is furnished with three pairs of hooked feet, and the posterior with two pairs of swimming-feet. No doubt there are a good many stages of development to go through before they assume the mature form, but it has not yet been possible to follow them out. It is not the least curious part of the history of these singular-looking animals that the young should thus stand on a higher stage of development than the mother; and that their progress from youth to maturity should be in the directly opposite ratio to that of all the other *Crustaceæ*. At what period of their existence they fasten themselves upon their prey is at present unknown; but no sooner apparently does this happen than the eye disappears, and the feet either disappear also, or are transformed into other organs. In some they are changed into foot-jaws, by means of which they fix themselves upon the body of the fish they select for their habitation. In others they are transformed into long and strong prolongations like arms, which unite together either at the tips only, or from the roots all the way up to the point, where they send forth a short horny stem, that widens into the shape of a round button, and which, when buried in the skin or flesh of the fish, forms such a strong attachment, that the *Lerneadæ* cannot be detached without being torn, or by being carefully dissected out. Most probably the species in which this development takes place first fasten themselves to their foster-mother by the foot-jaws, as the first-mentioned set do, and after being buried in the flesh, these organs assume this peculiar formation, otherwise it is difficult to conceive how such an instrument could penetrate deeply into the body of the fish. A third mode of transformation of the feet appears to be into a series of horny branchlets developed round the mouth, and which, when they have penetrated deeply into the soft parts of their host, serve effectually to retain the parasite in its place. The adult *Lerneadæ* show, with the exception of taking food and laying eggs, very few and feeble signs of life, whether attached to the nourishing animal or when separated from it. Many of the genera show no external signs of life at all after separation from their foster-mother;

others move their jaws for a short period, or their head may be seen to move leisurely in different directions for a little time and then cease. In one species (*L. branchialis*) Kroyer tells us that he observed a singular phenomenon that nobody else had before noticed. When he touched an individual, it squirted, he says, "from the vent a transparent stream of fluid to the distance of a foot and a half, and this it repeated several times one after another."

That part of the history of the *Lerneadæ* which is connected with their sexual relations and propagation is still involved in much obscurity; but the details we have received from Nordmann and Kroyer with regard to the males are no less singular than many of the other curious parts of the history of these animals. By some of the earlier observers it was supposed that those individuals which had not oviferous tubes were males, while others imagined that they were hermaphrodites. Neither of these opinions however will stand the test of inquiry. The ovaries of the female, after the eggs have attained maturity, burst and disappear, and thus, as Kroyer observes, "the *Lernea* which to-day was considered a female to-morrow might be regarded as a male." In the course of investigating different species of *Lerneadæ* Nordmann discovered, in several instances, small bodies adhering to the generative organs of the females, which on closer inspection proved to be animals that differed very much in appearance from the female, and, on the contrary, bore considerable resemblance to the young ones in the first stage of their development. These, he believed, were the males, and though Burmeister has thrown great doubts as to the entire accuracy of Nordmann's observations, his statements as to the fact of these animals being males are borne out by Kroyer and others. It is probable, as Nordmann remarks, "that the males and females are mixed together when they come out of the eggs, but that they develope themselves differently at the last change of skin." They continue to show uniformity in regard to the form of the head, and the form and situation of the parts connected with it, but they want the apparatus for attaching themselves which the females possess, having instead two pairs of strong hooked feet. They differ constantly in the form of the other parts of the body, and show a remarkable diversity from the female with respect to size, being very much smaller. These males bear a strong resemblance to each other, even in different genera, in which the females are very unlike. This fact and the preceding, namely, the great difference of size, have been considered by Burmeister as strong objections to the truth of Nordmann's conclusions. It is true many experiments and careful anatomical investigations are still wanting to establish conclusively the facts as stated by Nordmann, but still the observations made by him upon one or two genera leave little room to doubt the truth of the opinion, as regards these individuals at least. Kroyer considers that the *Lerneadæ* are at a very early age capable of breeding, though it is not yet known at what stage of development exactly they become so. Certain it is we see, in small specimens of some of these animals, small ovaries and a few eggs contained in them, whilst as the females increase in size the ovaries become larger and the eggs more numerous. Burmeister affirms that the *Lerneadæ* only propagate once, and the ovary continues to increase in size, and the eggs to increase in number, till they become mature, and that then the parent *Lernea* has played her part. Kroyer doubts this; and the opposite opinion holds better with the analogy of the other Entomostracous *Crustacea*. But upon this point direct experiments are wanting.

M. Milne-Edwards divides the *Lerneadæ* into three families, characterised by the manner in which these parasites attach themselves to their prey. Some fix themselves by means of great brachiform appendages, united together towards the end, and terminated by a horny median bouton. Others adhere by their jaw-feet, which are armed with very strong hooks. Others again attach themselves by the whole head, which is furnished for this purpose with horny prolongations of various forms. The first correspond to the *Lerneopoda* of M. de Blainville, and are designated as Lerneopodians; the second have the genus *Chondracanthus* for their type, and form M. Milne-Edward's family Chondracanthians; and the third he denominates Lerneocerians, because the genus *Lerneocera* belongs to that family, and the name recalls one of their principal characters. With regard to the establishment of generic divisions, and the characters of species, he can only, he observes, refer, in the greater number of instances, to the mode of organisation in the females; for the males are nearly entirely unknown to him, and, in his descriptions, the females are designated, unless the contrary is specified.

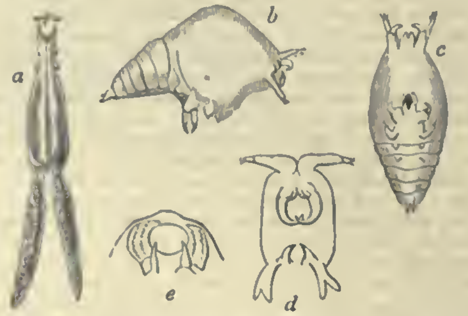
Chondracanthians.

The female Chondracanthians fix themselves upon their prey by the aid of small anchor-like jaw-feet inserted at the anterior extremity of the head and under the front. The thoracic appendages do not serve for the same use, and have the form of ordinarily two-oared feet of extreme smallness, or fleshy lobes, free at their extremity, and not prehensile. The head is in general tolerably distinct from the thorax, and nearly always carries a pair of antennæ and two pairs of unciform and anchor-like jaw-feet. On the sides of the mouth may be ordinarily perceived a pair of appendages, which represent the second pair of jaw-feet, and which are sometimes anchor-like, similar to the others, but are often rudimentary. The mouth is sometimes situated very far behind the anterior jaw-feet, and is armed with small appendages representing the mandibles. The number and disposition of the appendages corresponding to the thoracic feet vary; sometimes two pairs only are to be counted, sometimes three, and even four. The oviferous tubes spring from the posterior edge of the body, so that the abdomen is rudimentary, and is only represented by one or two small median tubercles. The male is often found attached under the anus of the female: he is extremely small, and does not resemble her in the least, but differs little from the males of the succeeding family. (Milne-Edwards.)

Genera, *Selius*, *Æthon*, *Clavella*, *Cycnus*, *Tucca*, *Peniculus*, *Lernanthropus*, *Chondracanthus*.

Selius consists of but one species (*S. bilobus*), found on the branchiæ of the dotted Polynöe; nor does *Æthon* comprise more, consisting only of *Æ. quadratus*, found on a *Serranus*, and about a line in length. *Clavella* has two species—*C. Hippoglossi*, found on the Holibut, and *C. Scari*. *Cycnus* has only one species (*C. gracilis*), found on the branchiæ of a cod-fish; and this is the case with *Tucca*, which has only one (*T. impressus*), found on *Diodon Hystrix*. *Peniculus* has but one (*P. Fistula*), found on *Zeus Aper*. *Lernanthropus* consists of two species, separated by M. Milne-Edwards into two sections—*L. pupa*, found on a Brazilian *Platax*, and *L. paradoxus*, found on the Mullets. M. Milne-Edwards remarks that *L. Musca* (De Blainville), found on a *Diodon* from Manilla, belongs to his first section.

Chondracanthus is separated by M. Milne-Edwards into two sections, with sub-divisions, and contains seven species:—*C. cornutus*, found on several flat-fish (*Pleuronectes*); *C. crassicornis*, found on a wrasse; *C. Soleæ*, found on soles; *C. Triglæ*, found on gurnards; *C. Merlucci* (from which the *C. Xiphiæ* of Cuvier does not appear to M. Milne-Edwards to differ, and to which he thinks *Lernæa radiata* of Müller, found in the buccal cavity of *Coryphæna rupestris*, appears to be very close); *C. Zei*; and *C. Delarochiana*, the last found upon the Tunny.



Chondracanthus cornutus.

a, female, magnified after Nordmann; *b*, male seen in profile, and more highly magnified; *c*, the same seen from below; *d*, head of the female seen from below; *e*, mouth still more highly magnified.

Lerneopodians.

In the females of this group the head is formed nearly as in the Chondracanthians, that is to say, distinct from the thorax, furnished with a pair of antennæ, and armed with two pairs of anchor-like jaw-feet; but the anterior jaw-feet are less proper for serving these small Crustaceans for attaching themselves to their prey, and the thorax, which carries neither feet nor fleshy appendages similar to those which represent the two first pairs of thoracic members in the preceding division, give origin to a pair of very large brachiform prolongations, which unite together, sometimes at their base, sometimes towards their extremity only, and terminate by a horny button, by the aid of which the parasite strongly adheres to the animal on which it has established its dwelling. These organs of adhesion appear to replace the first pair of thoracic limbs.

The male of only a small number of Lerneopodians is known, and where known differs extremely from the female. He has the body divided into two very distinct parts; one anterior, the cephalic, which carries the antennæ, a pair of anterior unciform jaw-feet, the sucker, and, farther back, two pairs of well-developed appendages, which represent the posterior jaw-feet and the arms of the female, but which have the form of stout hands carried on a cylindrical peduncle, and terminated by a small ill-formed pincer. The young undergo the ordinary metamorphoses. (Milne-Edwards.)

There are six genera:—*Basanistes*, *Achtheres*, *Brachiella*, *Tracheliastes*, *Lerneopoda*, and *Anchorella*.

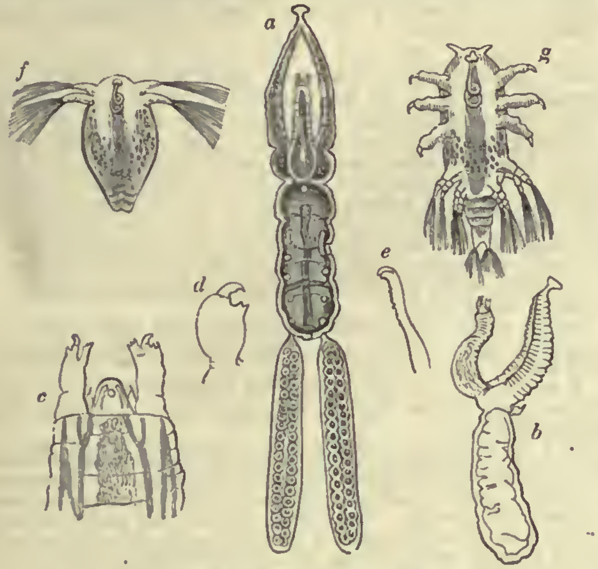
Basanistes comprises two species:—*B. Huchonis*, found on the gill-cover of the Huchen (*Salmo Hucho*), and *B. salmonea*, found on the Grayling. M. Milne-Edwards states that *Lerneopoda Brongniartii* (De Blainville) belongs to this genus.

Achtheres consists of but one species (*A. Percarum*), found on the fins of the river Perch and of the Sandra. Length about two lines.

Brachiella comprises five species, distributed into two sections, with subdivisions:—*B. Thynni* (length about ten lines, of male about half a line), found on the gills of the Tunny; *B. impudica* (length about four lines, of male about a third of a line), found on the gills of the

Haddock (*Gadus Æglefinus*); *B. bispinosa* (about three lines in length male unknown), found on the gills of the Sapphirine Gurnard (*Trigla Hirundo*); *B. rostrata*, closely approaching the preceding, found in the Greenland Seas upon *Pleuronectes pinguis;* and *B. Lophii*, found on the gills of the Sea-Devil, Toad-Fish, or Frog-Fish, at Naples.

Tracheliastes has three species, divided into two sections :—*T. polycolpus*, found on the fins of the Chub; *T. maculatus*, found on the scales of the Bream; and *T. Stellifer*, found on the branchial arches or within the mouth of *Silurus Glanis.*



Tracheliastes polycolpus. Milne-Edwards.

a, female magnified and seen from above; *b*, the same seen on the side, and deprived of the oviferous bags; *c*, anterior extremity of the body more highly magnified; *d*, appendage representing the second pair of jaw-feet; *e*, mandible; *f*, larva of the same; *g*, second age of the larva.

Lerneopoda consists also of five species, divided into two sections :—*L. stellata*, found on the fins of a Sterlet in Norway; *L. elongata* (about two inches in length), found fixed to the eye of a Shark in the Polar Seas; *L. Carpionis*, nearly approaching the preceding, found on the Salmon in the north of Europe; *L. Galei* (length about three lines, male about the same size), found on the fins of a Tope Shark (*Milandre*); and *L. obesa* (about two lines in length), found upon *Squalus Acanthias*, the Picked-Dog, or Hound-Fish.

M. Milne-Edwards thinks that *L. Dalmanni*, found on *Raia Batis*, the Skate; *L. bicaudata* (about two lines long), found on the Red Gurnard; and *L. salmonea*, belong to this genus. The last species does not seem to M. Milne-Edwards to be determinable specifically, and he makes the same remark on the *Lernæa* found by Hermann on the Dace.

Of *Anchorella* five species are recorded, distributed into two sections :—*A. emarginata* (about six lines long), found upon the gills of the Wolf-Fish (*Anarrhicas Lupus*); *A. brevicollis* (about four lines long), found fixed on the anal fin of the Variable Cod-Fish (*Gadus callarias*); *A. ovalis* (about two lines long), found upon the Red Gurnard; *A. rugosa* (about three lines long), found on the Wolf-Fish; and *A. uncinata*, found on the gills of divers *Gadi.*

M. Milne-Edwards is of opinion that *Lerneomyzon pyriformis* and *L. pinnarum* (De Blainville) belong to this genus, as well as *Lernæa adunca* of Strom and *L. anomala* of Abdilgaard.

Lerneocerians.

The female Lerneocerians, like the Chondracanthians, fix themselves to their prey by the anterior extremity of their body only, and have no brachiform thoracic appendages serving for this purpose, as may be seen in the Lerneopodians; but the arming of their mouth is far from having the form which this apparatus offers among the Chondracanthians, and the whole head of the parasite is plunged in the tissue of the animal on which it establishes its dwelling, and is there retained by horny prolongations, of varied form, which spring from its posterior or occipital part. In general the head is not very distinct from the thorax, and seems to be completely deprived of antennæ; the mouth is armed with but one pair of jaw-feet, which are simple and unciform. The feet, when they exist, are of extreme smallness, and sometimes no trace of them is to be perceived. The portion of the trunk which is situated behind the point where the oviferous tubes take their origin, and which represents the abdomen, is, in general, much more developed than in the other females of the same order.

The male of the Lerneocerians is unknown, except in very few species; and, where known, seems as imperfect as that of the Chondracanthians: his body is globular, offers no distinct thorax, and does not carry rudiments of feet behind the appendages which represent the jaw-feet. The metamorphoses which the young undergo are analogous to those of the other Lerneocerians. (Milne-Edwards.)

Genera.—*Penella, Lerneonema, Lerneocera, Lernæa.*

Penella consists of four species, divided into two sections :—*P. sagitta* (about four inches long), found on *Lophius marmoratus; P. filosa*, and *P. Blainvillii*, the last found on the Flying-Fish (*Exocœtus volitans*); and *P. Sultana* (about an inch long), found in the mouth of *Carenx Ascensionis.*

Lerneonema, also divided into two sections, comprises three species :—*L. Lesuerii* (about two inches long), found in the American Seas upon the Flying-Fish; *L. monilaris* (about an inch long), found fixed to the sclerotic coats of the eye of the Sprat (*Clupea Sprattus*); and *L. abdominalis* (about twenty lines long).

Lerneonema monilaris, magnified. Milne-Edwards.

M. Milne-Edwards states that *Lerneocera Surriraiis* (De Blainville) belongs to this group, and that it much resembles the preceding species, but is distinguished by the brevity of the abdominal portion of the body; and he is of opinion that the genus *Sphyrion* of Cuvier is too imperfectly known to enable him to determine its natural affinities, though it appears probable to M. Milne-Edwards that its place is between *Penella* and *Lernæa.*

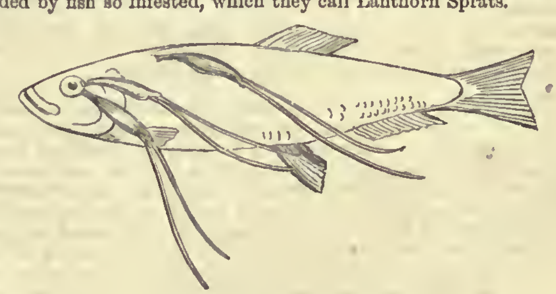
Lerneocera comprises four species, divided into two sections and sub-divisions :—*L. cyprinacea* (about eight lines long), found in Sweden on *Cyprinus Carassus; L. esocina, L. cruciata*, found in Lake Erie, on *Cichla ænea* (Lesueur); and *L. radiata*, found on *Clupea Tyrannus*, United States of America.

M. Milne-Edwards thinks that *Lernæa ocularis* of Cuvier belongs to the second section of the genus *Lerneocera.* It is found fixed to the eye of Herrings.

Lernæa consists of two species, each placed in a separate section :—*L. branchialis*, found on the gills of several species of *Gadi*, in the North Sea; and *L. multicornis.*

M. Milne-Edwards states that *L. cyclopterina* is distinguished from *L. branchialis* by certain tubercles about the head and neck. He remarks that M. Kroyer has represented it without horns, but he thinks that arose from the mutilation of the animal observed by M. Kroyer. This parasite is found in the Greenland Seas on *Cyclopterus spinosus.*

The subjoined cut, from Sowerby's 'Miscellany,' shows the external appearance of a sprat infested by these Lerneans. Mr. Sowerby names the parasite *Lernea Sprattæ* (*Lernæa Spratti*). These crustaceans are stated to be luminous at night; and the fishermen say that the shoal is often headed by fish so infested, which they call Lanthorn Sprats.



Lerneans in situ on a Sprat.

The following is Dr. Baird's arrangement of the British species of this family :—

Tribe I.—*Anchorastomacea.*

Females.—Attached to their prey by means of their foot-jaws, which are stout and armed with strong hooks. One pair of antennæ; generally very distinct. Thoracic feet nearly rudimentary, or represented by appendages of considerable size, but differing in form from ordinary feet.

Males.—Free and unattached; very small, and differing totally in appearance from the females.

Family *Chondracanthidæ.*

Organs representing thoracic feet, in form of considerable-sized, cartilaginous-looking, not articulated appendages; generally three pairs in number. Three pairs of foot-jaws.

Genus 1.—*Chondracanthus.*

Two pairs of foot-jaws prehensile, the third nearly rudimentary. Appendages of thorax representing the feet, in form of digitated, but not articulated, and not setiferous lobes or tubercles. Oviferous tubes very short, broad, and flattened.

C. Zei. Body short, and rather thick. Head rounded; antennæ short, and rather broad; neck narrow, short. Thorax carrying on the under surface two pairs of small appendages, each consisting of three divisions or fingers, and furnished laterally with three pairs of longer prolongations, of many divisions, the terminal one on each side larger than the others, and embracing the oviferous sacs; the upper part of the thorax is covered with short, conical, sharp-pointed spines. Abdomen rudimentary. Oviferous sacs flattened, containing many small ova.

It is found adhering to the gills of the *Zeus faber.*

Genus 2.—*Lernentoma.*

Foot-jaws and thoracic appendages as in *Chondracanthus.* Oviferous tubes long, either club-shaped and stout or slender and twisting.

1. *L. cornuta.* Female:—Head oval, rather elongated; antennæ flattened, of considerable size, and projecting. Thorax elongated, club-shaped; anterior portion narrow for about a third of its length, the other two-thirds much broader, and terminating posteriorly in two sharp lateral tubercles of moderate length, and a middle one representing the abdomen, which is nearly quite rudimentary. Two pairs only of thoracic appendages are visible, occurring at the upper portion of the narrow part, each divided into two digitations, and situated at a short distance from each other. The oviferous sacs are of considerable size, cylindrical, and about two-thirds the length of the body. Length nearly 3 lines.

Male:—Somewhat pyriform in shape. Head very large, swollen. Thorax conical, divided into five segments, and terminated by a rudimentary abdomen armed with two small hooks. Antennæ slender, setaceous, projecting from the anterior extremity of the head, and underneath them a pair of hook-shaped foot-jaws. Mouth situated far back, and provided with mandibles; and behind the mouth two other pairs of foot-jaws are visible. Following these we observe two pairs of setiferous tubercles representing the feet. Length, a quarter of a line.

It is found on the branchiæ of a sole.

2. *L. asellina.* Female:—Body somewhat square-shaped. Head small, and situated at the end of a long and slender neck; it is rounded at the anterior extremity, and a little below the antennæ exhibits on each side a round lobe or tubercle. The antennæ and foot-jaws are very small. The neck nearly equals in length the rest of the body. The thorax is broad, and of a somewhat quadrangular shape, with a deep indentation on each side about the middle of its length. On the upper half we see two pairs of prolongations or appendages, each divided into three digitations; and on the lower half there are three smaller appendages, but simple, not digitated. The posterior angles of the thorax are prolonged also into short horns or appendages, which are also simple. The abdomen is in form of a short tubercle, with a rounded blunt point. The oviferous sacs are of about the length of the whole animal, of considerable size, and cylindrical.

The male is similar, according to Milne-Edwards, to that of *Chondracanthus* (*Lernentoma*) *cornutus.*

It is found attached to the branchiæ of the *Triglæ.*

3. *L. Lophii.* Female:—Body rather elongate, and somewhat gibbous. Head small, having on each side a small horn-shaped appendage directed a little obliquely backwards. Antennæ small, conical, and slightly curved. Thorax divided into four portions by as many contractions. The first narrow like a neck, having on the upper portion a short spine, and on the under surface a pair of appendages or prolongations of two divisions or digitations; the second is somewhat quadrilateral, with on the middle line of the back two conical tubercles and on the sides two others, the upper pair the longer, and having on the under surface a pair of appendages of two digitations; the third part is larger than the preceding, and has the same tubercles and prolongations, and in addition a small spine on the superior portion, and in the mesial line of the under surface; the fourth portion is rather the largest, with two horns or tubercles on the upper surface, a third on the median line of the under surface, and on each side a long terminal prolongation, rather blunt. Abdomen in form of a short tubercle in the centre of the posterior part of the thorax. Oviferous tubes very long, slender, and twisted. Length, 6½ lines; breadth, 2½ lines.

The male is very similar to that of the *Chondracanthus cornutus* already described.

It is found on the *Lophius piscatorius,* in the pouches.

Tribe II.—*Anchoracarpacea.*

Attached to their prey by means of two long appendages which arise from the thorax. They unite together either at the base or near the tip only, and terminate there in a rounded knob like a button, by means of which the animal maintains its hold of the part to which it has attached itself. No thoracic feet, or they are represented by these arm-shaped appendages.

Males in general differ very much in appearance from the females, being greatly smaller and unattached.

Family I.—*Lerneopodadæ.*

Arm-shaped appendages long, wide apart from each other at their base, and united only at the tip.

Genus *Lerneopoda.*

Female.—Body generally elongated, oval. Head short and thick. Two pairs of foot-jaws, well-developed, and placed near each other. External ovarics of moderate length and cylindrical.

Male.—Body divided into two nearly equal portions of an ovoid shape; one representing the head, the other the thorax. Much smaller than the female.

1. *L. elongata.* The head is very distinct, of a horny texture, ovate, depressed, broad at the base, and obtusely pointed in front, resembling very much the shape of the body of the common Spider-Crab. The second pair of foot-jaws is large and well developed, consisting of a large rounded oval basal joint, and a more slender curved hooked terminal one, with a pretty strong tooth on its inner edge. The head is united to the body by a short narrow neck; the thorax is long and narrow, of a somewhat club-shaped form, and gives origin to two long cylindrical arms, which considerably exceed the length of the body. At the posterior portion, which is somewhat truncate, we see two small lobes; and on each side of these spring the ovaries, which are about the length of the entire body, thick, straight, and cylindrical.

Length of whole animal nearly 3 inches. Head, one line and three-quarters. Body, 7½ lines. Arms, one inch and one line. Ovaries, one inch and one line and a half.

A specimen of this arctic species was found attached to the eye of a shark caught on the English coast, and brought to London in the winter of 1848.

2. *L. galei.* Female:—The head is oval, depressed, and of a hard horny substance; the thorax is long, rather slender, and somewhat cylindrical, narrow where it is attached to the head, and broadest at its posterior extremity. The arms are slender, and nearly the length of the thorax. At the posterior extremity of the body are two small lobes, between which, on the middle line, is a small tubercle representing the abdomen. Ovarian tubes of moderate length, not quite equal to the length of the thorax.

Length of the whole body, including arms, about three-fourths of an inch.

Male:—Body divided into two portions, of an ovoid form, and nearly of equal size; the upper half represents the head, and carries a pair of antennæ, and two pairs of foot-jaws of considerable magnitude; the lower half, representing the thorax, has at its posterior extremity two sub-globular appendages a little longer than those in the female.

The female was found attached to the cavity posterior to the vent of the *Squalus galeus.*

3. *L. salmonea.* Linnæus's description of this species, as far as it goes, is very good:—"Body ovate; thorax obcordate; the two arms linear, approximated." The head is rather small, somewhat bulging out at the back part, broader there, and rather sharp-pointed at the anterior extremity. From the base of the head spring the two arms, which are rounded, and slightly shorter than the body. The thorax is pyriform and short, and at its lower extremity we see two minute eminences. The ovarian tubes are of considerable thickness, cylindrical, and about the same length as the whole animal.

The colour of the animal is white. Length about half an inch.

It is found in the gills of the Salmon, in the London markets.

Family II.—*Anchorelladæ.*

Arm-shaped appendages very short, and united to each other from the base, so as to resemble a single organ.

Genus *Anchorella.*

Female:—Body in general short, and somewhat swollen. Head small, and situated at the extremity of a long neck, which is generally curved backwards. Two pairs of foot-jaws well developed, and a third rudimentary. Antennæ rudimentary. Ovarian tubes of moderate length, and cylindrical.

The male differs in appearance very much from the female, and is very small.

1. *A. uncinata.* Female:—The body of the animal is thick, oblong, of a milk-white colour, smooth, and opaque. Head very small, situated at the extremity of a long slender neck, which has a wrinkled appearance, and is nearly the length of the thorax. The arms spring from the upper portion of the thorax, and are rather short, terminating in a rounded knob or button. At the posterior portion of the thorax there is on the middle line a small protuberance representing the abdomen. The ovarian tubes are cylindrical, straight, smooth, and about the length of the body. Length from 6 to 8 lines.

Male:—Body globular, terminated in front by a small conical eminence, at the extremity of which is the mouth, and having at its base one pair of rudimentary appendages, and a pair of rudimentary foot-jaws. On the middle of the body, on the inferior surface, there are two pairs of large hooked claw-like members. Length, one-fourth of a line.

The female fixes itself to the fins and gill-covers of the Cod and Haddock, and is most probably the most common species of our seas. (Johnston.)

2. *A. rugosa.* Body nearly of a square shape, a little emarginated on each side. Head small; neck slender, and nearly cylindrical. A rounded tubercle on the middle line represents the abdomen. Ovaries rather larger than the thorax, nearly cylindrical, or slightly club-shaped. Length, about 3 lines.

Found in the mouth of the *Gadus cellarius.*

Tribe III.—*Anchoraceracea.*

Females:—Attached to their prey by the anterior extremity of their body only, thrusting the entire head into the tissues of the animal to which they adhere, and being retained there by means of a kind of horns, which are various in form, and spring from the posterior part of the head. No antennæ. Only one pair of foot-jaws, which is simple and hooked. Feet either very small or often wanting altogether.

Males:—Very small. Body globular, and more imperfect than in the preceding tribes, having no distinct thorax, and no rudiments of feet behind the appendages which represent the foot-jaws.

Family I.—*Penelladæ.*

Several pairs of feet situated on the under surface of the body near the head, but very small and rudimentary.

Genus *Lerneonema.*

Body long, slender, narrowed anteriorly in the form of a neck, which is terminated by a swollen head furnished with two or three simple curved horn-shaped appendages. Abdominal portion of body of inconsiderable length, and simple. Oviferous tubes long and slender.

1. *L. spratta*, the Eye-Sucker. Body slender, considerably larger at the posterior extremity. Head of tolerable size, rounded, and provided with two narrow rather hooked horns at its back part, directed backwards. The head is connected to the body by means of a long and very slender cylindrical neck, which is furnished with about a dozen constrictions, which make this part of the body appear as if it were beset with an equal number of rings or knobs.

A short distance beneath the head it is very narrow, gradually increasing in size as it joins the body. Abdominal portion small, blunt, and obliquely truncate. The ovarian tubes are very long and slender, about as long again as the whole body of the animal. Length of the body about an inch; ovaries one inch and a half.

It is found attached to the eyes of Sprats.

2. *L. encrasicoli.* Body cylindrical, shorter than the preceding, and of about the same size at both extremities. The neck is long and slender, quite smooth, and destitute of the constrictions which mark so decidedly the preceding species. The neck is white, and the body is of a brown horny colour.

The abdomen is like that of the preceding, and the ovarian tubes are long and slender, at least twice the length of the body. Turton describes the ovaries as "clear white." Perhaps they may be so in the living animal, but in the specimens preserved in spirits they are of exactly the same colour as the body. In one specimen however one of the tubes is broken, and the ova have escaped, and in this the tube is white. Length of the body about half an inch; ovaries fully one inch.

It is found attached to the bodies of the *Clupea encrasicolus* and *C. sprattus.*

Family II.—*Lerneoceradæ.*

No vestiges of feet on under surface of body, nor any appendages representing them.

Genus I.—*Lerneocera.*

Body long and slender; head furnished with horn-shaped appendages, which are simple and symmetrical in form. Ovarian tubes straight, and of moderate length. Abdomen very small.

L. cyprinacea. Head furnished with four horn-shaped appendages, which are somewhat long and slender. The two outer or posterior are bifurcated; the anterior simple.

The thorax is very slender anteriorly, forming a long neck, but becomes much broader posteriorly, and when it terminates in the small abdomen appears obliquely truncate. The oviferous tubes are cylindrical, and rather long. The length of the whole animal is about 8 lines.

It is found on the sides of the Carp, Bream, and Roach, in many of our ponds and rivers, in great abundance.

Genus 2.—*Lernea.*

Body more or less twisted, and outré in appearance. Head furnished with horn-shaped appendages, which are irregularly branched. Ovarian tubes twisted into round masses, and placed under the posterior portion of the body. Abdomen of considerable size.

The genus *Lernea* is now restricted within very small limits. Established by Linnæus upon the *L. branchialis*, it is at the present day confined to that species and one or two others.

L. branchialis. Head rounded, and furnished with three horn-shaped appendages, each of which is divided at the tip into three short branches.

The anterior portion of the thorax is long, cylindrical, and very slender, like a long narrow neck, while the body itself is very much swollen in the middle, and abruptly twisted upon itself in the form of the letter S.

The abdominal portion of the body is long, blunt at the extremity, and of considerable size. The ovarian tubes are slender, and very much twisted.

The whole animal is about an inch and a half in length, and is of a very firm consistence, being hard and horny.

It is found on the gills of the Cod.

(Baird, *History of British Entomostraca;* Milne-Edwards, *Histoire Naturelle des Crustacés.*)

LESTRIS. [LARIDÆ.]

LETTUCE. [LACTUCA.]

LEUCÆTHIOPES. [ALBINOS.]

LEUCHTENBERGITE, a Mineral occurring in large but not perfectly developed crystals in the form of the rhomboid. Colour yellowish in masses, but in thin laminæ white. The texture lamellar. Lustre pearly. Transparent in small crystals. Hardness between calc-spar and selenite; is impressed by the nail. Feels greasy. Specific gravity 2·71. It is found in the Schischminsk mines in the district of Slatonst. The following is its analysis by Komonen:—

Silica	34·23
Alumina	16·31
Magnesia	35·60
Peroxide of Iron	3·33
Lime	1·75
Water	8·68
	99·90

LEUCI'SCUS, a genus of Fishes of the family *Cyprinidæ*, and section *Abdominales.* This genus, which was established by Klein, contains numerous species, of which the Roach, Dace, and Bleak afford familiar examples. The characters which distinguish them from others of the *Cyprinidæ*, or Carp tribe, consist in the comparative shortness of the dorsal and anal fins, and the want of strong spiny rays at the commencement of either, the simple lips, and deficiency of barbules about the mouth. The various species of *Leuciscus* are divided into two sections, according to the position of the dorsal fin. Firstly, those in which this fin is situated immediately above the ventral, as in the Roach, Dace, &c., and, secondly, those species in which the dorsal fin is placed above the space intervening between the ventrals and anal, as in the Chub, Rud, Bleak, &c.

L. rutilus, Cuvier, the Roach, is common in most parts of Europe, swims in large shoals, and frequents rivers, lakes, &c.; preferring somewhat still and deep waters, feeding upon worms and aquatic vegetables. It usually attains from 12 to 15 inches in length. The length of the head, compared with the whole length of the fish is as one to five; the depth, at the commencement of the dorsal fin, is to the body alone (without the head or tail) as two to five. The number of the fin-rays are—dorsal, 12; pectoral, 17; ventral, 9; anal, 13; and caudal, 19. The scales are large, and the number forming the lateral line is 43; the number of scales in the oblique line is 11; the colour of the back and upper part of the head is bluish-green or dusky green, becoming lighter on the sides of the body, and shaded into silvery-white on the belly. The dorsal and caudal fins are dusky, tinged with red; the anal, pectoral, and ventral fins are bright-red; the irides bright-yellow.

L. vulgaris, Cuvier, the Dace, is more slender and elongated than the Roach; the scales are proportionately smaller; the mouth is more deeply cleft, and the eye is not so large. The length of the head compared with that of the head and body, not including the tail, is as two to nine; the depth of the body, compared to the whole length, is as one to five. The number of scales composing the lateral line is 52: there are eight scales in the oblique line above it, and below the lateral to the ventral fin there are four. The dorsal fin commences rather behind the middle of the body, whereas in the Roach it is exactly half way between the nose and the base of the tail fin. The colouring of the upper part of the head and back is dusky-blue, becoming paler on the sides of the body, and shaded into silvery-white on the belly. The dorsal and caudal fins are pale-brown; the pectoral, ventral, and anal are almost white, but tinted with pale-red. The fin-rays are—dorsal, 9; pectoral, 16; ventral, 9; anal, 10; and caudal 19. The habits of the Dace are very similar to those of the Roach. It is found in Italy, France, and Germany, as well as our own country, generally frequenting the deep clear water of quiet streams.

"*L. Dobula*, Cuvier, the Dobule," says Mr. Yarrell, "is found in the Oder, the Elbe, the Weser, and the Rhine, as well as in the smaller streams which run into them." As yet however but one specimen has been found in this country, and was fortunately caught by the author of the 'History of British Fishes,' while fishing, in the month of August, 1831, in the Thames, below Woolwich. It is of a slender form, and the scales are of moderate size, 50 forming the lateral line, above which there are 7 in an oblique line under the dorsal fin, and below the lateral line there are 4. The length of the head, compared with that of the head and body alone, is as two to nine, and the depth of the body is equal to the length of the head. The dorsal fin commences about half-way between the anterior edge of the eye and the base of the tail-fin. The colouring is the same as in the Dace, excepting that the pectoral, ventral, and anal fins are pale orange-red. In the number of the fin-rays it agrees with the Dace.

L. Lancastriensis, Yarrell, the Graining. Pennant appears to be the first author who noticed this fish, but its characters were never clearly defined until Mr. Yarrell's account appeared in the 'Transactions of the Linnæan Society,' vol. xvii., p. 7, pl. 2, fig. 1. M. Agassiz having examined the species when in England, immediately recognised it as an inhabitant of some of the lakes of Switzerland. In this country it appears to be chiefly, if not wholly, confined to the Mersey and some streams connected with that river, where it is met with in considerable abundance.

The adult Graining is from about 7 to 9 inches in length: the length of the head, compared to the whole length of the body and tail, is as one to six; and the depth of the body, compared to the whole length, as one to five; the nose is more rounded than in the Dace, the eye is rather larger; the pre-operculum is less angular, the dorsal line is less convex, and the scales are rather larger and wider. The dorsal fin commences exactly half-way between the point of the nose and the base of the tail-fin. There are 48 scales in the lateral line, those in the oblique line from the dorsal fin to the lateral line are 8 in number, and below this line to the ventral fins there are 4. The top of the head, the back, and upper part of the sides are of a pale-drab colour tinged with bluish-red, separated from the lighter-coloured inferior parts by a well-defined boundary-line. The irides are yellowish-white; cheeks and gill-covers shining silvery-white, tinged with yellow; all the fins pale yellowish-white. The fin-rays are—dorsal, 9; pectoral, 17; ventral, 10; anal, 11: and caudal, 19.

L. Idus, Cuvier, the Ide, a species which is found in Norway, Sweden, Denmark, Russia, and some other parts of Europe, is said to have been taken at the mouth of the Nith. Its form is somewhat bulky, compared with the other species here described. "The head is large, and appears somewhat truncated; the muzzle blunt; the mouth small, without teeth, as is the case also with the other species of this extensive family; the upper jaw rather the longer; the eye of moderate size; the dorsal line convex; abdominal line almost straight; the scales of the body large; the lateral line curved in its descent from the upper edge of the operculum to the centre of the body. The fin-rays in number are—dorsal, 10; pectoral, 17; ventral, 11; anal, 13; caudal, 19; vertebræ, 41.

"In colour the irides are straw-yellow, the pupils black; forehead, nape, and back, very dark bluish-black; the sides bluish-gray; the belly white; pectoral fin orange; ventrals immediately under the dorsal fin, red in the middle, the first and last rays white; base of the anal fin white, the other part red; dorsal fin and tail gray; all the rays branched." (Yarrell.)

L. Cephalus, Flem., the Chub, is of a moderately elongated and thick form. The greatest depth of the body is contained four times and a half in the entire length, and the thickness is equal to two-thirds of the depth. The muzzle is somewhat obtuse, and the gape large. The scales are large; the number forming the lateral line is 44. Above this there are 6 scales in the oblique line to the dorsal fin; and below the lateral line there are 3 in the oblique line to the ventral fin. The dorsal fin commences half-way between the point of the nose and the base of the tail-fin; and the ventral commences in the same vertical line as the dorsal. The fin-rays are—dorsal, 10; pectoral, 16; ventral, 9; anal, 11; and caudal, 19. The colour of the upper parts is dusky-green, the sides of the body and belly silvery-white; the lateral scales are dotted with black: on the cheeks and gill-covers there is a golden hue; the irides are very pale yellow; dorsal and caudal fins dusky; pectorals pale; anal and ventral fins tinged with red, with the exception of the two or three last rays.

The Chub is common in many of the rivers of this country, often frequenting holes near the roots of trees. It lives upon insects and worms, spawns in April and May, and rarely attains a weight exceeding five pounds.

The remaining species of *Leuciscus* belong to the second division; that is to say, they have the dorsal fin placed above the intervening space between the anals and the ventral.

L. erythophthalmus, Cuvier, the Rud, or Red-Eye, somewhat resembles the Roach in form; its body however is higher and thicker, and is distinctly raised at the fore part of the dorsal fin, so as to form an obtuse angle. The greatest depth of the body is rather more than one-fourth of the entire length, and the head is one-fifth; the thickness is not half the depth. The snout is obtuse, the mouth small, the lower jaws slightly exceeding the upper in length. The scales are large: the number contained in the lateral line is about forty. In an oblique line ascending to the dorsal fin there are seven, and below the lateral line to the ventral there are four. The dorsal fin commences half-way between the point of the nose and the end of the shorter tail-rays. The fin-rays are—dorsal, 10; pectoral, 15; ventral, 9; anal, 13; caudal, 19. The upper parts are of an olivaceous colour tinged with green and blue; the sides and the belly golden-orange; irides orange-red; dorsal and caudal fins dusky; pectorals pale; anal and ventrals tinged with red, excepting two or three of the last rays.

The Rud is found not uncommonly in rivers and other deep waters in various parts of England. It spawns in April or May, and feeds upon worms, *Mollusca*, and vegetable substances.

L. cæruleus, Yarrell, the Azurine, a beautiful species, first described by Mr. Yarrell, from specimens received from Knowsley in Lancashire, approaches the Roach in shape, but is more tapered anteriorly and posteriorly, and is at once distinguished by its colour, which is slate-blue above and on the sides of the body, with the lower parts silvery-white, and by the position of the dorsal fin. This commences half-way between the eye and the end of the fleshy portion of the tail. The fins are white, the dorsal and caudal inclining to dusky. The greatest depth of the body is rather more than the entire length, and the head is equal to one-fifth of the length. The scales are rather large; the number contained in the lateral line is about forty-two. In an oblique line, from the dorsal fin to the lateral line, there are seven scales, and below the lateral line to the origin of the ventral there are three. The fin-rays are—dorsal, 10; pectoral, 15; ventral, 9; anal, 12; caudal, 19.

The only locality in England in which this fish is found is in the township of Knowsley. Mr. Yarrell however is informed by M. Agassiz that it is an inhabitant of some of the Swiss lakes.

L. alburnus, Cuvier, the Bleak, is of a more slender and elongated form than either of the preceding. The tail is very long and deeply forked. The greatest depth of the body is equal to one-fifth of the entire length, and the greatest thickness is about half the depth: the lower part projects beyond the upper. The scales are of moderate size, the number contained in the lateral line being about forty-eight. The dorsal fin commences half-way between the anterior edge of the eye and the end of the short central rays of the tail: the anal fin commences in a vertical line under the base of the last ray of the dorsal, and occupies half the space between its commencement and the base of the tail. The number of fin-rays are—dorsal, 10; pectoral, 17; ventral, 9; anal, 18; caudal, 19. The general colour is silvery-white, which is shaded into an olivaceous green on the upper parts; all the fins are whitish; the irides are silvery.

The Bleak is a small species, rarely attaining eight inches in length, and is usually about six or seven inches long. It is common in many parts of Europe, as well as of this country, usually occurring in the same streams as the Roach and Dace; it swims in great shoals, and spawns in May. The position of the fin, and colour of the eye and fins, render it easy to distinguish the species from the Dace, which it approaches nearest in general appearance.

L. phoxinus, Cuvier, the Minnow, or Minim. This pretty little fish, a well-known inhabitant of most of our running streams, appears to depart somewhat from the typical species of *Leuciscus*. Its form is slender and rounded, the greatest depth being about one-fifth of the entire length, and the thickness equal to half the depth. The fins are proportionately large, especially the dorsal, anal, and caudal. The last is not very deeply forked, and has the extremities somewhat rounded. The dorsal fin commences about half-way between the anterior edge of the eye and the end of the fleshy portion of the tail. The lateral line is straight from the tail to above the origin of the ventral fin, when it rises gradually to the upper edge of the operculum. The fin-rays are—dorsal, 9; pectoral, 16; ventral, 8; anal, 9; and caudal, 19. The top of the head and back are of a dusky olive colour; the sides of the body are paler and mottled; the belly is white and of a fine rosy pink tint in the summer, varying in intensity according to the vigour of the fish; the irides and gill-covers are silvery; the dorsal fin is pale brown; the other fins are paler, excepting the tail, which is light brown, with a dark brown spot at the base of the rays.

The scales of several of these fishes have been used in the manufacture of artificial pearls. "On the inner surface of roach, dace, bleak, whitebait, and other fishes," writes Mr. Yarrell, "is found a silvery pigment which gives the lustre those scales possess. Advantage has been taken of the colouring matter thus afforded to imitate, artificially, the oriental pearl. When this practice was most in fashion, the manufactured ornaments bore the name of patent pearl, and the use was universal in the bead-trade for necklaces, ear-drops, &c. At present it seems confined to ornaments attached to combs, or small beads arranged with flowers for head-dresses. So great was the demand formerly at particular times, that the price of a quart-measure of fish-scales has varied from one guinea to five. The Thames fishermen gave themselves no trouble beyond taking off the side scales, and throwing the fish into the river again; and it was the custom for hawkers, regularly, before selling any White-Fish, as they were called, to supply the bead-makers with the scales. The method of obtaining and using the colouring matter was, first carrying off the slime and dirt from the scales by a run of water; then, soaking them for a time, the pigment was found at the bottom of the vessel. When thus produced, small glass tubes were dipped in, and the pigment injected into thin hollow glass beads of various forms and sizes. These were then spread on sieves, and dried in a current of air. If greater weight and firmness were required, a further injection of wax was necessary. Of this pigment, that obtained from the scales of roach and dace was the least valuable; that from the bleak was in much greater request; but the white-bait afforded the most delicate and beautiful silver, and obtained the highest price, partly from the prohibitory regulations affecting the capture of this little fish, the difficulty of transmission, and rapid decomposition." (Yarrell, 'History of British Fishes.')

LEUCITE (*Amphigene*), a Mineral which occurs imbedded in lava, in trapezoidal crystals and massive. The primary form is a cube. The cleavage is parallel to the planes of the cube and the rhombic dodecahedron. Fracture conchoidal, undulating, shining. Hardness 5·5 to 6. Scratches glass with difficulty. Colour yellowish, grayish, or reddish-white. Streak white. Lustre vitreous. Transparent, translucent, opaque. Specific gravity 2·483.

Massive variety amorphous, granular. Reduced to powder, it renders vegetable blues green. Before the blow-pipe alone it is infusible; with borax difficultly forms a clear glass.

Analysis by Klaproth, from Vesuvius (No. 1), and by Arfwedson, from Albano (No. 2):—

	No. 1.	No. 2.
Silica	53·75	56·10
Alumina	24·62	23·10
Potash	21·35	21·15
Oxide of Iron		0·95
	99·72	101·30

LEUCO'JUM, a genus of Plants belonging to the natural order *Amaryllidaceæ*. It has a 6-parted perianth, bell-shaped; the segments all equal, and thickened at their points; the stamens equal.

L. æstivum, the Summer Snow-Flake, has a many-flowered spathe; a style thickened upwards. The height is from 2 to 2½ feet. The flowers are white and drooping; the tips greenish. Leaves broadly linear, keeled; scape 2-edged; spathe usually as long as the flowers. It is found in wet meadows in Great Britain.

LEUCOPHANE, a Mineral occurring crystallised in four-sided prisms, but is seldom regularly crystallised. Cleavage imperfect in three directions. Colour pale dirty-green and deep wine-yellow. Transparent and colourless in thin fragments. Lustre vitreous on cleavage surface. Hardness 3·50 to 3·75. Specific gravity 2·974. It is found at Langesundfiord in Norway. Its analysis by Erdmann gives—

Silica	47·82
Glucina	11·51
Lime	25·00
Fluorine	6·17
Sodium	7·59
Protoxide of Manganese	1·01
Potassium	0·26
	99·36

LEUCOSIA. [OXYSTOMA.]

LEVYNE, a Mineral occurring crystallised. Primary form an acute rhomboid. Cleavage parallel to its planes. Fracture conchoidal. Hardness 4·0. It scratches carbonate of lime. Colour and streak white. Lustre vitreous. Translucent. Specific gravity 2·15. When heated it yields water, and becomes opaque; swells up when heated on charcoal; with phosphoric salt gives a transparent globule, which contains a nucleus of silica, and becomes opaque on cooling. It is suspected to be merely a variety of *Chabasite*. It is found in Ireland, Faröe, and some other places. Analysis by Berzelius:—

Silica	48·00
Alumina	20·00
Lime	8·35
Soda	2·75
Potash	0·41
Magnesia	0·40
Water	19·30
	99·21

LEYCESTE'RIA, a genus of Plants belonging to the natural order *Rubiaceæ*, named after the late W. Leycester, Esq., of the Bengal Civil Service, who paid much attention to horticulture in India. The genus consists of only a single species.

L. formosa is a native of the Himalaya Mountains, at elevations of from 6000 to 7000 and 8000 feet, in Nepaul and Sirmore, where it grows among oaks and pines, and is therefore well suited to the climate of England, where indeed it may be seen growing in great luxuriance in some gardens, and showing that many others from the same situations are equally suitable to this climate, which is not the case with many shrubby Rubiaceous plants. It forms a large and very showy shrub, with numerous luxuriant smooth and cylindric fistulous shoots issuing from the root, which are of a purplish colour. The leaves are opposite, ovate-lanceolate, and glaucous; the flowers white, with a tinge of purple, arranged in drooping racemes, which are furnished with coloured foliaceous bracts.

LI'ALIS, a genus of Reptiles.

LIAS, in Geology, the name of a series of argillaceous and calcareous strata, forming the basis of the Oolitic System. The term was originally applied, in the south of England, to the calcareous beds which are at the bottom of the thick argillaceous deposits, now ranked in the Lias Formation. The lime burnt from the lias of Aberthaw, Bath, and Barrow-on-Soar, has the valuable property of setting in water. [OOLITIC SYSTEM.]

LIBELLULA. [LIBELLULIDÆ.]

LIBELLULIDÆ, a family of Neuropterous Insects, of which the Common Dragon-Fly is the type. The Dragon-Flies have horny strong mandibles and maxillæ, covered by the labrum and labium; their tarsi are 3-pointed; their wings are equal; the posterior extremity of the abdomen is furnished with hooks or peculiar appendages. The size, beauty, and habits of these insects have rendered them favourite objects of study with the entomologist. In the larva state they live entirely in the water, engaged in unceasing war with other insects, which by singular devices they entrap and devour. Their pupa state is also passed in water, and, contrary to the usual habit of insects, is a period of activity and locomotion. They are then furnished with an extraordinary mask, formed out of that part of the head which replaces the lower lip, and by which they cover the jaws and the whole under part of the head. They use it to alarm and seize their prey, projecting it at will. When perfect insects they become inhabitants of air, and are endowed with extraordinary power of flight and precision of movement, performing astonishing evolutions. Their habits continue as ferocious as they were before. When taken and imprisoned they have been known to devour their own bodies! Several valuable monographs have been published on these interesting insects by De Geer, Roesel, Vander Linden, and Charpentier; but the most important is that of M. de Selys Longchamps, entitled 'Monographie des Libellulidées d'Europe.' In this work 61 species are described, arranged under the genera *Libellula*, *Cordulia*, *Lindenia*, *Gomphus*, *Cordulegaster*, *Æshna*, *Anax*, *Calepteryx*, *Lestes*, *Sympecma*, and *Agrion*.

In the arrangement of Westwood ('Introduction to the Modern Classification of Insects') the genera of *Libellulidæ* inhabiting Great Britain are grouped under two sub-families, *Libellulides* and *Agrionides*. The following table exhibits the chief characters of the British genera:—

Sub-Family 1.—*Libellulides*.

A. Ocelli in a row	*Anax* (1 species); anal angle of posterior pair of wings rounded. *Æshna* (7 species); anal angle of posterior pair of wings more or less angulated in the male. *Cordulegaster* (1 species); anal angle of posterior wings strongly angulated.
B. Ocelli in a line; eyes remote	*Gomphus* (2 species).
C. Ocelli in a triangle	*Cordulia* (3 species); anal angle of posterior wings angulated in the male. *Libellula* (15 species); anal angle of posterior wings rounded in both sexes.

Sub-Family 2.—*Agrionides*.

A. Wings membranous	*Agrion* (13 species); stigma rhomboidal; areolets mostly quadrangular. *Lestes* (3 species); stigma oblongo-quadrate; areolets mostly pentagonal.
B. Wings coriaceo-membranous; stigma obsolete	*Calepteryx* (4 species).

LI'BER, the inner bark of a plant, is a layer consisting of woody tissue, cellular substance, and vessels of the latex, forming a compact zone immediately applied to the wood. The woody tissue of which it is composed quickly becomes thick-sided, by the addition of internal ligneous strata, the consequence of which is that such tissue in this part is more tough than elsewhere. Hence it is usually from the liber that are extracted the fibres employed in making cordage or linen-thread: this at least is its source in hemp, flax, the lime-tree, the lace-bark, and the many other Exogens which furnish thread; but in Endogens, which have no liber, as the Cocoa-Nut, it is the ordinary woody bundles of the leaves, stem, and husks of the fruit from which the fibre used for ropes is procured. It is said that certain Exogens, such as *Menispermaceæ*, have no liber. ('Comptes Rendus,' v. 393.) In many plants a new layer of liber is formed annually, comtemporaneously with a new layer of wood, but this is by no means universal; on the contrary, the oak and the elm increase their liber slowly and irregularly. [BARK.]

LIBETHENITE, *Phosphate of Copper*, a Mineral occurring in small octohedral crystals and in radiated masses. Primary form a right rhombic prism. Colour dark green. Streak green. Fracture uneven. Hardness 4·0. Transparent, translucent. Lustre resinous. Specific gravity 3·6. It is found at Libethen in Hungary. Its analysis by Berthier gives—

Phosphoric Acid	28·7
Oxide of Copper	63·9
Water	7·4
	——100

LIBI'NIA (Leach), a genus of Brachyurous *Crustacea*. [MAIIDÆ.]

LICHANO'TUS (Illiger), a genus of Cheiropeds, or *Quadrumana* (*Indri* of Lacépède, Geoffroy, and others), belonging to the family *Lemuridæ*.

The Indris are inhabitants of Madagascar, and two species only seem generally recognised, namely, *Indri brevicaudatus* of Geoffroy, *Lemur Indri* of Gmelin; and *I. longicaudatus* of Geoffroy, *L. laniger* of Gmelin, *I. laniger* of Fischer. Cuvier indeed recognises but one species, namely, that first above named, and says in a note that the other requires consideration ("a besoin d'être revu").

Dr. Fischer adopts both under the names of *I. brevicaudatus* (Geoff.) and *I. laniger*, marking however the latter as doubtful.

M. Lesson, in his 'Manuel,' also gives both species under the generic name of *Indri* (Lacépède), and the specific names of *I. brevicaudatus* Geoff. (L'Indri, Sonnerat), and *I. longicaudatus*, Geoff. (Le Maki Fauve, Buffon; Le Maki à Bourre, Sonnerat); with the following dental formula:—Incisors, $\frac{4}{4}$; canines, $\frac{1-1}{1-1}$; molars, $\frac{5-5}{5-5} = 32$; the same number recorded for both species by Fischer. M. Temminck ('Mammalogie') notices only one species.

Dr. Gray places *Lichanotus* and *Indris* in his sub-family *Lichanotina*, between *Lemurina* and *Loridina*, in his third family *Lemuridæ*, which is the first in his second or Quadrupedoid section of his order *Primates*. ('Annals of Philosophy,' 1825.)

Mr. Swainson confines the generic term *Indris* (Lacépède) to the *Lemur laniger* of Gmelin, and that of *Lichanotus* to the *Lemur Indri* (Gmelin). To both Mr. Swainson assigns the same number of incisors and grinders as that above stated; but he gives canine teeth $\frac{1-1}{1-1}$ to *Lichanotus* only. He places these two genera between *Lemur* (Linn.) and *Scartes* (Sw.), in the family *Lemuridæ*. ('Classification of Quadrupeds,' 1835.)

M. Geoffroy ('Magaz. Encyclopédique') observes that there are four cutting teeth in the upper jaw, not two, as mentioned by Sonnerat.

F. Cuvier states that the dental system of *Indri* is only known to him from the extremity of the jaws, which offers in the upper jaw incisors like those of the Red Lemur, a canine tooth very much curved and entirely like two false molars which are found immediately next to it, and which have only a single point; in the lower jaw two incisors only, the first very narrow, and the second wider, but both couched forwards ("couchées en avant"), like those of the Makis or True Lemurs, the canine small, and resembling a false molar which follows it, which has only a single point, and which is much wider before than behind, thickening from the external to the internal edge.

The figures and descriptions of these two species are given by Sonnerat in his 'Second Voyage,' and seem to be the source whence the subsequent accounts have been principally taken.

Black or Tailless Indri.

The first, noticed by Pennant as the Indri (under the title Maucauco), is described as a large animal 3½ feet high, entirely black, except on the face, which is grayish, on the lower part of the abdomen, where a grayish cast prevails, and on the rump, which is white. The face is stated to be of a lengthened dog-like form, the ears rather short but much tufted, the hair or fur silky and thick, curly in some parts. The nails are said to be flat but pointed, and there is no appearance of a tail. Like most other *Lemuridæ* it is a native of Madagascar.

The animal is described as gentle and docile, and as being trained when young for the chase, as dogs are. Its note is stated to resemble a child's crying, whence not improbably its Madagascar name Indri, which is said to signify Man of the Wood.

The other species, Flocky Lemur of Shaw, is stated to be 1 foot 9 inches from nose to end of tail, the tail being 9 inches. The colour pale yellowish ferruginous above, and white beneath; the tail bright ferruginous. The fur extremely soft, and curled deepest about the loins. Face black; eyes large and greenish-gray. The animal is described as having two fore-teeth in the upper jaw and four in the lower, and pentadactyle feet, with long claws, except the thumbs, which are furnished with rounded nails.

Dr. Shaw observes that Pennant, in the last edition of his 'History of Quadrupeds,' seems to think this animal no other than the *Lemur Mongooz*, or Woolly Maucauco; but the Doctor adds, that if Sonnerat's description be just, the species must certainly be a different one from *L. Mongooz*.

Flocky Indri.

Dr. Shaw is of opinion that Le Petit Makis Gris (Buffon, 'Supp.,' tom. vii. p. 121, pl. 34) and the Autre Espèce de Maki (Buff., 'Supp.,' tom. vii. p. 123, t. 35) are smaller varieties of the Flocky Lemur; but this view does not seem to be adopted by the more modern zoologists. Skeletons and skins of the Indris would be an acquisition to our museums, and would clear up doubtful points. [LEMURIDÆ.]

LICHAS, Dalman's name for a group of *Trilobites*, forming a division of the great genus *Asaphus* of Brongniart. [TRILOBITES.]

LICHEN ISLANDICUS. [CETRARIA.]

LICHENIN, a peculiar vegetable product, sometimes called Lichen Starch. It is obtained from the *Cetraria Islandica*, the Iceland Moss, which is to be cut small and infused in eighteen times its quantity of cold water, in which about a quarter of an ounce of carbonate of potash is dissolved for every pound of the liverwort employed. After remaining twenty-four hours the infusion is drained from the liverwort without pressure: it is then to be repeatedly washed with cold water, and afterwards boiled in nine times its weight of water down to six; the decoction is strained and the liverwort squeezed while hot; a gelatinous white substance is soon formed, which, after being dried gently on cloth, becomes of a dark colour and hard. Being redissolved in boiling water and again strained, it gelatinises.

When pure it is white, and it retains water; but on drying it becomes yellowish. In thin plates it is transparent. It is tough, tasteless, nearly inodorous, swells up when put into cold water, but dissolves sparingly in it. With hot water a gelatinous solution is obtained, which is decomposed, and yields a precipitate with di-acetate of lead, and with solution of iodine gives either a dingy green colour, or, as is stated by some authors, a blue one, as starch does.

LICHENO'PORA. The Fossils ranked under this title by Defrance are thought by De Blainville to be young *Retepora*. ('Actinologie,' p. 407.)

LI'CHENS, or LIVERWORTS, a large and important natural order of imperfectly organised Plants, belonging to the class *Cryptogamia*. The species are numerous, and are employed in the arts as pigments, and as articles of food. It is principally in the former respect that they are of economical interest, in consequence of the great consumption of Orchall, or Archil [ARCHIL, in ARTS AND SC. DIV.], Cudbear (*Lecidea tartarea*), and others by the dyer; the estimated value of the annual imports of these plants being from 60,000*l.* to 80,000*l.* [CUDBEAR, in ARTS AND SC. DIV.]

Lichens are perennial plants, requiring free access to light and air, of the most simple organisation, forming irregular patches upon the surface of stones, trees, the earth, and other bodies. Their structure is imperfectly cellular, without any trace of vascularity. The cells of which they consist are spheroidal or cylindrical, tubular or fibrous, empty or filled with a grumous matter, in a loose and indefinite state of aggregation, but generally consolidated into two strata, the one external or cortical, the other internal or medullary. The membranous or other expansion, which in these plants consists of a combination of stem and leaf, is of the most unequal and uncertain degree of development, in some species appearing like misshapen leaves spreading over the surface on which it grows, in other cases rising up as a stem of various figures; but always more or less unsymmetrical, and in many instances constituting little more than a stain upon the face of a tree or rock; this body is a frond, or, as it is technically called, a Thallus. The fructification of Lichens consists of a round or linear, convex or concave cup, called Apothecium, or Shield, at first closed, but afterwards expanding and producing a nucleus (stratum proligerum) in which are embodied the spores. The shield is surrounded by a border (excipulus) which originates either from the substance of the thallus (thallodes) or from the base of the shield itself (proprius), or from both (thallodes and proprius).

The prevalent principles found in Lichens are a peculiar kind of starch called Lichenin [LICHENIN], a bitter secretion, and a resin combined with an unctuous colouring matter, yielding purple, yellow, and brown dyes. In consequence of their bitterness some have been employed as febrifuges, as *Variolaria faginea*, *Parmelia parietina*, and several others.

The following cut shows the various stages of development in the Lichens of this country.

Lichens in fructification, in various stages of development.

1, *Usnea barbata*, with a stem and rudimentary leaves; 2, 3, *Cladonia pyxidata*, in the same state, but with its leaves disappearing; 4, *Ramalina calicaris*, with the stem nearly lost, and the shields borne upon irregular unsymmetrical expansions; 5, *Sticta herbacea*, with the stem entirely lost, and the leaves spreading over the surface of the ground; 6, *Parmelia pallescens*, with the stems and leaves consolidated, and forming only a crust with a definite margin; 7, *Opegrapha scripta*, in which nothing is formed except the letter-like fructification.

Lichens are distributed over all parts of the world, forming in the polar and similar regions a food for animals and man. *Cladonia rangiferina* supports the Rein-Deer; *Cetraria Islandica* furnishes the nutritious Iceland Moss of the druggists' shops; and various species of *Gyrophora*, under the name of Tripe de Roche, form a part of the supply of food scantily furnished by nature for the Canadian hunter. In warmer countries they acquire a firmer consistence, and appear to form secretions of a peculiar kind in much greater abundance than in the northern parts of the world. Orchall, for example, grows in Great Britain and the Canaries, and botanists can detect no external differences between the plants of these two countries; yet in the former its dyeing matter is secreted so abundantly that Canary samples fetch from 250*l.* to 350*l.* a ton in the market, while the English are unsaleable.

The order consists of between 50 and 60 genera, with about 2400 species, which are divided by Fries into 4 sub-orders—*Hymenothalami*, *Gasterothalami*, *Idiothalami*, and *Coniothalami*: to these some systematists add *Byssaceæ*. [BYSSACEÆ.] These are again subdivided into several tribes, each tribe comprising several genera.

The tribe *Usneaceæ* is characterised by having an open disc, and being destitute of an hypothallus. It embraces the genera *Usnea*, *Everina*, *Roccella*, *Ramalina*, and *Cetraria*. Several species of *Usnea* are known by the common names of Jupiter's Beard, Tree-Beard, &c., on account of their hair-like appearance. They are amongst the most common of the Lichens which cover the trunks of aged trees, and give to them a picturesque appearance. *Usnea plicata* is a common species on old trees, park-palings, &c., and has been recommended as a remedy in hooping-cough.

The species of the genus *Everina* are common in Great Britain. One of them, *E. prunastri*, has a peculiar power of imbibing and retaining odours, and on this account is in much request as an ingredient in perfumed cushions and sweet-pots. It has been recommended as a remedy in pulmonary affections. It is frequently found on the oak and other trees. Evelyn says of it:—"This very moss of the oak that is white composes the choicest cypress-powder, which is esteemed good for the head; but impostors familiarly vend other mosses under that name, as they do the fungi for the true agaric (excellent for hæmorrhages and fluxes), to the great scandal of physic." It is said that *E. vulpina* is poisonous to wolves, hence its name, but little is known of its real properties.

The genus *Ramalina* is found associated with the last two on the trunks and branches of trees, especially of the fir, the birch, the ash, the oak, the sloe, and the hawthorn. Lightfoot says that the *R. scopulorum* "will dye a red colour, and promises in that intention to rival the famous Lichen *Roccella*, or Argol, which is brought from the Canary Islands."

For the properties and uses of the species of *Roccella* and *Cetraria* see ARCHIL, in ARTS AND SC. DIV., and CETRARIA.

The tribe *Parmeliaceæ* is characterised by a horizontal thallus. To it belong the genera *Peltigera*, *Sticta*, *Borrera*, *Parmelia*, &c.

Two of the species of *Peltigera*, *P. canina* and *P. aphthosa*, have been used in medicine: the former as a remedy in hydrophobia; the latter is boiled in milk and administered in the thrush.

The species of *Parmelia* are exceedingly numerous; one of the most common throughout Europe is the *P. parietina*, Yellow Moss. The thallus and shields are both of a yellow colour; and Lightfoot says, "It is affirmed to dye a good yellow or orange colour if mixed with alum." It has also a very bitter taste, which has caused it to be used as a tonic in medicine, and it has been recommended as a remedy in intermittent fever. *P. tartarea* (*Lecanora tartarea*) yields the dye known by the name of Cudbear. [PARELLA.] *P. Parella* (*Lecanora parella*) affords the substance known as Litmus, or Lacmus. [LITMUS, in ARTS AND SC. DIV.]

One of the species of the genus *Sticta*, *S. pulmonacea*, has been used as a substitute for the Iceland Moss. [CETRARIA.] It is used in Siberia for giving a bitter flavour to beer. It is a native of Great Britain, and is found on the trunks of trees in mountainous districts, almost entirely covering them with its large shaggy fronds.

A species of *Borrera* [BORRERA], *B. furfuracea*, is reputed to be astringent and febrifuge. It is found on the trunks and branches of old trees, especially when decaying, and on old pales.

The tribe *Lecidinæ* embraces the important genus *Cladonia* [CLADONIA], and also *Cenomyce* and *Scyphophorus*, which are often only regarded as subgenera of *Cladonia*. The *S. pyxidatus* and *S. cocciferus* are elegant lichens, having their apothecia elevated above the thallus in the form of little cups, those of the latter species being coloured scarlet. They have both been used in medicine as astringent and febrifuge.

The tribe *Sphærophoreæ* contains the genera *Sphærophoron*, *Plocaria*, and *Isidium*. They are an exceedingly elegant group of Lichens, but the species have not been much used for economical purposes. *Isidium corallinum* is said to be rich in colouring matter.

The genera *Endocarpon* and *Porina* belong to the tribe *Endocarpeæ*. The species of the former genus are found on rocks and stones, whilst those of the latter are interesting as forming distinguishing marks between various kinds of barks used in medicine. Fée, in his 'Méthode Lichénographique,' has endeavoured to apply a knowledge of the various species of Lichens to the distinguishing not only between the bark of different species of *Cinchona*, &c., but also between good and bad barks of the same species.

The principal genus of the tribe *Verrucarinæ* is *Verrucaria*, of which the species are very numerous. [VERRUCARIA.]

The tribe *Graphideæ* is remarkable for the forms which the apothecia assume, bearing a resemblance to the letters of Eastern alphabets. This may be seen in *Opegrapha scripta* in *fig.* 7. As an indication of the value of the Lichens in distinguishing the various species of Cinchona Bark, Fée states that the *Graphis interrupta* is only found on the bark of *Cinchona lancifolia*. Although the study of the Lichens on the officinal barks has not produced all the advantages anticipated by Fée, there can be no doubt of its value in many cases. Referring to this subject, Burnett observes:—"Until the publication of Fée's memoir on the Cryptogamic Epiphytes of the officinal barks, the study of the Opegraphas and their allies seemed to be one rather of speculative amusement than of practical utility. But now the case is wholly changed, since these graphic plants, these living letters, written by nature's hand, are shown to constitute inscriptions legible by men. Always curious indeed, and admirable even to the least tutored eye, did the examination of these mimic characters appear; and as fancy traced the likeness to various Oriental signs, so were these little plants called Scripture-Worts, some Hebrew (*Opegrapha Hebraica*), some Chinese (*Arthonia Sinensigraphia*), and so forth. But, like the hieroglyphics of the Egyptian fanes, their meaning was buried in obscurity, and so little guessed at, that it often was doubted whether they had any secrets to reveal. They were sources of wonder rather than wisdom, until the Young and the Champollion of the vegetable world arose, and by means of a natural Rosetta-Stone deciphered these hitherto unknown manuscripts, and taught us to peruse this part of the sacred Scriptures of creation." The tribes *Calycidæ* and *Pulveraridæ* embrace several genera, amongst which are *Lepraria*, *Coniocybe*, &c.

(Burnett, *Outlines of Botany;* Lindley, *Natural System;* Lindley, *Flora Medica;* Fries, *Lichenographia Europæa Reformata*.)

LI'CINUS (Latreille), a genus of Coleopterous Insects included in the great group *Carabus* of the older authors. The genus *Licinus* is placed by Dejean in his section *Patellimanes*, and, together with the genera *Dicælus*, *Rembus*, and *Badister*, constitutes a little section or sub-family, distinguished from other Patellimanes by the want of the tooth-like process in the emargination of the mentum.

In the genus *Rembus* (Latreille) the three basal joints of the anterior tarsi are dilated in the male sex: the terminal joints of the palpi are elongated, somewhat ovate, and truncated at the apex; the mandibles project but little, are slightly arched, and pointed; the thorax is narrower than the elytra, which are almost parallel.

But two or three species of this genus (the *Carabus politus*, and *C. impressus* of Fabricius) are known; they are found in the East Indies, and are of a black colour.

Genus *Dicælus* (Bonelli) may be distinguished by the following characters:—terminal joint of the palpi securiform; labrum emarginated and having a longitudinal impression; mandibles projecting but little, without internal denticulations, slightly arched and pointed; thorax nearly square; elytra moderately long, parallel or somewhat ovate; the three basal joints of the anterior tarsi are dilated in the male sex. The species of *Dicælus* appear to be confined to North America, and about 12 or 15 are described. They are in general of a tolerably large size, averaging perhaps about three-quarters of an inch in length, or rather less. Some of the species are of a beautiful purple or bluish tint; they are however most commonly black.

Genus *Licinus*. In this genus the head is broad, short, and rounded; the thorax is generally of a rounded form, and the body depressed and ovate; the labrum is short, and emarginated in front; the terminal joint of the palpi is securiform; the mandibles are stout, short, obtusely pointed, and dentate internally; the two basal joints of the anterior tarsi are dilated in the male sex. In Dejean's 'Catalogue des Coléoptères' there are 12 species of the present genus enumerated, nearly all of which inhabit Europe. Three species inhabit this country. (Stephens's 'Illustrations of British Entomology.')

The genus *Badister* (Clairville) is distinguished by the mandibles being short and obtuse; the three basal joints of the anterior tarsi dilated in the male sex; the terminal joint of the palpi elongated, oval, and somewhat pointed; the head rounded, and the thorax cordiform. Of this genus five species are enumerated by Dejean, all of which inhabit Europe. Their small size however renders it probable that very many more will be discovered; already as great a number as that given by Dejean has been found in this country, some of which are certainly unknown to that author. The genus *Trimorphus* of Mr. Stephens appears not to be sufficiently distinct from *Badister*.

LICUALA, a genus of Palms of the tribe *Coryphinæ* of Martius, so named by Rumphius, from the Maccassar name of the species *L. spinosa*, figured by him in 'Herb. Amboin.,' i. t. 9, and which is found in the islands of Maccassar and of Celebes. Another species, *L. peltata*, is described by Dr. Roxburgh as a native of the mountainous and woody parts near Chittagong, which separates that province from the Birman territories. Both species are small, with palmate somewhat fan-shaped leaves, but of little use. Rumphius describes the narrow leaves of his tree as being formed into pipes for smoking tobacco, while the broader are employed for wrapping up fruit, and for other domestic uses.

LIEBIGITE, a Mineral containing carbonate of uranium and lime. It is found near Adrianople in Turkey, and occurs in mammillary concretions of an apple-green colour.

LIEVRITE. [IRON.]

LIFE. [VITALITY.]

LIGAMENTS, in Anatomy, the organs by which the various articulations of the animal body are held together. [ARTICULATION.] They are generally very strong membranes, and in their structure and composition resemble tendons. [TENDON.] They are in most instances attached to two bones, and assist in the formation and strengthening of the joints. Ligaments are of various forms: some completely enclose the joint as in a case or capsule, and are then called Capsular Ligaments, as is seen in the knee, hip, and shoulder joint; others form straight bands passing from one bone to another; whilst others, again, are inserted into the heads and cavities of bones within the joints. The ligaments are principally composed of the modification of areolar tissue called Fibrous Tissue. [AREOLAR TISSUE.]

LIGIA. [ISOPODA.]

LIGNIN is the substance which remains after a plant or a portion of it has been treated with water, weak alkaline and acid solutions, with alcohol, and ether, in order to dissolve all the matters soluble in these agents.

Lignin, properly speaking, constitutes the skeleton of the trunk and branches of the tree. It varies, in different kinds, as to its colour, hardness, texture, and specific gravity; and it is probable, on account of these differences, that its composition also varies. The texture of lignin is always porous, because it contains longitudinal vessels, and it is easy to split it in the direction assumed by them. The pores of lignin, when fresh, contain the juices of different substances. During the drying of lignin the water evaporates, and leaves the matters dry which it held dissolved. It is on this account that wood contracts, in drying, in breadth, but preserves its length. It is commonly admitted that timber in general consists of ninety-six parts of lignin and four parts of the substances which were held in solution by the evaporated moisture.

When lignin has been dried, it is a non-conductor of electricity; but on account of its porous nature and the deliquescent substances which it contains, it acquires moisture when exposed to the air, and then becomes a conductor: this absorption may be prevented by varnish. It is well known that wood swims in water: but when deprived of air it becomes heavier and sinks in it; its specific gravity then varying from 1·46, which is the specific gravity of fir, to that of 1·53, the specific gravity of oak and beech. Wood is gradually decomposed when exposed to the simultaneous influence of light, air, and water; but under water it may be preserved for an almost indefinite period, as is proved by the trunks of trees which have been found in a perfect state buried in the bottom of peat-mosses, and which must have been there from a period anterior to history: also when it is kept perfectly dry it is not subject to decay. The wood inclosing Egyptian mummies is found in good preservation, although some of it must be about 3000 years old.

When wood or lignin is treated with chlorine, it becomes white, but does not dissolve. Concentrated sulphuric acid in the cold converts it into gum; and if the mass thus obtained be boiled with water, it is changed into grape sugar. When treated with sulphuric acid, it is decomposed, becomes black owing to the separation of charcoal, while sulphurous and carbonic acid gases are evolved. When treated with strong nitric acid, oxalic acid is obtained; when boiled in concentrated hydrochloric acid, it becomes first reddish, then brown, and afterwards black, without being soluble either in the acid or in water.

The caustic alkalis dissolved in a large quantity of water act but feebly on wood; but if sawdust be treated with an equal weight of hydrate of potash dissolved in a little water, it swells, yields water with an empyreumatic smell, and a homogeneous liquid is formed; when this has cooled, it is of a blackish brown colour, and contains oxalic and acetic acids, with a substance resembling soot treated with an alkali. When wood is heated in iron cylinders with the necessary arrangements for the condensation of the volatile products, a great variety of important substances are obtained, besides charcoal: in this way are procured acetic acid, commonly called, till purified, pyroligneous acid, pyroxilic spirit, creasote, and tarry matter.

Some botanical and chemical writers distinguish from this substance cellulose, but as they both form the investing walls of the cells of plants it is probable they are modifications of the same chemical compound.

Cellulose may be procured from all the parts of plants without exception, by dissolving (by certain re-agents) the other substances associated with it. Pure cellulose is easily obtained from the pith of the elder-tree, or from very young roots. The substances most commonly associated with it are, starch, gum, fats, resins, vegetable alkalies, salts, sugar, and the peculiar woody matter termed by Payen matière incrustante, or lignin of the other writers. After the removal of these substances by extraction with alcohol, ether, dilute potash, hydrochloric acid, and water, the cellulose, which was previously solid and dense, assumes a spongy appearance. As a proof of its constant composition, it is worthy of mention that the following substances, previously purified in this matter, gave similar results, namely, the ovula of almonds, of apples, of the *Helianthus annuus*, the sap of cucumbers, the tissue of the cucumber, the pith of the elder-tree, the pith of the *Æschynomene paludosa*, cotton-wood, the leaves of endive and of *Aylanthus glandulosa*, the tracheæ of the *Musa sapientum*, films from the pith of oak-trees, cellulose from cow-dung (the cow fed with meadow-grass), the internal tissue of the leaves of *Agave Americana*, the skeleton of a wasp's nest, the perisperm of the *Phytelephas*, extracted lichen, membranes of the *Chara*, &c. From these and various other substances, the purified cellulose always gave a result approximating to the formula $C_{24} H_{21} O_{21}$. It is thus apparent that the proper tissue of all plants leaves a substance which is identical for all of them,—a substance which contains carbon and the elements of water, which is isomeric with inulin, and therefore easily convertible into starch and sugar; and that in its turn it may easily be produced from dextrine [DEXTRINE; STARCH], the change consisting only in the loss or gain of the elements of water. It has been shown by Von Baumhauer that sulphuric acid or diastase will convert cellulose into dextrine. It is also by the same process converted into starch. Hence it is concluded that the cellular substance is closely allied to starch, dextrine, gum, and sugar, causing their production in the vegetable kingdom, and no doubt being itself produced from one of them, namely, from dextrine. It is therefore of great importance to the animal body. It explains the nourishing power of those plants in which the incrustation of the cellulose is prevented by artificial means, as of greens, endive, sea-kale, &c. The cellulose of these plants, being easily converted into dextrine, may fairly be reckoued amongst the substances which are most serviceable in maintaining the vital functions of animals.

Further, as cellulose exists ready formed in the youngest parts of plants, it belongs, together with protein, to the first vegetable products of the food of plants; and, further, it follows that from cellulose, or from vegetable substances similarly formed, especially from one soluble in water, namely, dextrine, starch, gum, and sugar are occasionally formed. In many parts of plants we find starch, especially in the Lichens, which consist for the most part of cellulose. In many fruits containing a large proportion of cellulose, there is much sugar. These different substances may be produced from the same cellulose, simply by a change in its physical character and a new chemical arrangement of its constituents. On the other hand we observe that fleshy fruits, from being sugary, become mealy when kept through the winter; this being a converse change of sugar into cellulose. Hence, as Mulder remarks, "we may consider the cellular plants as consisting chiefly of cellulose and of protein-compounds; the vascular plants containing in addition the incrusting or real woody matter. These together are the most indispensable constituents of plants; they are found everywhere and in all their organs. Cellulose is to plants what gelatin is to animals; they form together the cells in these two kingdoms. In the cells both of plants and animals protein-compounds are either deposited in solid particles or are dissolved in the liquids with which their organs are permeated. In plants the cell-walls are thickened by the woody matter; in animals the cells contain fat and other substances; in animals, as well as in plants, the cellular substance is the chief agent in connecting all the other existing organs."

Mohl and Schleiden have shown that the cellular membrane of many parts of plants is coloured blue by iodine, just as if it contained starch. This apparent identity of reaction would lead us to infer that cellulose can often be modified as it were into starch, though still retaining the appearance of cellular membrane. The similarity of the chemical constitution of these two substances renders their conversion apparently easy. For 1 eqiv. cellulose ($C_{24} H_{21} O_{21}$) = 2 eqiv. starch ($C_{24} H_{20} O_{20}$) + 1 eqiv. water (H O). Hence, by a separation of water and a re-arrangement of the molecules, cellulose may be converted into starch; and conversely, by the absorption of water, starch may be converted into cellulose. Cellulose is the basis of the substance called Gun Cotton, which again on being dissolved in ether forms Collodion.

(Mulder, *Chemistry of Animal and Vegetable Physiology*; Gregory, *Organic Chemistry*.)

LIGNITE. Fossil wood carbonised to a certain degree, but retaining distinctly its woody texture, is thus designated. A greater degree of change constitutes Cannel and Common Coal, in which the original structure of the constituent plants can only with difficulty be traced; a less change belongs to Peat.

Dr. M'Culloch observes:—"In its chemical properties Lignite holds a station intermediate between peat and coal; while among the varieties a gradation in this respect may be traced; the brown and more organised kinds approaching very near to peat, while the more compact kinds, such as jet, approximate to coal." ('On Rocks,' p. 636.)

His synopsis of Lignite runs thus:—

A. Jet. Hard, compact, with pitchy lustre.

B. Surturbrand. Less compact and more brittle than jet.

C. Moor Coal of some authors. Friable.

D. Bovey Coal. Fibrous, the vegetable texture very apparent, colour brown or brownish-black.

E. Cologne earth, earthy and pulverulent mass. The thickness said to be 50 feet.

F. Basaltic Coal. Of variable structure; some parts like wood, others like coal.

Lignite often occurs in beds of considerable thickness and extent, and supplies to particular districts a bad substitute for coal. It is often accompanied by iron pyrites (Alum Bay), lies in alternating series with arenaceous and argillaceous beds, and is sometimes covered by fresh-water limestone (Käpfnach), and presents many analogies with coal; but in general Lignite is most plentiful in the tertiary strata, and Coal among the older rocks of the secondary series.

In the Isle of Wight (Alum Bay) Lignite beds (the wood coniferous) occur amidst the sands and clays of the lower part of the (Eocene) tertiary strata; in a depression of the surface near Bovey Tracey, Devon, a more considerable deposit of like nature occurs under several alternating beds of clay and gravel of considerable thickness. (De la Beche, 'Geol. Manual.') These deposits deserve attentive comparison with the peat moors of high and low situations in England, with and without buried forests, with the Lignite Coal of the Sussex Wealden, the Coal of the Yorkshire Oolites derived from *Equiseta*, and the Coal of the older rocks in which coniferous wood appears an abundant ingredient.

According to Brongniart ('Tableau des Terrains'), at least three deposits of Lignite of different geological ages may be distinguished in the series of tertiary strata, namely, the Lignite of Switzerland, of Mont Rouge, and of Aisne (all of Eocene date, according to Lyell's classification). Among the secondary strata one deposit is noticed by Brongniart, namely, in the Isle of Aix, belonging to the Lower Greensand, and occurrences of less importance in the Wealden of Sussex, the Kimmeridge Clay, Lias, and Grès Bigarré. Hardly any of the clays of the Cretaceous or Oolitic formations are deficient of jet, which sometimes forms considerable floors (as near Whitby), but generally lies in small portions.

The plants occurring in all these deposits are terrestrial; in the Swiss and French Lignites there are remains of palms; in the Meissner there are coniferous woods. *Mammalia* occur, especially in the Swiss Lignites, at Käpfnach, near Zürich, where *Mastodon angustidens*, *M. Turicense*, Beaver, *Rhinoceros tichorhinus*, and other remains are mentioned by different writers. One of the most characteristic genera of the animals found in Lignite (Tuscany, Styria) is the *Anthracotherium*.

LIGULATE FLOWERS are such as have a monopetalous corolla slit on one side, and opened flat, as in the Dandelion Lilac.

LIGURITE, a Mineral. Its primary form is an oblique rhombic prism. Colour apple-green. Streak grayish-white. Fracture uneven. Hardness above 5·0. Lustre of the surface of fracture between vitreous and resinous. Transparent and translucent. Specific gravity 3·49. It is found on the banks of the Stura, in the Apennines of Liguria. Its analysis, by Viviani, gives—

Silica	57·45
Alumina	7·36
Lime	25·30
Magnesia	2·56
Oxide of Iron	3·00
Oxide of Manganese	0·50
	96·17

LIGUSTRUM, a genus of Plants belonging to the natural order *Jasminaceæ*. It has a fleshy fruit, the berry containing two membranous 1-seeded nuts. The calyx is short, tubular, and 4-toothed; the limb of the corolla 4-parted, and spreading; stamens two, with short filaments. The species are shrubs or low trees, natives of Europe and Asia.

L. vulgare, Common Privet, has elliptic lanceolate glabrous leaves; compound racemes; sweet-scented flowers, white at first, but soon changing to a reddish-brown. The berries are dark purple, almost black. It is a bushy sub-evergreen shrub, growing in hedges and thickets in Great Britain, and native of the south-west of England. This plant was formerly called Prim, or Primwort, from its being used for verdant sculptures, or topiary-work, and for primly cut hedges. The common English name Privet seems to have been given to it from its being frequently planted to conceal private places. In German, Dutch, Danish, and Swedish it is called Ligster; in French, Troêue; in Italian, Ligustro; in Spanish, Alhena; and in Portuguese, Affena. It is probably the Σπίραια of Theophrastus, 'Hist. Plant.' i. 14. In point of utility and ornament few shrubs exceed the privet. Its chief use is to form hedges either for shelter or ornament. It bears cutting well, and is not liable to be disfigured by insects; having fibrous roots, it robs the ground less than almost any other shrub. It is one of the few plants that will grow in the smoke of London; it also thrives under the dripping of other trees. The wood is hard and fit for timber. From the pulp of the berries a rose-coloured pigment may be prepared; with the addition of alum they dye wool and silk of a good durable green. The following varieties are those found chiefly in our gardens:—

L. v. leucocarpum, the White-Berried Privet.
L. v. xanthocarpum, the Yellow-Berried Privet.
L. v. chlorocarpum, the Green-Berried Privet.
L. v. sempervirens, the Italian or Evergreen Privet.
L. v. variegatum, the Variegated-Leaved Privet.
L. v. angustifolium, the Narrow-Leaved Privet.

L. Sinense has lanceolate tomentose leaves, white flowers, and very small brown berries. It is a native of China, near Canton.

L. Japonicum is a native of Japan, with oblong ovate grooved leaves, and white flowers growing to the height of 6 or 8 feet.

L. spicatum has elliptic acute leaves, hairy beneath, as well as the branchlets. Flowers crowded, almost sessile, spicate, disposed in a thyrse, having the axis very hairy, and minute bracteas. It is an evergreen shrub, native of Nepaul, on mountains, growing from 6 to 8 feet in height.

All the species of Privet are of easy culture, and will grow in any kind of soil. Cuttings root without difficulty. *L. lucidum* requires some protection in the winter.

(Don, *Dichlamydeous Plants*; Babington, *Manual of British Botany*; Fraas, *Synopsis Floræ Classicæ*; Loudon, *Encyc. of Trees and Shrubs.*)

LI'GUUS, De Montfort, a genus of terrestrial Testaceous *Mollusca* belonging to the family *Helicidæ*. Dr. J. E. Gray ('Zool. Proc.,' 1834) describes a species from Africa (*L. tenuis*), and observes that in shape it is most like to the young of *Helix flammigera* of Férussac, but differs in colour, in tenuity, and in the shape of the front of the pillar-lip.

LILAC. [SYRINGA.]

LILIA'CEÆ, *Lilyworts*, an important natural order of Endogenous Plants, containing many of the most beautiful of that class of the vegetable kingdom. A large proportion, especially of those of cold countries, consists of bulbous plants, producing annually a stem which perishes after having produced its leaves and flowers; others have an annual duration with perennial fleshy roots; and a few acquire, in warm countries, a stem of very considerable size, as the Dragon-Tree (*Dracæna Draco*), of which there is an ancient specimen in Teneriffe with a stem many feet in diameter.

The flowers of Liliaceous Plants are generally large and showy, especially in those with annual stems, as the Lily itself, the Fritillary, Hyacinth, Star of Bethlehem, &c.; but when they acquire an arborescent stem the size of the flowers contracts, so that the largest trees among them have the smallest flowers. Their leaves are always quite simple and undivided, and usually have the veins of the leaves running straight from the base to the apex; but in some Dracænas they diverge from the midrib to the margin, as in the Plantain. Among other Endogens they are readily known by having a flower of 6 coloured pieces, 6 stamens with the anthers opening inwards, and a superior 3-celled ovary changing to a 3-celled fruit.

Tulipa sylvestris.

1, a magnified view of the stamens and pistil; 2, the pistil; 3, a transverse section of a ripe fruit, showing the cells and seeds.

This order is divided into several sections, of which Dr. Lindley gives the following account in his 'Vegetable Kingdom:'—

Tulipeæ are the *Lilia* of Jussieu, and they may be justly regarded as the type of the order of Lilies. Bulbs: annual stems little or not at all branched; flowers usually large and gaily coloured, without membranous spathes, but axillary to leaves but little changed, the calyx and corolla and their parts scarcely united, although often arranged in a tube; anthers swinging lightly by the fine-drawn point of a stiff filament; and finally a dry seed-vessel—separate the group from all that follow. They are amongst the gayest of our garden flowers, as Tulips, Fritillaries, and Dog's-Tooth Violets testify. One of them, the *Lilium chalcidonicum*, a plant that covers the plains of Syria with its scarlet flowers, is most memorable from having been selected by our Saviour as the subject of allusion in his Sermon on the Mount.

The *Hemerocalleæ*, or Day-Lilies, differ from the last in nothing except their calyx and corolla being so joined to each other as to form a tube of conspicuous length, and in their want of a bulb in many instances. The *Agapanthus* and the fragrant Tuberose are the more remarkable among them; but *Funkia*, *Hemerocallis*, *Blandfordia*, and the Veltheimias and Tritomas, are also species of familiar occurrence. *Phormium*, which yields the celebrated flax of New Zealand, with its hard perennial leaves and panicles of yellow flowers, must be considered to connect the present division with that of Aloes. There is so little to separate *Aloineæ*, or Aloes, from the Day-Lilies, that scarcely anything can be named except their succulent foliage, and even that disappears in *Yucca*, which has the hard leaves of *Phormium*, with which however its distinct sepals and petals forbid its being associated.

With the *Scilleæ*, or Squills, we reach a division of the order abounding in beautiful species, all of which are bulbous, with annual stems. Their peculiarity consists in the anthers not being so lightly attached to the filaments as in *Tulipeæ*, and in the leaves from whose axils the flowers proceed acquiring a membranous condition.

Conanthereæ are Squills with the ovary partially adhering to the calyx and corolla, and springing from tubers, not bulbs. They offer a direct transition to Amaryllids.

Anthericeæ, or Asphodels, agree with the last in having tubers or fleshy fascicled roots, and not bulbs, but their ovary is free; they are therefore tuberous fibrous-rooted Squills. *Chrysobactron*, a genus gathered by Dr. Joseph Hooker in Auckland and Campbell's Islands, is described as diœcious, but apparently is polygamous. The fruit in these three last orders is a capsule.

Aphyllantheæ are plants with the habit of Rushes, and the bracts so membranous and closely imbricated as to give the appearance of Xyrids when the flowers are past. They seem to form a connection between Lilies and some plants of the Juncal or Xyridal Alliances. The genera have been very insufficiently examined. Xanthorrhæas, called Grass-Trees in Australia, are very different in habit from the remainder: their shrubby stems, which emulate small palm-trees in appearance, bear tufts of long wiry foliage at their extremities, from the midst of which rise very long cylindrical spikes of densely-compacted flowers, resembling Bullrushes. [TYPHA.]

Asparageæ are Lilies with a succulent fruit. They consist of plants extremely dissimilar in appearance, the Common Asparagus and the Lily of the Valley being associated under this title. In general their leaves are broad; in the genus *Cordyline* they even acquire the expanded form and diverging veins of the Amomal Alliance: their stems, although among the dwarfest that the Lilies comprehend, are in the Common Asparagus branched and of considerable size, and in the Dragon-Trees they acquire the dimensions and age of large trees. A tendency to the separation of sexes occurs here on the part of the genus *Ruscus*, but it is not carried so far as to constitute a diclinous structure.

With respect to *Aspidistreæ*, concerning whose structure we have very insufficient information, they are principally known by a large mushroom-shaped stigma. Their foliage is that of *Zingiberaceæ*. Their flowers are dingy purple or green, with a campanulate perianth, on whose sides the stamens are inserted. In many respects they are very like *Orontiaceæ*, to which perhaps they ought to be referred.

In like manner the *Ophiopogoneæ*, or Teat-Worts, have a foliage hardly belonging to Lilies, *Peliosanthes Teta* resembling a Ginger more than a plant of this order. They are remarkable for their seeds bursting through the sides of the ovary at a very early period, growing freely though exposed to air, and finally acquiring the succulent appearance of a tuber. It is very uncertian whether they have any claims to the rank of Lilies.

The geographical limits of this order are as wide as its differences of structure. Upon the whole however the species are much more abundant in temperate climates than in the tropics, where they chiefly exist in an arborescent state. Aloes are mostly found in the southern parts of Africa; one species is a native of the West Indies, and two or three more of Arabia and the East. Dracænas, the most gigantic of the order, attain their largest size in the Canaries; a *D. Draco* there is described as being between 70 and 75 feet high, 46½ feet in circumference at the base, and was known to have been a very ancient tree in the year 1804. The northern flora comprehends for the most part plants of the genera *Scilla*, *Hyacinthus*, *Allium*, and *Ornithogalum*. In the East Indies Lilyworts are rare; in Australia they form a distinctly-marked feature of the vegetation; and in New Zealand they are represented by the *Phormium*, or Flax-Bush. A very considerable number are employed for useful purposes. Among them are those whose fibre is strong enough to furnish cordage, such as *P. tenax*, New Zealand Flax. The Onion, Garlic, and Leek, long known as articles of diet, Chives, Shalots, and Rocambole, are species of the genus *Allium*. [ALLIUM.] Aloes and Squills indicate the value of some *Liliaceæ* in medicine. As purgatives the Aloes are in extensive use. Resinous matters are yielded by some species, whence they have been useful in dysenteries. Of these the most celebrated is Dragon's Blood, a tonic astringent resin. The roots of *Asparagus racemosus* and *A. adscendens* are both employed medicinally in Northern India. *Polianthes tuberosa*, or the Tuberose, is well known for its delicious fragrance. Other species are found to contain special properties, which render them serviceable to man in various ways.

There are 133 genera in this order, and 1200 species.

(Lindley, *Vegetable Kingdom.*)

LILIALES. [ENDOGENS.]

LI'LIUM (the Latin *Lilium* and Greek Λείριον), a genus of Plants the type of the natural order *Liliaceæ*. It has a perianth of 6 leaves spreading or reflexed, with a longitudinal nectariferous furrow at the base of each; an undivided style, capitate stigma, and flat seeds. The colour of the flowers is either white, yellow, or red.

L. candidum, Common White Lily, has lanceolate scattered leaves attenuated at the base; a bell-shaped smooth corolla; the petals of a beautiful shining white on their inside, ridged and not quite so transparent or luminous on their outside. The flowers are large, white, and in a cluster at the top of the stem. It blossoms early in the summer, and has been cultivated in our gardens from time immemorial. Great doubts had existed respecting the native habitat of this species, till Mr. Hawkins, the friend and companion of Dr. Sibthorp, found it growing wild in that classical and celebrated spot the Vale of Tempe. It is the κρίνον of Theocritus ('Id.' 23) and of Dioscorides (3, 106). Both Pliny and Ovid have added their testimony to the general admiration in which this plant has been universally held. The flowers have a pleasant sweet smell, and were formerly used for medicinal purposes, particularly as an anti-epileptic and anodyne. A water distilled from them had reputation as a cosmetic, but the odorous matter they contain is so exceedingly volatile that it is impossible to preserve it, as it is wholly carried off by evaporation. The roots only are found available in medicine, and they are frequently employed as emollient poultices, owing to the mucilaginous matter which they contain. It is however doubtful whether they are more efficacious than poultices formed of bread or farina. Gerard prescribes the lily-root internally in dropsies, and for this purpose bread was made of barley-meal with the juice of the roots instead of water, and eaten for a considerable length of time. This species, as well as others, is cultivated in Siberia, and eaten as the potato. The scent of the Lily is exceedingly powerful, and peculiarly distressing in some cases. Murray mentions an instance of death ensuing from exposure to the odour of this plant.

L. bulbiferum, Bulb-Bearing or Orange Lily, has linear-lanceolate scattered leaves; a bell-shaped erect corolla, glandular and rough on the inside, downy without. The flowers are large and handsome, of a beautiful red or orange colour, pale on the outside, and without any scent. The bulb is composed of numerous thick white loosely-imbricated scales. This species, and *L. chalcedonicum*, is probably the κρίνον of Theophrastus ('Hist. Plant.,' 6, 6), and undoubtedly the ἡμεροκαλλὶς of Dioscorides (3, 127). It is a native of Italy, Austria, and North America.

L. superbum, Superb Martagon Lily, has a revolute corolla, the lower leaves whorled, the rest scattered. The flowers form a branched reflexed pyramid, and are large and handsome, one at the end of each branch, red or yellow with dark spots; their smell is disagreeable. The bulb is as white as ivory. It is a native of North America, whence it was imported by Mr. Peter Collinson in the year 1738.

L. Martagon, Turk's-Cap Lily, has whorled elliptic lanceolate leaves, a pubescent scabrous stem, nodding flowers, and a reflexed perianth. Though not a native of Great Britain it is naturalised in copses in many places.

The species enumerated are those most commonly cultivated in our gardens, each of which has many varieties and sub-varieties. They are capable of being propagated by planting the offsets of the roots and by sowing seeds to obtain new varieties. Every year the roots produce many offsets, which however, unless greatly wanted, are better left on for two or three years. The proper time for separating them is in summer and autumn, when the winter is past and the stalks decayed, either by taking them from the mother-bulbs in the ground, or removing the whole and dividing the offsets from the main bulb when uncovered; they should then be planted in beds a foot asunder and three inches deep, to remain a year or two; the large roots set again in the borders singly. The sowing of seed is chiefly practised to obtain new varieties of Martagons; it should be done in the autumn, soon after the seed is ripe, in pots or boxes of rich light sandy earth, with holes in the bottoms half an inch deep. The pots or boxes should be placed in a sheltered position during the winter, and refreshed often at first with water. The plants will appear in the spring; in August they should be transplanted into nursery-beds in flat drills an inch deep and three or four inches asunder. After having grown in this situation till the August or September following they should be again transplanted into another bed, and at greater distances; after which they may be finally removed into the pleasure-ground. The bulbs should be planted singly, as they soon increase by offsets into large bunches. All the species and varieties of *Lilium* are valuable as plants of ornament for the beauty of their flowers, which have a noble appearance. They are proper for the pleasure-ground, and if planted with judgment succeed each other in blooming upwards of three months. The Common White Lily, the Orange-Lily, and Martagon will thrive under trees. The Orange-Lily also answers well for small gardens and confined situations in towns and cities.

LILY. [LILIUM.]

LILY-BEETLE. The *Crioceris merdigera*, a species of *Coleoptera*, is thus named. [CRIOCERIDÆ.]

LILY-ENCRINITE. [ENCRINITES.]

LIMA. [PECTINIBRANCHIATA.]

LIMACELLA. [LIMAX.]

LIMACIDÆ. [LIMAX.]

LIMACINA. [HYALÆIDÆ.]

LIMACI'NEA, M. De Blainville's name for his third family of *Pulmobranchiata*, the first order of his second sub-class, *Paracephalophora Monoica*. M. de Blainville thus defines the family, which comprises the genus *Helix* of Linnæus:—

Animal very variable in form; the head provided with two pair of tentacula completely retractile into the interior, the posterior pair longest, carrying the eyes on their extremities; one tooth in the upper lip; the lingual mass small, and covered with a skin beset with microscopic teeth.

Shell of a form as variable as the body of the animal, rarely sub-ampullaceous, often normal, oval, or globular, sometimes turriculated, pupaceous, or discoid, almost constantly without an epidermis, rarely hairy (velue), with the summit always blunt; the aperture round, semilunar, oval or angular, but never notched.

M. De Blainville adds, as an observation, that all the animals of this family are terrestrial; and that, with the exception of *Testacella*, all feed on vegetable substances.

The following are the genera comprehended under the *Limacinea* in the 'Malacologie' of the author above quoted:—

Succinea, comprehending also *Amphibulimus* of Lamarck.

Bulimus, comprehending also *Bulimulus* of Leach.

Achatina, comprehending also the genera *Liguus* of Denys de Montfort, and *Polyphemus* of the same author.

Clausilia.

Pupa, comprehending also the genera *Chondrus* of Cuvier, *Gibbus* of Denys de Montfort, *Vertigo* of Müller, and *Partula* of De Férussac.

Tomogeres of De Montfort (*Anostoma* of Lamarck).

Helix, comprehending the genera *Carocolla*, Lamarck; *Iberus*, De Montfort; *Caracolus*, De Montfort; *Acavus*, De Montfort; *Helicella*, Lamarck; and *Zonites*, De Montfort.

Helicolimax (Vitrine), including the genus *Helicarion* of De Férussac; *Testacella, Parmacella, Limacella.*

Limax, including the genera *Arion*, De Férussac; Philomique of Rafinesque; and Eumèle of the last-named author.

Onchidium, including *Veronicella*, Blainville. [HELICIDÆ; LIMAX.]

LIMAX, the Latin name for those air-breathing naked Gastropodous Molluscs, so injurious to the agriculturist and horticulturist, vernacularly known by the name of Slugs.

Linnæus employed the term *Limax* as a generic appellation for the Naked Slugs, placing the genus at the head of his (*Vermes*) *Mollusca*, and comprehending under it eight species, all terrestrial excepting the last, namely, *L. papillosus*, to which he assigns the European Ocean as a locality, adding that the animal is submarine, and should probably be rather referred to the genus *Doris.*

The following is the definition given by Linnæus:—

Body oblong, repent, with a fleshy shield above and a longitudinal flat disc below. A dextral lateral foramen for the genitals and excrements. Four tentacles above the mouth. ('Systema Naturæ,' ed. 12, 1767.)

In addition to this employment of the term, Linnæus used the word *Limax* to designate the soft parts of most of the genera of his (*Vermes*) *Testacea*, indeed of all that progress upon a flattened disc or foot, marine as well as terrestrial; for the very imperfect information of the time when he wrote did not enable him to make those distinctions which modern zoologists have pointed out, aided by more copious materials, and by the labours of accurate zootomists and observers bestowed upon those materials. Thus we find in the 'Systema Naturæ:'—"*Conus.* Animal Limax."—"*Cypræa.* Animal Limax."—"*Bulla.* Animal Limax."—"*Voluta.* Animal Limax." In short, the animal of each genus of his 'Univalvia spirâ regulari,' with the exception of *Argonauta* and *Nautilus*, is stated to be a *Limax;* and the same animal is also assigned to *Patella*, which stands at the head of his 'Univalvia absque spirâ regulari.'

Cuvier, in the first edition of his 'Règne Animal' (1817), places the 'Limaces' (*Limax*, Linn.) at the head of his Pulmonés Terrestres, nearly all of which he describes as having four tentacles; two or three only of very small size not having exhibited the lower pair—"n'ont pas laissé voir le paire inférieure." Those among them, he adds, which have no apparent shell formed, according to Linnæus, the genus *Limax*, which Cuvier subdivides into the groups of the Limaces, or Slugs properly so called (*Limax*, Linn.); the Testacelles (*Testacella*, Lam.); and the Parmacelles (*Parmacella*, Cuv.). In the last edition of the 'Règne Animal' (1830), he adds under *Limax* the subdivisions distinguished by De Férussac, namely, *Arion* and *Vaginulus*.

In both editions he describes the 'Limaces proprement dits' as having an elongated body, and for a mantle a fleshy compact disc, which occupies the anterior part of the body alone, and covers the pulmonary cavity only. This disc contains, he adds, in many species, a small oblong and flat shell, or at least a calcareous secretion in lieu of it. The orifice of respiration is on the right side, towards the front, and the anus is pierced at its posterior border. The four tentacles are put forth and withdrawn by unrolling themselves (en se déroulant) like the fingers of gloves, and the head itself can be withdrawn in part under the disc of the mantle. The organs of generation open under the right upper tentacle. There is but one jaw (upper), in the form of a dentilated crescent, which serves them to gnaw with much voracity the herbs and fruits to which they do so much damage. Their stomach is elongated, simple, and membranous.

Lamarck ('Histoire Naturelle des Animaux sans Vertèbres,' tom. vi. part. ii. 1822) thus defines his Limaciens:—Branchiæ creeping (rampantes), under the form of a vascular net upon the wall (paroi) of a particular cavity, the aperture of which is a hole which the animal contracts or dilates at its pleasure. They respire the free air only.

The same zoologist remarks that the Limacians constitute a natural family and a very remarkable one, inasmuch as the animals which compose it are the only ones among the Gastropods whose respiratory organ, which is truly branchial, breathes nothing but free air, and he thence names them Pneumobranchea. These mollusca, he continues, are naked or nearly naked. Their body is elongated, creeping upon a ventral disc which is not separated from it, and bordered on the sides by a mantle which is most frequently very narrow. Originally from the waters (originaires des eaux), they live habitually in their neighbourhood; but some inhabit, nevertheless, places which are at a distance from the water, but nearly always in cool and humid localities. They have accustomed themselves (ils se sont accoutumés) to breathe air with their branchiæ; so that this habit has become a necessity to them. Here it is, for the first time, as regards the mollusca, that the free air is the fluid breathed. This fluid penetrates by a hole, and without either trachea or bronchiæ into a particular cavity which is not divided into many partitions (loges) or cellules, but on the walls of which little lace-like vessels or a vascular network (des cordonnets ou des lacis de vaisseaux) creep in divers forms and receive the influence of the respiration. A similar or analogous cavity is found in a great number of the Trachelipods; but in those which respire air only, the influence of this fluid, being very superior to that of water, requires in the organ presented to it only a very small surface. Thus the vascular lace-like work (cordonnets vasculaires) which creeps over the walls of the cavity, and which in that respect resembles the same parts in the Limacians, projects very little; whilst in those which respire water only the cavity offers very projecting and vascular parts (such as pectinated laminæ of different sizes) to the influence of the fluid respired. The branchial cavities of which we are speaking, even that which is adapted for breathing air only, cannot be reasonably confounded with a lung, which is a respiratory organ of a particular fashion, adapted to organisations of a superior order, an organ which is essentially cellular, and into which the fluid respired is introduced at least by an internal trachea, and often by bronchiæ besides. This modification, then, of the respiratory organ has peculiar characters which branchiæ or gills, whatever be their form and situation, never offer. If, in order to determine the name or the kind (espèce) of a respiratory organ, that organ is considered only with reference to the fluid respired, then all animals which respire free air may be said to possess a lung; but if, in order to facilitate the study of the different modifications of organs which serve for respiration, and in order to seize the means which nature has employed to effect the progressive composition of the animal organisation as well as its perfection, one considers the characters proper to each sort of respiratory organ, it will then be evident that no mollusc nor any other invertebrate animal respires by means of a lung, although many among them respire the free air. Besides, independently of the particular and well-known structure of every lung, the air never penetrates except by the mouth of the animal, whilst in every respiratory organ distinct from a lung the fluid respired, whatever it be, is always introduced by another passage. To confound objects so different, each of which is appropriated to the degree of organisation to which it belongs, and can only exist in an organisation of that degree, is, in our opinion, to render the knowledge of the order of nature in her productions impossible. In fact, in the course of the animal kingdom, such a function could not be executed except by an organ or system of organs differently modified, because it must be in relation with the state of organisation of which it forms a part.

To return, continues Lamarck, to the particular object before us, I will say that branchiæ, although they present themselves under a multitude of forms and different situations, never resemble, notwithstanding, a lung. This respiratory organ, then, is peculiar; and we know that it has the power of habituating itself to respire air. In fact many Crustaceans which live nearly constantly on land respire there this last fluid only with their branchiæ. If the Colimacés, as well as the Limneans, have a branchial cavity similar to that of the Limacians, and breathe the free air only, this cavity is also the same as that of the Melanians and other Trachelipods which breathe water only. But in the first the respiratory organ presents a small surface only to the fluid respired; whilst in the second the organ in question offers a much larger extent of surface. In each case these organs are always branchial, but adapted to the power of the influence of the fluid respired, and situated in analogous cavities.

Thus far Lamarck, who concludes by comprehending under his Limacians the following five genera:—*Onchidium*, *Parmacella*, *Limax*, *Testacella*, and *Vitrina*.

The second section of the Limacineans of M. De Blainville, or those which have the anterior border of the mantle enlarged into a species of buckler, the shell being null or nearly membranous, consist of the genera *Vitrina*, or *Helicolimax*, *Testacella*, *Parmacella*, *Limacella*, *Limax*, and *Onchidium* [LIMACINEA]. With regard to the marine species, which Cuvier has approximated to these, M. De Blainville observes that they constitute his genus *Peronia* in his order of Cyclobranchians. [NUDIBRANCHIATA.]

M. Rang arranges the Limaces of Férussac (Limaciens of Lamarck, Limacinés of De Blainville, Nudilimaces of Latreille) as the first family of the Pulmonés Inoperculés of De Férussac (Pulmobranches of De Blainville), and makes it consist of the genera *Onchis*, Fér.; Onchidie, Cuv.; *Peronia*, De Blanv.; *Onchidium*, Buchanan; *Veronicella*, De Blanv.; *Vaginulus*, De Fér.; having a general cuirass.

The genera *Limacella*, Blainv.; *Limax*, Lam. (including *Arion*, Fér.); *Parmacella*, Cuv.; which have a partial cuirass: and

The genus *Testacella* (including the Plectrophoro) of Férussac, which is without any cuirass.

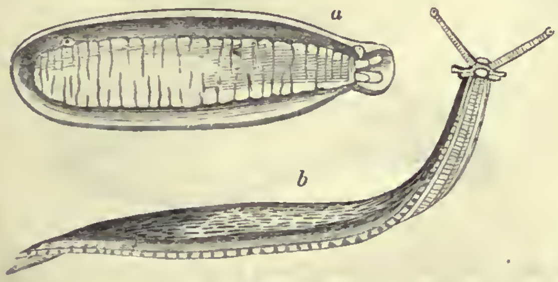
M. Deshayes makes the following remarks on Lamarck's classification of this group of *Mollusca*:—"We have already censured in the method of Lamarck the separation of the Gastropods and the Trachelipods—a separation artificial and useless, especially as regards the grand series of molluscs, where this division is the less tolerable, because there it is that the passage of the Gastropods, properly so called, and of the Trachelipods is effected in the most imperceptible manner and by means of a curious series of modifications. Cuvier, who, in his memoir on the *Limaces* and *Helices*, has justly advanced the proposition that there scarcely exist any zoological characters proper for the distinction of these two genera, could not coincide in the opinion of Lamarck, and in this he was wisely imitated by the greatest number of zoologists. M. de Férussac collected into two orders all the air-breathing molluscs, according as they were or were not provided with an operculum. Those which are operculated are few, and consist of two genera only, which we find among the Trachelipods of Lamarck. Those which are not operculated comprise a considerable number of genera grouped in families. The first is that of the Limaces, corresponding exactly enough with the family of Limacians of Lamarck. It comprehends however twelve genera, whilst that of Lamarck only contains five; but when we come to examine attentively these different genera admitted by M. de Férussac, we soon perceive that many are too uncertain to be definitely adopted. M. De Blainville himself has rejected many of the genera of this family which he had at first adopted; and in his 'Treatise on Malacology' he has reduced them to five. M. Cuvier, in the last edition of the 'Règne Animal,' has not adopted more than the genus *Vaginulus*, to which M. De Blainville has given the name of *Peronia*, which occasions a sad confusion in nomenclature. It will suffice then to add the genus *Vaginulus* to the family of *Limacians* of Lamarck, to render it as complete as the most positive observations require."

Dr. J. E. Gray is of opinion that at present only a few genera, as *Arion* and *Helicarion*, Fér., *Nanina*, Gray, and *Stenopus*, Guilding, can be referred with certainty to the *Arionidæ*, though he thinks it very probable that, when the animals of other shells are known, many of them may be found to belong to that family. In this state of our information we shall confine ourselves in this article to those forms of the naked truly terrestrial *Limacidæ*, which are for the most part popularly known under the name of Slugs, and shall notice the genera with external shells under their respective titles, though we quite agree in the principle of the general similarity of the zoological characters of the *Limaces* and *Helices*, and the almost imperceptible gradation of form among them. [HELICIDÆ.]

Vaginulus (Férussac). Animal oblong, elongated, often very slender in its state of extension, convex above; a cuirass covering the whole of the body, extending beyond it, and forming in front a sort of hood, wherein the head can be withdrawn; mouth armed with an upper jaw; four contractile tentacles, the two upper ones long and oculiferous, the anterior short, and, as it were, palmated or bifurcated at their extremity; the foot oblong, elongated; the respiratory cavity towards the middle of the body having its orifice behind, at the extremity of a long canal, and separated from the anus by a membrane only: organs of generation very distinct on the right, the male organ being near the small tentacle, and the orifice for the eggs towards the middle; no terminal mucous pore.

Shell null, there being neither rudimentary internal shell nor calcareous concretion. (Rang.)

V. Taunaisi (*Onchidium lœve*, Blainville), may be taken as an example.



Vaginulus.

a, the animal contracted (under side); *b*, the animal extended and in progression.

The genus *Vaginulus* is found in East and West Indies. M. Rang, who remarks that they have been said to be both terrestrial and fresh-water, states that he never met with them in Bourbon and Martinique, except in the woods and gardens under old fallen trunks.

There is great confusion about the nomenclature of *Onchidium*, *Peronia*, *Veronicella*, and *Vaginulus*. Cuvier observes that *Vaginulus* is different from *Onchidium*, with which M. De Blainville has united it, at the same time that he has detached the true *Onchidia*, to form his genus *Peronia*. It appears in fact, as M. Deshayes observes, that M. De Blainville has made of the marine *Onchidia* of Cuvier his (De Blainville's) genus *Peronia*, which he places in his family *Cyclobranchiata* near *Doris*, and that he collects the fresh-water species under the genus *Vaginulus*, to which he unites his genus *Veronicella*, which last he has himself rejected.

Limacella (De Blainville).—Animal elongated, sub-cylindrical, provided with a foot as long and as large as itself, from which it is separated only by a furrow; enveloped in a thick skin, forming at the anterior part of the back a sort of buckler for the protection of the pulmonary cavity, the orifice of which is at its right border; the orifices of the generative apparatus distant, that of the oviduct at the posterior part of the right side, and communicating by a furrow with the termination of the male organ, situated at the root of the right tentacle.

L. Elfortiana is a good example.

Limacella Elfortiana.

Limax.—Animal oblong, more or less elongated, demi-cylindrical, furnished with a cuirass at the anterior part; head sufficiently distinct, retractile under the cuirass, carrying two pairs of tentacles equally retractile, terminated in a rising (bouton), the upper pair long and oculiferous, the lower pair short; foot great and oblong, the pulmonary cavity situated under the cuirass, and opening under its right border; orifice of the anus at the posterior border of that of the respiratory cavity; organs of generation united and showing themselves at the right side anteriorly, near the great tentacle; sometimes a terminal mucous pore. A rudimentary internal shell, or calcareous concretions in the thickness of the cuirass.

Such is the general definition of *Limax* by M. Rang. He observes that M. De Férussac seized on certain anomalies in the characters of these molluscs, which led the latter to separate a certain number, out of which he forms his genus *Arion*. M. Rang observes that this distinction has not been adopted by M. De Blainville, excepting for the establishment of two sections; but M. Rang thinks it better to form the whole into two sub-genera, namely, *Arion*, Férussac, and *Limax*, the latter consisting of the slugs properly so called.

M. De Blainville divides the genus *Limax* into four sections: the 1st consisting of those species in which the pulmonary orifice is very anterior, the tail carinated, and the rudiment of the shell most evident. This section consists of the Gray Slugs; *Limax griseus* is given as an example.

The 2nd section consists of species whose pulmonary orifice is more posterior; the tail not carinated, hollowed at its extremity into a blind sinus, and the rudiment of the shell granulous. This section consists of the Red Slugs (genus *Arion*, De Férussac). The example given is *L. rufus*.

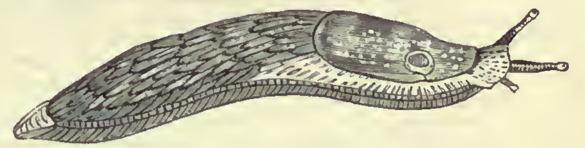
The 3rd section consists of species whose buckler is not distinct, and which have the ocular tentacles club-shaped, and the others lateral and oblong (genus Philomique of Rafinesque). The example given is *L. Oxyurus*.

The 4th section comprehends those species whose buckler is not distinct, and which have the two pairs of tentacles cylindrical, nearly on the same line, the smaller ones being between the greater (genus *Eumeles*, Rafinesque). The example given is *L. nebulosus*.

The two last sections are not noticed by M. Rang; and Cuvier is of opinion that the two genera recorded by M. Rafinesque are too imperfectly indicated to be admitted into his (M. Cuvier's) work. M. Raug also declines to admit them till there is more informatiou ou the subject.

Sub-genus *Arion*.—Respiratory orifice situated comparatively forward, towards the anterior part of the buckler, which is rough (chagrinée) aud contains small calcareous concretions. There is a terminal mucous pore.

A. rufus, De Fér., *Limax rufus*, Linn. This species is sometimes nearly quite black.



Red Slug (*Arion rufus*).

Sub-genus *Limax*.—Respiratory orifice situated comparatively backwards; the buckler is marked with fine and concentric striæ, containing a testaceous rudiment which is solid but without any volutatory impression. There is no terminal mucous pore.

L. antiquorum, De Fér., *L. maximus*, Linn., Gray Slug.

Gray Slug (*Limax antiquorum*, De Fér.; *Limax maximus*, Linn.).

a, internal shell; *b*, the same enlarged; *c*, internal view of the shell from another individual.

The geographical distribution of this genus is very wide; but the northern and temperate countries of both continents seem to be plagued with a greater number than those of the torrid zone. They are found in Africa, and have been noticed at each extremity of that quarter of the globe. Messrs. Quoy and Gaimard describe some from Australia, and M. Rang saw them in Iudia and in the island of Mauritius.

The species of this genus can hardly be of any direct utility to man, with the exception of the supposed virtues of a decoction or 'bouillon' of Red Slugs in disorders of the chest, whilst the injury which they inflict on the gardeu and the field is most devastating, notwithstanding the number of birds which prey upon them. Gardeners are constantly racking their invention to free themselves from these devouring hosts. Quicklime, soot, fine coal ashes, and saw-dust have been used as defences for young and tender plants. The virtue of the first is soon exhausted and the slugs do not care much for the second after a while, but if the soot be plentifully and frequently renewed it will keep them away in great measure. Coal-ashes, not too coarse, and saw-dust annoy them by sticking to their foot and impeding them. A stout coarse horsehair line, such as is used for hauging clothes out to dry, coiled round the stems of wall fruit-trees and stretched along the wall, will operate as a protection to the fruit from both snails and slugs, in consequence of the bristly surface presented to them, and which they shrink from encountering. Care must of course be taken that they do not get under it. Watering evening and morning with strong fresh lime-water is said to have a good effect, for it penetrates about the roots of the plants and into the earth, where they lie hid. Thin slices of any vegetable of which they are more fond than of the crop to be protected will allure them, and they may be thus killed by scores early in the morning by dividing them suddenly with a sharp instrument. The dead bodies should be left on the spot as a bait, for we have seen the living slugs preying upon the exposed bowels of the dead ones, most probably attracted by the half digested vegetable matter. Ducks destroy great numbers of these pests, whilst they improve themselves, but they are apt to trample down a young and delicate crop of vegetables.
